focus on the measures summarizability concept. In Section 3, we develop the formal background, notations, and definitions of our proposal. Section 4 studies our contribution. Section 5 describes our algorithm. In Section 6, we conduct some experiments performed on real data warehouse. Finally, Section 7 gives a conclusion and future research directions.

II. Related works

In this section, we present the related works.

A. Discretization of quantitative attributes

The *equal frequency* technique divides the range of possible values into N bins, each of which holds the same number of training instances. In the multidimensional context, Palaniappan et *al.* underline that the *equal frequency* method performs respectable results and is lossless time consuming.

B. Cyclic patterns

The extraction of the CAR was introduced by Ozden et *al.* in order to better identify sales trends cyclicly. It involves the association rules mining from articles characterized by their regular variation over time, such as the daily, weekly, quarterly, or annual regular variation which is naturally cyclic. Such cycles are specified by the user to divide the data into disjoint segments. Several algorithms were proposed such as INTERLEAVED and SEQUENTIAL introduced by [9] or MTP presented by Thuan [13], [14] or the Chiang's method to combine cyclic and sequential patterns [5] or PCAR, proposed by [1].

C. Inter-dimensional association rules mining

Falling within the combination of several analysis dimensions on association rules mining and based on the quality evaluation of the generated patterns, two main pools can be distinguished: (i) Approaches using the COUNT function; (ii) Approaches using the SUM function.

1) Count-based evaluation of inter-dimensional association rules: The main idea is to compute the support and the confidence of inter-dimensional association rules according to the COUNT function. In fact, a COUNT cell of the cube stores the number of occurrences of the corresponding multi-dimensional data values. Several works have investigated this challenging solution. Firstly, Kamber et *al.* use the COUNT function [7]. Plantevit et *al.* advanced an OLAP-sequential multi-level mining [12]. Besides, Ben Ahmed et *al.* [3] study the CAR mining from data warehouses.

2) SUM-based evaluation of inter-dimensional association rules: Ben Messaoud et *al.* redefine the support and the confidence metrics using the SUM aggregation function [4]. Such contribution scrutinizes facts according to summarized values of measures more meaningful than the regular number of occurrences of facts.

Except the proposal of plantevit et *al.* [11], where an initiation to the mining process of association rules from quantitative measures is investigated, all the remainder approaches neglect the measures during the mining process of association rules. In addition, they are restricted to the COUNT function to evaluate the derived rules except the proposal of Ben Messaoud which is mainly based on the SUM function. Nevertheless, in real situations, the aggregation of some fact attributes might not be semantically meaningful along all dimensions. For that reason, the exclusive use of the COUNT or the SUM aggregation function is mostly unfitting so the generated rules are imperfectly evaluated.

D. Measures Summarizability

Mandatory to determine the appropriate aggregation operators, Lenz and Shoshani distinguish three types of measures [8], namely, *(i)* ***Additive measure*** values can be combined meaningfully along any dimension (e.g., Add the total sales or the external turnover over `location` and `time`); *(ii)* ***Semi-additive measure*** values cannot be combined along one or more of the dimensions, most often the `time` dimension (e.g., Do not sum inventory item because the quantity may be counted several times, but we can sum inventory levels across products); *(iii)* ***Non-additive measure*** values cannot be combined along any dimension, usually because of the chosen formula (e.g., Compute the item price and the cost per unit of a product).

In this paper, we use the concept of measures summarizability proposed by Lenz [8] to introduce a general process by coupling both of dimensions and measures to mine measure-based CAR with a specific evaluation of each measure depending on its appropriate aggregate functions. To do this, an algorithm based on the Apriori and incorporating dimensions and measures is introduced to extract cyclic rules on one side. On the other side, we integrate the summarizability of data cube measures in the computation of the support and the confidence of such rules to better evaluate the derived patterns.

III. Formal background and notations

In this section, we introduce our innovative basic concepts inspired of the proposal of Plantevit et *al.* that will be of use in the remainder.

A. Context partition

We consider that all is set in a multi-dimensional context. The three necessary data for cyclic mining drawn from classic context (Customer, Product, Date) become in a multi-dimensional context sets. Let us consider a relational table $\mathscr{T}$, in which transactions issued by customers are stored, defined on a set D of d dimensions and a set M of m measures. The table is partitioned into two sets: *(1) Endogen context* composed of the context dimensions $\mathscr{D}_C$ and the context measures $\mathscr{M}_C$ included in the analysis process; *(2) Exogen context* related to all the excluded dimensions and measures from the analysis. We focus on the following on the endogen context.

1) Context dimensions: The context dimensions $\mathscr{D}_C$ can be divided into three subcategories: *(i) Temporal dimension* $\mathscr{D}_T$ (date in classical context); *(ii) Reference dimensions* $\mathscr{D}_R$ (customer in classical context); *(iii) Analysis dimensions* $\mathscr{D}_A$ (product in classical context). All reference dimensions $\mathscr{D}_R$ are a conjunction of several dimensions where each dimension can have a single attribute value or a set of occurrences.

2) Context measures: The context measures $\mathscr{M}_C$can be partitioned into two subcategories: *(i) Reference measures* $\mathscr{M}_R$ (table is partitioned according to tuple values over reference measures); *(ii) Analysis measures* $\mathscr{M}_A$ (tuples over

analysis measures are those that appear in the items that constitute the cyclic patterns to be mined).

The analysis measures can be divided into four subcategories: *(1) Set of additive measures* $\mathscr{M}_{SUM}$ when the SUM function can be used for data aggregation; *(2) Set of maximal measures* $\mathscr{M}_{MAX}$ when the MAX function can be applied to aggregate the data; *(3) Set of minimum measures* $\mathscr{M}_{MIN}$ when the MIN aggregation function can be used; *(4) Set of average measures* $\mathscr{M}_{AVG}$ when the AVG aggregation function can be applied.

In our running example shown by table 1, we consider the whole table as our endogen context composed of : *(i)* context dimensions $\mathscr{D}_C$=$\{T, R, L\}$ with the temporal dimension $\mathscr{D}_T$=$\{T\}$, the reference dimension $\mathscr{D}_R$= { *L*:"Jordan" } and the analysis dimensions $\mathscr{D}_A$=$\{R\}$; and *(ii) context measures* $\mathscr{M}_C$=$\{Q, ER, ET\}$ with the analysis measures is equal to all existing measures and no reference measure is limited to a fixed value of measure and $\mathscr{M}_{MAX}$=$\{ Q\}$ and $\mathscr{M}_{MIN}$=$\{ET\}$ and $\mathscr{M}_{AVG}$=$\{ER\}$.

Definition 1: ***(Endogen Sub-cube)***: Let $\mathscr{D}' \subset \mathscr{D}$ a nonempty set of p dimensions $\{\mathscr{D}_1,...,\mathscr{D}_p\}$ extracted from the data cube *C* (p $\leq$ d) with d the cardinality of all dimensions and $\mathscr{M}' \subset \mathscr{M}$ a nonempty set of q measures $\{\mathscr{M}_1,...,\mathscr{M}_q\}$ extracted from the data cube *C* (q $\leq$ m) with m the cardinality of all measures.

The e-tuple $(\delta_1,...,\delta_t)$ is called an endogen sub-cube of data *C* according to : (i) $\mathscr{D}'$ iff $\forall$ i $\in \{1,...,p\}$, $\delta_i \neq \emptyset$ and $\delta_i \in$ Dom($\mathscr{D}_i$); (ii) $\mathscr{M}'$ iff $\forall$ j $\in \{1,...,q\}$, $\gamma_j \neq \emptyset$ and $\gamma_i \in$ Dom($\mathscr{M}_j$).

In our example, in the endogen sub-cube, each e-tuple e = (d_1,...,d_p,m_1,...,m_q) can be written in the form of a triple e = (r, a , t) where r is the restriction of $\mathscr{D}_R$ and $\mathscr{M}_R$, a is the restriction of $\mathscr{D}_A$ and $\mathscr{M}_A$ and t is the restriction of $\mathscr{D}_T$.

B. Measure-Based Uni-dimensional Cyclic Item and Inter-dimensional Cyclic Itemset

Definition 2: ***Measure-based Uni-Dimensional Cyclic Item***: Let the analysis dimensions $\mathscr{D}_A$ = $\{\mathscr{D}_1,...,\mathscr{D}_p\}$ and the analysis measures $\mathscr{M}_A$ = $\{\mathscr{M}_1,...,\mathscr{M}_q\}$ and a length of cycle *l*. A measure-based uni-dimensional cyclic item α is an item satisfying at least one of the following conditions:

- belonging to one of the analysis dimensions, namely, $\mathscr{D}_k$ and having a value of α= d_k on the date *t* and compulsorily on the date $t+l$ such that $\forall$ k $\in$ [1,p], d_k $\in$ Dom($\mathscr{D}_k$);
- belonging to one of the analysis measures, namely, $\mathscr{M}_l$ and having a value of α =m_l on the date *t* and necessarily on the date $t+l$ such that $\forall$ l $\in$ [1,q], m_l $\in$ Dom($\mathscr{M}_l$).

Typical examples of measure-based uni-dimensional cyclic item, considered in the multi-dimensional context, shown by the table III and the delimitation of the context considered previously, is α= (*Licensed Range*) because it belongs to the `Range` dimension *R*, being a part of analysis dimension and its value *Licensed Range* belongs to the `Range` domain and is repeated each odd quarter of 2007. Or α= (77500) because it belongs to the `sold quantity` measure *Q*, being a part of analysis measure and its value 77500 belongs to the `sold quantity` domain and is repeated each odd quarter of 2007.

Definition 3: ***Measure-Based Inter-dimensional Cyclic Itemset***: A measure-based inter-dimensional cyclic itemset *I* defined on $\mathscr{D}_A$ = $\{\mathscr{D}_1,...,\mathscr{D}_k\}$ or $\mathscr{M}_A$ = $\{\mathscr{M}_1,...,\mathscr{M}_j\}$ is a nonempty set of items I = $\{\alpha_1,...,\alpha_t\}$ with $\alpha_1 \in \mathscr{D}_A$ and $\forall$ π $\in$ [2, θ], α_π is a measure-based uni-dimensional cyclic item defined on $\mathscr{D}_A$ and/or $\mathscr{M}_A$ and $\forall$ π, e $\in$ [1, θ], $\alpha_\pi \neq \alpha_\theta$.

Example 1: An example of measure-based inter-dimensional cyclic itemset is *I*:[*L* = Jordan, *R* = Licensed Range,*Q* = 77500] because it is composed of three measure-based uni-dimensional cyclic items *i.e.*, α_1=(Jordan), α_2=(Licensed Range) and α_3=(77500). It is repeated quarterly.

C. Support computation of measure-based uni-dimensional cyclic item and measure-based inter-dimensional itemset using appropriate aggregate functions

Definition 4: ***The Support of measure-based uni-dimensional cyclic Item***: The support of the measure-based uni-dimensional cyclic item α, denoted $Supp(\alpha)$ is computed as follows:

- If α does not belong to one of the analysis measure: the support is equal to the number of tuples that contain the item; $Supp(\alpha) = \frac{COUNT(\alpha)}{COUNT(ALL)}$;
- If α belongs to one of the analysis measure $\mathscr{M}_l$, the support is computed in the respect of:
  1) $\mathscr{M}_l \in \mathscr{M}_{SUM}$, the support of α is the quotient of the value of α and the sum of values belonging to the current measure because the latter is aggregating using the SUM function; $Supp(\alpha) = \frac{\alpha}{SUM(\mathscr{M}_l)}$;
  2) $\mathscr{M}_l \in \mathscr{M}_{MAX}$, $Supp(\alpha) = \frac{\alpha}{MAX(\mathscr{M}_l)}$; the support of α is the quotient of the value of α and the maximum of values belonging to the current measure because the latter is aggregated using the MAX function;
  3) $\mathscr{M}_l \in \mathscr{M}_{MIN}$, the support of α is the quotient of the difference between the value of α and the minimum value of the measure, and the difference between the maximum and the minimum of the current measure: $Supp(\alpha) = \frac{\alpha - MIN(\mathscr{M}_l)}{MAX(\mathscr{M}_l) - MIN(\mathscr{M}_l)}$;
  4) $\mathscr{M}_l \in \mathscr{M}_{AVG}$
     - If $(\alpha \leq AVG(\mathscr{M}_l))$, if α belongs to the measure aggregating using the AVG function and the value of α is lower than the average value of the current measure, the support of α is the quotient of the value of α and the average of values belonging to the current measure; $Supp(\alpha) = \frac{\alpha}{AVG(\mathscr{M}_l)}$;
     - else the support of α is the quotient of the difference between the value of α and the minimum value, and the difference between the maximum and minimum of the current measure; $Supp(\alpha) = \frac{\alpha - MIN(\mathscr{M}_l)}{MAX(\mathscr{M}_l) - MIN(\mathscr{M}_l)}$.

In our running example referring to the table III, we consider the following items:

- (α_1=77500) $\in$ *Q* and $Q \in \mathscr{M}_{MAX}$, α_1 has a support

equal to $Supp(\alpha_1) = \frac{\alpha_1}{MAX(\mathscr{M}_l)} = \frac{\alpha_1}{MAX(Q)} = \frac{77500}{80000} = 0.968$

- (α_2=700) $\in$ ET and $ET \in \mathscr{M}_{MIN}$, α_2 has an a support equal to $Supp(\alpha_2) = \frac{\alpha_2 - MIN(\mathscr{M}_l)}{MAX(\mathscr{M}_l) - MIN(\mathscr{M}_l)} = \frac{\alpha_2 - MIN(ET)}{MAX(ET) - MIN(ET)} = \frac{700-600}{700-600} = 1$;
- (α_3=1,382%) $\in$ ER and $ER \in \mathscr{M}_{AVG}$ with AVG(ER)=$\frac{(1,947*4)+(1,382*2)}{6} = 1,758$.
  α_3=1,382% $< AVG(ER)$ =1,758 so α_3 has a support equal to $Supp(\alpha_3) = \frac{\alpha_3}{AVG(ER)} = \frac{1,382}{1,758} = 0.786$.

Definition 5: ***The Support of Measure-Based Inter-dimensional Cyclic Itemset***: Let's consider a measure-based inter-dimensional cyclic itemset $I = \{\alpha_1, ..., \alpha_p ..., \alpha_n\}$ composed p dimensions of $\mathscr{D}_A$ and/or $n-p$ measures of $\mathscr{M}_A$. The support of I, denoted $Supp(I)$ is decomposed into the support of measure-based uni-dimensional items belonging to p dimensions and computed using the following formula $\frac{COUNT(\alpha_1 \bigcup \alpha_p)}{COUNT(\mathscr{D}_A = ALL)}$ and the ones belonging to $n-p$ measures and obtained using the following formula $\prod_{i=p+1}^{n} SUPP(\alpha_i)$. $Supp(I) = \frac{COUNT(\alpha_1 \bigcup \alpha_p)}{COUNT(\mathscr{D}_A = ALL)} * \prod_{i=p+1}^{n} SUPP(\alpha_i)$;

Example 2: The measure-based inter-dimensional cyclic itemset I=[L = *Jordan*, R = *Licensed Range*,Q = 77500] has a support related to the sales of 77500 units of the *Licensed Range* sold in *Jordan* $Supp(I) = \frac{COUNT(L=Jordan, R=Licensed\ Range)}{COUNT(\mathscr{D}_A = ALL)} * \prod_{i=2}^{3} SUPP(Q = 77500) = \frac{COUNT(L=Jordan, R=Licensed\ Range)}{COUNT(\mathscr{D}_A = ALL)} * SUPP(Q = 77500) = \frac{4}{6} * \frac{Q=77500}{MAX(Q)} = \frac{4}{6} * \frac{77500}{80000} = 0.666 * 0.968 = 0.645$.

D. Support and Confidence of Measure-Based Inter-dimensional Cyclic Rule

Definition 6: ***Support of Measure-Based Inter-dimensional Cyclic Rule***: The rule support $\mathscr{R} : X \Rightarrow Y$, denoted $Supp(\mathscr{R})$, is equal to the ratio of the support of X and Y to the total number of tuples in the subcube.

$$Supp(\mathscr{R}) = \frac{SUPP(X \cup Y)}{SUPP(ALL, ALL)};$$

The support of de $\mathscr{R}$, $Supp(\mathscr{R}) \in [0, 1]$.

Definition 7: ***Confidence of Measure-Based Inter-dimensional Cyclic Rule***: The rule confidence $\mathscr{R} : X \Rightarrow Y$, denoted $conf(\mathscr{R})$, is equal to the ratio of the number of tuples that contain X and Y to the number of tuples that contain X in the subcube.

$$conf(\mathscr{R}) = \frac{Supp(\mathscr{R})}{Supp(X)};$$

The confidence of $\mathscr{R}$, $conf(\mathscr{R}) \in [\ 0,\ 1\ ]$.

In our running example, the rule $\mathscr{R}$: R = Licensed Range $\Rightarrow$ $Q = 77500$ has : $Supp(\mathscr{R}) = Supp(R = LicensedRange \cup Q = 77500) = \frac{COUNT(R=Licensed\ Range)}{COUNT(ALL)} * SUPP(Q = 77500) = \frac{4}{6} * \frac{77500}{MAX(Q)} = \frac{4}{6} * \frac{77500}{80000} = 0.666 * 0.968 = 0.645$. $Conf(\mathscr{R}) = \frac{Supp(R)}{Supp(Y)} = \frac{Supp(R)}{Supp(R=Licensed\ Range)} = \frac{0.645}{0.666} = 0.429$.

IV. Mining Measure-Based Inter-dimensional Cyclic Association Rules

Starting from a data cube, we propose the following two phases to generate measure-based inter-dimensional cyclic association rules:

- ***Pre-processing phase*** contains two steps which are : *(i)* the derivation of the endogen sub-cube based on the user-specification of the endogen context using an SQL query; *(ii)* the discretization of continuous valued measures within the equal frequency discretization technique;
- ***Processing phase*** consists on the mining of measure-based inter-dimensional CAR from data cube.

In what follows, these phases are detailed.

A. Pre-processing phase

Date	Location	Range	Sold Quantity	Exchange Rate	External Turnover
D	*L*	*R*	*Q*	*ER*	*ET*
Q1 of 2007	Jordan	Licensed Range	75000-80000	1,946%- 1,948%	450-750
Q2 of 2007	Jordan	Licensed Range	75000-80000	1,946%- 1,948%	450-750
Q3 of 2007	Jordan	Licensed Range	75000-80000	1,946%- 1,948%	450-750
Q4 of 2007	Jordan	Licensed Range	75000-80000	1,946%- 1,948%	800-1000
Q1 of 2008	Yemen	Model Hospital	71100-75000	1,38%- 1,382%	450-750
Q2 of 2008	Yemen	Model Hospital	75000-80000	1,38%- 1,382%	800-1000

TABLE II

TABLE $\mathscr{T}$ WITH A DISCRETIZATION OF MEASURES USING **EQUAL FREQUENCY** TECHNIQUE

Based on the user-specification of the endogen context, an SQL query can be launched to derive the endogen sub-cube in the respect of the selected analysis dimensions and measures and restrictions on reference dimensions and measures.

Time	Location	Range	Sold Quantity	Exchange Rate	External Turnover
T	*L*	*R*	*Q*	*ER*	*ET*
Q1 of 2007	Jordan	Licensed Range	77500	1,947%	600
Q2 of 2007	Jordan	Licensed Range	77500	1,947%	600
Q3 of 2007	Jordan	Licensed Range	77500	1,947%	600
Q4 of 2007	Jordan	Licensed Range	77500	1,947%	700
Q1 of 2008	Yemen	Model Hospital	73050	1,381%	600
Q2 of 2008	Yemen	Model Hospital	77500	1,381%	700

TABLE III

TABLE $\mathscr{T}$ OBTAINED AFTER THE PREPROCESSING PHASE

To generate the measure-based inter-dimensional cyclic association rules from the endogen sub-cube, a discretization of the context measures is compulsory. We choose in our context the equal frequency technique for many reasons, namely, the intervals are created so that, roughly, the frequency of each interval is constant and each interval contains roughly the same number of contiguous data samples. In our case, the expert specify the depth to forty otherwise the forty nearest values will compose an independent interval. For example, 77520, 75000, 77520, 80000 and thirty six other values belonging to the range of 75000 and 80000 in the `sold quantity` measure compose the interval [75000-80000].

According to the same method, the obtained sub-cube after the discretization step is depicted by the table II. Once we obtain the discretized intervals, we use the median value for each interval related to continuous valued measure so that we can involve the summarizability of measures on the mining process. In fact, the median value can be computed using the following formula $V_{median} = \frac{V_{max} + Vmin}{2}$. For example, in our case (table II), the considered item for the `sold quantity` measure is $\alpha = \frac{V_{max} + Vmin}{2} = \frac{75000+80000}{2} = 77500$. The output table is shown by the table III which is the input of our method.

B. Mining phase: Extraction of Measure-based Inter-dimensional Cyclic Association Rules Using Appropriate Aggregate Functions

After deriving the endogen sub-cube and discretization of valued measures and dimensions and the transformation of valued analysis measures using the median of each interval, the MEasure-based inter-Dimensional Cyclic Association Rules using Aggregate functions algorithm, called MEDCAR takes as input the decortication of the analysis measures according to the appropriate aggregate functions to sets, the set of the minimum threshold of support $Minsupp$ and the minimum threshold of confidence $MinConf$ and the length of cycle. It outputs the list of measure-based inter-dimensional CAR. The used notations are depicted by table IV and its pseudo-code is illustrated by the algorithm in the following. In fact, MEDCAR, an iterative process, operates in three successive steps. First, we proceed by an increasing level wise search for measure-based inter-dimensional cyclic large i-itemsets, where the level (i) designs the number of items in the set.

Notation	Description
SC	Endogen Sub-cube
α	Potential measure-based uni-dimensional cyclic item
I	Measure-Based Inter-dimensional cyclic itemset
$\mathscr{C}_i$ (resp.$\mathscr{F}_i$)	Set of candidates (resp. frequent) measure-based inter-dimensional cyclic i-itemsets.
$\mathscr{M}insupp$	Minimum support threshold
$\mathscr{M}inconf$	Minimum confidence threshold
$\mathscr{D}_t$	Date t
l	Length of cycle
$Supp(\mathscr{C})$	Support of the measure-based inter-dimensional cyclic itemset $\mathscr{C}$
$\mathscr{M}_{MAX}$	set of measures that can be aggregated using MAX
$\mathscr{M}_{AVG}$, $\mathscr{M}_{SUM}$)	function(resp. $\mathscr{M}_{MIN}$ (resp. MIN, AVG, SUM)

TABLE IV

LIST OF USED NOTATIONS IN THE MEDCAR ALGORITHM.

We denote by $C(i)$ the measure-based inter-dimensional cyclic candidate i-itemsets potentially frequent, and $F(i)$ the measure-based inter-dimensional cyclic frequents i-itemsets. For each level (i), if the set $C(i)$ is not empty, the first step of our algorithm derives the measure-based inter-dimensional frequent cyclic patterns $F(i)$ from $C(i)$ with respect of two conditions: (C1) A measure-based inter-dimensional cyclic itemset $A \in C(i)$ must be a conjunction of members from analysis dimensions or/and analysis measures; (C2) and a measure-based inter-dimensional cyclic itemset must have a support above the $Minsupp$ to be included in $F(i)$. For an efficient extraction of measure-based inter-dimensional cyclic frequent itemsets, we exploit the anti-monotonicity property of the support in the multi-dimensional context. Indeed, any subset of a frequent cyclic set is frequent cyclic and any cyclic itemset failing to be frequent, all its supersets will not be frequent so they will be pruned. The second step uses the measure-based inter-dimensional cyclic large i-itemsets $F(i)$ to derive a new set $C(i+1)$ of $(i+1)$-candidates. A *(i + 1)*-candidate is formed by the union of two measure-based inter-dimensional cyclic i-itemsets A and B from $F(i)$ according to three conditions: (C1) A and B must have (i - 1) common measure-based uni-dimensional cyclic items; (C2) all measure-based inter-dimensional cyclic sub-itemsets A U B must be instances of $\mathscr{D}_A$ and/ or $\mathscr{M}_A$; (C3) and all nonempty measure-based inter-dimensional cyclic sub-itemsets of A U B must be measure-based inter-dimensional cyclic frequent itemsets.

Algorithm 1: MEDCAR: MEasure-based inter-Dimensional Cyclic Association Rules using Aggregate functions

Data: SC, $\mathscr{M}insupp$,$\mathscr{M}inconf$, l, $\mathscr{M}_{MAX}$,$\mathscr{M}_{MIN}$,$\mathscr{M}_{SUM}$, $\mathscr{M}_{AVG}$
Result: $\mathscr{R}$: Measure-based Inter-dimensional cyclic rules in SC using Aggregate functions

      if *Itemset I of $\mathscr{C}$ contains $\mathscr{M}_A$* **then**
        $Supp(\mathscr{C})$=*COUNT*($\mathscr{C}$ - *I*) $\prod_{i=1}^{n} Supp(i)$.
      $Supp(\mathscr{C})$=COUNT($\mathscr{C}$);
    NoMoreCyclic = true;
  Return $Supp(\mathscr{C})$;
end

Finally, the third stage consists on scanning $F(i)$ level by level. From every $A \in F(i)$, we extract the measure-based

inter-dimensional CAR with respect to condition, *i.e.*, having a confidence above the minimum confidence threshold *MinConf*.

V. Experimental results

Experiments were conducted on a Pentium PC with 1.73 GHz and 1 GB of main memory. In the following, we report experiments performed on a real sales data warehouse [1], which contains three dimensions (e.g., `Time` dimension, `Range` dimension, `Location` dimension) and one sales fact table. The data warehouse is built using relational OLAP (ROLAP). Figure 1.(a) shows the behavior of our approach when the frequency interval changes. In fact, the increase of the frequency intervals, decreases the performance of our method because if we rise the frequency, the number of measure-based inter-dimensional cyclic candidates itemsets will highly grow leading to an increase of the measure-based inter-dimensional cyclic frequent itemsets. Figure 1.(b) presents a test of our algorithm on varying the length of cycle. For small support values, the running time considerably increases by decreasing the length of cycle. However, for large supports, the length of cycle has a less effect on the performance of our algorithm. In the figure 1.(c), we clearly notice that the efficiency of the algorithm closely depends on the number of dimensions involved during the mining process. Similarly, the running time obviously increases according to the number of involved measures as shown by figure 1.(d). When the number of dimensions (respectively measures) is high, the number of measure-based inter-dimensional cyclic frequent itemsets mined among several candidates is high. On the contrary, when this number of dimensions (respectively measures) is low, the potential measure-based inter-dimensional cyclic frequent itemsets is also low).

Interestingly enough, these experiments highlight acceptable runtime processing. The efficiency of our algorithm is due to: (i) the use of constraint based mining through the choice of dimensions and measures analysis which highly reduce the search space of CAR and therefore, considerably decreases the runtime of the mining process; (ii) the use of the Apriori property which is definitely suited to sparse data cubes and considerably reduces the complexity of measure-based inter-dimensional cyclic large itemsets search. The usefulness of our proposal is motivated by coupling dimensions and measures.

VI. Conclusion

In this paper, we proposed a new method to extract measure-based cyclic association rules taking into consideration the summarizability of measures during the evaluation of the generated measure-based inter-dimensional patterns from the OLAP context. Thus, a new definition of measure-based inter-dimensional cyclic patterns is provided. A redefinition of their evaluation metrics inspired from the summarizability characteristic of involved measures is presented using the relevant aggregation functions characterizing such a measure. Accordingly, a new method called MEDCAR to extract such patterns is introduced.

Other avenues for future work mainly address the following issues: (i) use of other discretization technique to guarantee a lossless information for measure, (ii) discovery of unexpected cyclic patterns in OLAP context, (iii) mining of measure-based inter-dimensional cyclic patterns under time constraint such as the integration of excluded intervals.

[1]The data warehouse is related to pharmaceutical listed company. It is built using the available information at http ://www.bvmt.com.tn/companies/ ?view=listed.

Abstract

Social (or folksonomic) tagging has become a very popular way to describe content within Web 2.0 websites. Unlike taxonomies, which overimpose a hierarchical categorisation of content, folksonomies enable end-users to freely create and choose the categories (in this case, tags) that best describe some content. However, as tags are informally defined, continually changing, and ungoverned, social tagging has often been criticised for lowering, rather than increasing, the efficiency of searching, due to the number of synonyms, homonyms, polysemy, as well as the heterogeneity of users and the noise they introduce. To address this issue, a variety of approaches have been proposed that recommend users what tags to use, both when labelling and when looking for resources. As we illustrate in this paper, real world folksonomies are characterized by power law distributions of tags, over which commonly used similarity metrics, including the Jaccard coefficient and the cosine similarity, fail to compute. We thus propose a novel metric, specifically developed to capture similarity in large-scale folksonomies, that is based on a mutual reinforcement principle: that is, two tags are deemed similar if they have been associated to similar resources, and vice-versa two resources are deemed similar if they have been labelled by similar tags. We offer an efficient realisation of this similarity metric, and assess its quality experimentally, by comparing it against cosine similarity, on three large-scale datasets, namely Bibsonomy, MovieLens and CiteULike.

1. Introduction

The rise of Web 2.0 has transformed users from passive consumers to active producers of content. This has exponentially increased the amount of information that is available to users, from videos on sites like YouTube and MySpace, to pictures on Flickr, music on Last.fm, blogs on Blogger, and so on. This content is no longer categorised according to pre-defined taxonomies (or ontologies). Rather, a new trend called *social* (or *folksonomic*) *tagging* has emerged, and quickly become the most popular way to describe content within Web 2.0 websites. Unlike taxonomies, which overimpose a hierarchical categorisation of content, folksonomies empower end users by enabling them to freely create and choose the tags that best describe a piece of information (a picture, a blog entry, a video clip, etc.). However, this freedom comes at a cost: since tags are informally defined, continually changing, and ungoverned, finding content of interest has become a main challenge, because of the number of synonyms, homonyms, polysemy, as well as the inevitable heterogeneity of users and the noise they introduce.

In order to assist users finding content of their own interest within this information abundance, new techniques, inspired by traditional recommender systems, have been developed: for example, whenever a user searches from some content using query tags $\{t_1, \ldots, t_m\}$, new tags $\{t_{m+1}, \ldots, t_{m+n}\}$ are being added to the query, based on their *similarity* to their original query tags. This is done to increase the chances of finding content of relevance in these extremely sparse settings. Various metrics have been used to compute the similarity among folksonomy entities, including, for instance, cosine similarity, Jaccard coefficient, and Pearson Correlation. Performance results demonstrate an increase in accuracy and coverage of searches when using these techniques; however, evaluation has been conducted on manipulated datasets so to obtain a much denser one. We argue that such manipulations alter the nature of real folksonomies, and indeed eliminate the problem, rather than solving it.

Unmodified real-world folksonomies are characterized by two key properties: the *power law* distribution of tags, and the *non-independence* of data. Empirical studies [4, 5] illustrate that tag usage in folksonomies follows a power law distribution; this means that, if we were select any two tags, the probability that the resources jointly labelled by them is non-zero is extremely low. As a result, comput-

ing tag similarity on un-modified folksonomies, using traditional metrics like cosine similarity, would almost always yield close-to-zero values, thus failing to support users in retrieving resources relevant to their queries. Furthermore, metrics like cosine assume that tags are semantically independent of each other; once again, this assumption does not hold in real folksonomies, where tags may be synonyms to each other.

In this paper, we propose a novel similarity metric that can be used to accurately quantify tag similarity in large-scale real-world folksonomies (Section 3). This similarity metric is computed following an iterative algorithm, grounded on a *mutual reinforcement* principle: that is, two tags are similar if they label similar resources, and vice-versa, two resources are similar if they have been labelled by similar tags. We describe an efficient realisation of this similarity metric (Section 4), and empirically quantify its quick convergence on three large-scale datasets, namely BibSonomy[1], MovieLens[2], and CiteULike[3]. We measure Precision and Recall of our metric, and compare it to cosine similarity on these unprocessed datasets (Section 5). Our findings demonstrate that, when considering our unmanipulated datasets, the performance of our novel similarity metric provides higher Precision and Recall w.r.t. the cosine similarity. Section 6 covers related works on similarity measures, mainly applied to folksonomies. Finally, in Section 7 we draw our conclusions.

2. Background

In this section, we formally introduce some concepts that will be extensively used in the following, when presenting our approach. The first concept we consider is that of a folksonomy [12]:

Definition 2.1 *Let $US = \{u_1, \ldots, u_{n_u}\}$ be a set of users, let $RS = \{r_1, \ldots, r_{n_r}\}$ be a set of resource URIs and let $TS = \{t_1, \ldots, t_{n_t}\}$ be a set of tags. A* folksonomy *F is a tuple $F = \langle US, RS, TS, AS \rangle$, where $AS \subseteq US \times RS \times TS$ is a ternary relationship called* tag assignment set.

In this definition we do not make any assumption about the nature of resources; they could be URLs (like in Delicious), photos (as in Flickr), music files (as in Last.fm), documents (as in CiteULike), and so on.

According to Definition 2.1, a folksonomy F is a "three-dimensional" data structure whose "dimensions" are represented by users, tags and resources. In particular, an element $a \in AS$ is a triple $\langle u, r, t \rangle$, indicating that user u labelled resource r with tag t. To simplify modeling and management of folksonomies, their inherent tripartite graph structure is often mapped into three *matrices*, whereby each matrix models one relationship at a time (i.e., between tags and resources, tags and users, and resources and users) [19]. In this paper, we adopt the same matrix-based representation. Specifically, being n_r, n_t and n_u the number of resources, tags and users respectively, we represent a folksonomy as the following three matrices:

- $\mathbf{TR}$ (Tag-Resource): a $n_t \times n_r$ matrix such that $\mathbf{TR}_{ij}$ is the number of times the tag i labelled resource j;
- $\mathbf{TU}$ (Tag-User): a $n_t \times n_u$ matrix such that $\mathbf{TU}_{ij}$ is the number of times the tag i has been used by user j;
- $\mathbf{RU}$ (Resource-User): a $n_r \times n_u$ matrix such that $\mathbf{RU}_{ij}$ is the number of times resource i has been labelled by the user j.

Tag similarity within a folksonomy can then be computed by looking at the resources these tags have been attached to. In particular, each tag t_i can be mapped onto a vector $\mathbf{t}_r(i)$ corresponding to the i-th row of $\mathbf{TR}$. Given an arbitrary pair of tags t_i and t_j, their similarity $s(t_i, t_j)$ can be computed as the *cosine similarity* (CS) of the vectors $\mathbf{t}_r(i)$ and $\mathbf{t}_r(j)$:

$$s(t_i, t_j) = \frac{\langle \mathbf{t}_r(i), \mathbf{t}_r(j) \rangle}{\sqrt{\langle \mathbf{t}_r(i), \mathbf{t}_r(i) \rangle} \sqrt{\langle \mathbf{t}_r(j), \mathbf{t}_r(j) \rangle}} \quad (1)$$

being $\langle \cdot, \cdot \rangle$ the usual *inner product* in $\mathbb{R}^{n_r}$.

Cosine similarity has been successfully applied in the context of Information Retrieval [16]. Within a folksonomy, Equation 1 states that the similarity score of a pair of tags is high if they *jointly co-occur* in labelling the same subset of resources. However, two key properties of folksonomies, that are, *(i)* the power law distribution of tags and *(ii)* their non-independence, cause Equation 1 to yield very poor results in this domain, as we shall discuss next.

Power Law in Tag Distribution. Let us consider a real-world folksonomy like BibSonomy. BibSonomy [11, 13] is a social bookmarking service in which users are allowed to tag both URLs and scientific papers. A power law distribution of tags on scientific references emerges. In particular, resources were described by no more than 5 different tags (roughly 81%), and usually less than 3 (roughly 58%). A small portion of frequently adopted tags used to bookmark scientific references, and a long tail of tags (roughly 81%) being used less than 5 times.

Following the above observations, matrix $\mathbf{TR}$ is rather sparse; thus, if we were to select any pair of tags t_i and t_j, most of the components of the corresponding vectors $\mathbf{t}_r(i)$ and $\mathbf{t}_r(j)$ would be 0 and, therefore their inner product would be close to 0. The cosine similarity between *any* t_i and t_j would therefore be almost 0, regardless of the initial

[1] http://www.bibsonomy.org/
[2] http://www.movielens.org/
[3] http://www.citeulike.org/

choice of t_i and t_j. Such counter-intuitive result is an effect of the inadequacy of cosine similarity to capture properties of tags in large-scale real folksonomies.

Non-Independence of Tags. Cosine similarity implicitly assumes that the components of the vectors appearing in Equation 1 are *independent* of each other. Such an assumption does not often hold true. For instance, consider a folksonomy consisting of two resources r_1 and r_2, representing two different scientific papers, both discussing about folksonomies. Suppose that the paper associated with r_2 is an extension of the paper associated with r_1. Finally, assume to bookmark the resource r_1 with the tag t_1 = "folksonomy" and to bookmark the resource r_2 with the tag t_2 = "social tagging". In this case, the similarity between t_1 and t_2 computed according to Equation 1 would be 0, even if t_1 and t_2 should result similar each other. The mutual similarity between t_1 and t_2 can be assessed only if we consider the non-independence of the resources they label.

3. Approach Description

In this section, we present a new definition of tag (and resource) similarity, that is particularly suited to quantify similarity of elements (be them tags of resources) in datasets characterized by power law distribution and non-independence of data. Our definition of similarity relies on the *mutual reinforcement principle*:

> *Two tags are similar if they label similar resources, and conversely, two resources are similar if they are labelled by similar tags.*

In the following, we shall derive a mathematical formula to compute tag and resource similarity on the basis of the principle stated above. After this, we shall illustrate why our formula is able to effectively address the power law and non-independence challenges.

We designed an *iterative algorithm* to compute the similarity score. In the base case, given a pair of tags $\langle t_a, t_b \rangle$ and a pair of resources $\langle r_a, r_b \rangle$, we define the *tag similarity* $st^0(t_a, t_b)$ and the *resources similarity* $sr^0(r_a, r_b)$ as follows:

$$st^0(t_a, t_b) = \delta_{ab} \qquad sr^0(r_a, r_b) = \delta_{ab} \tag{2}$$

being δ_{ab} the *Kronecker symbol*[4]. Equation 2 reflects the fact that, in the initial step, each tag (resp., resource) is similar only to itself and it is dissimilar to all other tags (resp., resources).

At the k-th step, let $st^{k-1}(t_a, t_b)$ (resp., $sr^{k-1}(r_a, r_b)$) be the tag (resp., resource) similarity between the tags t_a and t_b (resp., resources r_a and r_b). We apply the following rules to update $st^{k-1}(t_a, t_b)$ (resp., $sr^{k-1}(r_a, r_b)$):

$$st^k(t_a, t_b) = \frac{ST^k(t_a, t_b)}{\sqrt{ST^k(t_a, t_a)} * \sqrt{ST^k(t_b, t_b)}} \tag{3}$$

$$sr^k(r_a, r_b) = \frac{SR^k(r_a, r_b)}{\sqrt{SR^k(r_a, r_a)} * \sqrt{SR^k(r_b, r_b)}} \tag{4}$$

where:

$$ST^k(t_a, t_b) = \sum_{i,j=1}^{n_r} \mathbf{TR}_{ai} * \Psi_{ij} * sr^{k-1}(r_i, r_j) * \mathbf{TR}_{bj} \tag{5}$$

$$SR^k(r_a, r_b) = \sum_{i,j=1}^{n_t} \mathbf{TR}_{ia} * \Psi_{ij} * st^{k-1}(t_i, t_j) * \mathbf{TR}_{jb} \tag{6}$$

Here Ψ_{ij} is equal to 1 if $i = j$ and it is equal to ψ if $i \neq j$, where ψ (called *propagation factor*) is a value belonging to the interval $[0, 1] \in \mathbb{R}$.

Equations 3–4 rely on the following intuitions. Given a pair of tags $\langle t_a, t_b \rangle$, at the k iteration, we consider *all pair of resources* $\langle r_i, r_j \rangle$ in our folksonomy and we take their similarity $sr^{k-1}(r_i, r_j)$ into account to compute $st^k(t_a, t_b)$. In particular, we compute a *weighted sum* of all the similarity values $sr^{k-1}(r_i, r_j)$, where the weights reflect the *strength of the association* between the tag t_a and the resource r_i, and the tag t_b and the resource r_j. As a consequence, the higher the similarity between r_i and r_j, the higher the contribution of the association between the tag t_a and the resource r_i, and the tag t_b and the resource r_j. Finally, the term Ψ_{ij} is instrumental to give higher relevance to tags that labelled the very *same* resources, w.r.t. the fact that they labelled two *similar* (but different) resources.

Note that, in the special case in which $\psi = 0$, our method does not depend on k and Equations 3–4 reduce to the cosine similarity formulation. In fact, in this particular case, all the contributions $sr^{k-1}(r_i, r_j)$ and $st^{k-1}(r_i, r_j)$ are disregarded when $i \neq j$, and are taken into consideration only when $i = j$. Since all contributions $sr^{k-1}(r_i, r_i)$ and $st^{k-1}(r_i, r_i)$ are equal to 1 by definition, it follows that Equations 3–4 reduce to the cosine similarity formulation.

Equations 3–4 are able to effectively address the power law and non-independence of data challenges we outlined above. In fact:

- In the computation of tag (resp., resource) similarity, we leverage on the similarity of all pairs of resource (resp., tag) similarities. As a consequence, unlike cosine similarity, we do not restrict ourselves to consider only the resources jointly labelled by two tags (resp., the tags jointly labelling two resources), which can be few, but we *iteratively propagate* similarity scores by considering all the pairs of similar resources jointly labelled by the two tags (resp., all the pairs of similar

[4]We recall that the Kronecker symbol δ_{ab} is equal to 1 if a and b coincide and 0 otherwise.

tags jointly labelling two resources). In this way we are able to face the power law occurring in tag usage.

- In our definition of similarity, if two tags label similar, *even if not coincident*, resources their similarity score will be greater than 0, whereas the cosine similarity would return 0. As a consequence, our similarity method takes into account forms of correlation among pairs of resources and/or tags rather than assuming their independence.

4. Realization

From a computational standpoint, Equations 3–4 could entail a large overhead for two reasons:

- From a theoretical standpoint, our approach may need an infinite number of iterations. As a consequence, we need a stopping criterion allowing us to safely terminate the execution of Equations 3–4 after a finite (and low) number of iterations.
- Equation 3 (resp., Equation 4) requires the computation of n_r^2 resource-resource (resp,. n_t^2 tag-tag) similarities, at each k-th step. This could make our similarity measure inapplicable in practical cases, because each iteration requires exactly $n_r^2 \times n_t^2$ computations.

Fortunately, there are two important results making our similarity measure applicable and entailing the same complexity level as cosine similarity. The first result can be stated by the theorem showed and proved in the Appendix[5] which affirms that the sequences $st^k(t_a, t_b)$ and $sr^k(r_a, r_b)$ defined as in Equations 3–4 converge.

This theorem ensures that, after a certain number of iterations, Equations 3–4 converge to stable values. During experimentation conducted on three real folksonomies (see Section 5.1), we empirically found that convergence was achieved after as little as five iterations, thus suggesting that our similarity measure is applicable in practical cases.

Furthermore, Equations 3–4 can be defined, without any loss of generality, as a simple matrix product (such as in cosine similarity). Specifically, let $\mathbf{st}^k$ and $\mathbf{sr}^k$ be the tag-tag and resource-resource similarity matrices respectively, with $\mathbf{st}^0 = \mathbf{I}_t$ and $\mathbf{sr}^0 = \mathbf{I}_r$; here $\mathbf{st}^0 = \mathbf{I}_t$ (resp., $\mathbf{sr}^0 = \mathbf{I}_r$) is the $n_t \times n_t$ (resp., $n_r \times n_r$) *identity matrix*. If we indicate with the symbol "$\circ$" the *Hadamard matrix product*[6] [7], at the k-th step, the $\mathbf{st}^k$ and $\mathbf{sr}^k$ matrices can be computed as:

$$\mathbf{st}^k = \mathbf{ST}^k \circ \mathbf{DT}^k \tag{7}$$

$$\mathbf{sr}^k = \mathbf{SR}^k \circ \mathbf{DR}^k \tag{8}$$

[5] See `http://tinyurl.com/proof-seke2011`.

[6] Given two matrices $\mathbf{A}$ and $\mathbf{B}$ of the same dimensions, the *Hadamard product* $\mathbf{A} \circ \mathbf{B}$ is a matrix of the same dimensions of $\mathbf{A}$ and $\mathbf{B}$ and it is defined as follows: $(\mathbf{A} \circ \mathbf{B})_{ij} = \mathbf{A}_{ij} \cdot \mathbf{B}_{ij}$

where:

$$\mathbf{ST}^k = \mathbf{TR} \times \left(\mathbf{\Psi_r} \circ \mathbf{sr}^{k-1}\right) \times \mathbf{TR}^t \tag{9}$$

$$\mathbf{SR}^k = \mathbf{TR}^t \times \left(\mathbf{\Psi_t} \circ \mathbf{st}^{k-1}\right) \times \mathbf{TR} \tag{10}$$

$$\mathbf{DT}^k_{ab} = \frac{1}{\sqrt{\mathbf{ST}^k_{aa}}\sqrt{\mathbf{ST}^k_{bb}}} \tag{11}$$

$$\mathbf{DR}^k_{ab} = \frac{1}{\sqrt{\mathbf{SR}^k_{aa}}\sqrt{\mathbf{SR}^k_{bb}}} \tag{12}$$

In the above equations, we have indicated with $\mathbf{\Psi}_r$ (resp., $\mathbf{\Psi}_t$) a square matrix $n_r \times n_r$ (resp., $n_t \times n_t$) where all the elements are set to ψ, with the exception of the diagonal where the elements are set to 1; the symbol $\mathbf{TR}^t$ represents the transpose of matrix $\mathbf{TR}$. We have thus reduced the computational complexity of each iterative step from $n_r^2 \times n_t^2$ to a simple matrix product; this reduction, coupled with the empirical observation that 5 iterative steps are sufficient to find convergence, makes our similarity metrics suitable in practical contexts. The last question that needs answering is how effective (in terms of Precision and Recall) our similarity metric is w.r.t. traditional ones like cosine. We answer this question next.

5. Experiments

In order to evaluate the performance of our similarity measure, we built a prototype in Java and MySQL and we conducted experiments using three well known social tagging websites: Bibsonomy, CiteULike, and MovieLens. The experiments we carried out aimed to answer the following question:

> *If we consider any two tags t_i and t_j belonging to a folksonomy, is our similarity measure capable of accurately assessing the extent to which they are related (similar) each other? And can it do so even when such tags have been drawn from the long tail of low popularity tags?*

5.1. The Dataset

To answer the above question, we conducted experiments on the following three datasets.

Bibsonomy. Bibsonomy is a social bookmarking website promoting the sharing of both scientific reference and general URL. We downloaded a snapshot of the website in June 2009, containing bookmarks made between January 1999 and June 2009.

CiteULike. CiteULike is a social bookmarking website that aims to promote and develop the sharing of scientific references amongst researchers. CiteULike enables scientists to organize their libraries with freely chosen tags which produce a folksonomy of academic interests. CiteULike

Dataset	*Users*	*Resources*	*Tags*	*Bookmarks*
Bibsonomy	4,696	578,587	147,076	648,924
CiteULike	57,053	1,928,302	401,620	2,281,609
MovieLens	4,009	7,601	15,240	55,484

Table 1. Features of our datasets

runs a daily process which produces a snapshot summary of what articles have been posted by whom and with what tags up to that day. We downloaded one such archive in November 2009, containing bookmarks made between November 2004 to November 2009.

MovieLens. MovieLens is a rate-based recommendation website that suggests to users movies they might like. We downloaded such dataset in January 2009, containing bookmarks made from December 2005 to January 2009.

Table 1 summarizes the features of the involved datasets.

5.2. Simulation Setup

Our experimental investigation aimed to quantify, in each of the above datasets, the extent to which our similarity measure was capable of identifying related tags, especially when tags were drawn from the long tail. To investigate this, for each dataset of Table 1 has been used as follows. We split it into two different sets, called *test set* and *train set*. Each train set was composed of 90% random bookmarks taken from the involved dataset; we used these bookmarks for training purposes. Test sets contained the remaining 10% of bookmarks which were used for testing. Each bookmark in a test set has then been used as a query; specifically, if the number of tags in such bookmark was large enough, then these were split into two different sets – if possible of the same size – called $tSet_Q$ (*query tag set*) and $tSet_E$ (*expected tag set*). In our experiments, a bookmark was considered large enough if it had at least 3 tags associated. Tags composing $tSet_Q$ were used to query the train set; in particular, we selected from the train set the k tags most similar to tags belonging to $tSet_Q$, according to two metrics: the one we proposed in Section 3, and cosine similarity, which we used as benchmark. We denote this set as $tSet_R$ (*result tag set*). The value of k was chosen equal to the size of the expected set in such a way that $tSet_R$ and $tSet_E$ had the same size. Finally, we compared $tSet_R$ with $tSet_E$: the higher the overlap between $tSet_R$ and $tSet_E$, the more effective the similarity measure in identifying related tags. This follows the intuition that, if a user associated a set of tags to a certain resource, such tags are related to each other (that is, $tSet_E$ contains tags related to those contained in $tSet_Q$).

To quantitatively evaluate our similarity measure, we computed two metrics commonly used in Information Retrieval, namely Precision and Recall [1]:

Propagation	*Bibsonomy*	*CiteULike*	*MovieLens*
$\psi = 0$	0.100638896	0.057922233	0.075126961
$\psi = 0.15$	0.128318833	0.063290603	0.112358995
$\psi = 0.3$	0.139761842	0.070652236	0.115026291
$\psi = 0.6$	0.140748308	0.079320913	0.115534133

Table 2. Precision values in our datasets

Table 3. Recall values in our datasets

$$Precision = \frac{|tSet_R \cap tSet_E|}{|tSet_R|} \quad (13)$$

$$Recall = \frac{|tSet_R \cap tSet_E|}{|tSet_E|} \quad (14)$$

We computed Precision and Recall values for each test bookmark; we repeated this process 10 times over different train and test splits of the datasets. The results we present next are averages of such runs.

5.3. Results

Tables 2 and 3 shows values of Precision and Recall we obtained by applying our similarity measure on the datasets of Table 1, for different values of ψ (see Equations 3–4). The benchmark is our similarity measure with $\psi = 0$, that is, the case in which our similarity measure reduces into cosine similarity.

From the analysis of Tables 2 and 3 we can draw the following main observation: in large scale folksonomies, classical approaches – such as cosine similarity ($\psi = 0$) – have difficulties finding similarity relationships among the tags belonging to the long tail, as their Precision and Recall is lower than those achieved with our iterative approach for any value of ψ. The considered datasets are characterized by a very long and prominent tail of low popularity tags; in these real cases, out iterative measure of similarity produces Precision/Recall that is approximately 40% better than cosine similarity for BibSonomy and CiteULike, and approximately 50% better for MovieLens.

6. Related Work

In the last few years, folksonomies have been the subject of extensive research. An interesting survey on the characteristics of folksonomies can be found in [4]. One of the first investigations into the characteristics of folksonomies

has been presented by Mathes [18]: in that work, the author discusses advantages (e.g., simplicity of use) and disadvantages (e.g., ambiguity, synonyms) of folksonomies, and investigates the community aspects behind folksonomies, on two scenarios, Flickr[7] and Delicious[8].

Despite their easy-of-use, the lack of structure that characterises folksonomies makes it difficult to browse and find relevant content. To tackle this issue, the research community has been actively researching techniques to support information retrieval. Approaches in this area have followed one of two streams: they have either tried to empirically derive an ontology from the underlying folksonomy, or they have tried to apply graph-exploration techniques on the folksonomy itself.

Lambiotte [14] and Mika [19], for example, were the first to extend the classic bipartite model of tag-resource towards a tripartite model, which takes into account both users (as actors), tags (as concepts) and resources (as instances); they showed that, by applying this model to Delicious, a lightweight ontology could be extracted from the underlying folksonomy. Similarly, [9] used similarity metrics to reconstruct a concept hierarchy.

Hotho et al. [12, 20] followed a different approach instead: they presented a formal model, which converts a folksonomy into an undirected weighted graph, and coupled it with a new search algorithm, namely "FolkRank", based on the well-known seminal "PageRank" [2]. They applied this algorithm to Delicious, and showed how it can be used as a tag recommender system. Other extensions of recommender systems to folksonomy structures have been explored [21, 10]; some of these have been assessed against one of the datasets we adopted in this study, namely BibSonomy [11, 13].

All the above approaches rely on a similarity measure to quantify tag relatedness. Measures which have been often used in the literature include the Jaccard coefficient [8], the cosine similarity [6], and a number of improvements over it [15, 22]. Liu et al. [15] dwelt further into the problem of computing similarities in folksonomies; in particular, they questioned the common assumption that text categorization can be mapped onto orthogonal spaces, due to problems of synonyms and ambiguities (as already figured out by [18]). They then devised an improved similarity metric ("SNOS", Similarity equations in the Non-Orthogonal Space) which is optimized for comparing objects mapped onto non-orthogonal spaces, considering a principle of "mutual reinforcement" from which we drew inspiration in this work. They proved the convergence of this technique and experimentally investigated the performance of SNOS on synthetic datasets, such as the formerly called MSN search engine (now, Bing[9]). Their novel metric was shown to outperform the classic cosine similarity, if applied to the context of finding similar queries. Some of their findings are here extended to the domain of folksonomies.

Similarity measures have often been evaluated on different datasets, making it difficult to assess their relative advantages and disadvantage in different domains. Furthermore, they have often been applied to manipulated datasets, making the comparison even more difficult. Indeed, in order to critically compare them, an evaluation framework has recently been proposed [17], with the aim of providing support to systematically compare several tag similarity measures, using data from Delicious [3]. This work contributes to the assessment of the suitability of similarity measures to scenarios characterized by power-law distribution of tags and non-independence of data, showing how traditional measures like cosine do not work, and proposing an alternative, iterative measure that provides good accuracy instead.

7. Conclusions

In this paper, we have shown that real world folksonomies are characterized by power law distributions of tags and non-independence of data. Under these conditions, traditional similarity measures like cosine similarity fail to capture tags relatedness. To remedy this, we have proposed a novel metric, specifically developed to capture similarity in large-scale folksonomies, that is based on the mutual reinforcement principle: that is, two tags are deemed similar if they have been associated to similar resources, and vice-versa two resources are deemed similar if they have been labelled by similar tags. We have described an efficient realisation of this similarity metric, and assessed its quality experimentally, by comparing it against cosine similarity, on three large-scale datasets, namely Bibsonomy, MovieLens and CiteULike.

Abstract

Semantic technologies provide the means to create a more efficient human-computer interaction. In this paper we showcase how to use semantic technologies in the design of a Document Management System (DMS) to re-engineer a legacy DMS using a text-based search. Due to the historical growth of the database, a text-based search without using domain knowledge delivers bloated result-sets that prevent an efficient use of the DMS. The requirement of an intelligent search can be suitably addressed by using semantic technologies, thus we propose such a new design of a DMS. We employ concepts used in ontologies to provide search results based on hierarchies that are based on concepts of natural language. We construct a metamodel for the application domain to deliver fitting suggestions along with the search results. Finally, we realise a prototype as a proof-of-concept based on the introduced design to highlight the evident advantages of a semantic approach.

1. Introduction

In recent times social interaction and collaboration entered the spotlight of websites, flaunting the title Web 2.0 [10]. After the wide acceptance and success of applications in Web 2.0, the semantic web as an evolutionary follow up of the classical web, which extends the classical web by using the context of information to process information, is rapidly gaining importance[9]. Folksonomies of Web 2.0 are the product of the collaboration of large amounts of individuals with unique perspectives. To be able to gain a foothold in daily life, semantic web products will have to extend Web 2.0 products like Folksonomies by semantic aspects.

A text-based search retrieves information containing the exact or terms similar to the search string. If you search just for a certain text, a text-based search is capable of delivering satisfying results. A text-based search is very likely to fail to find the context behind a search string, however. In the present study whe introduce a search capable of getting both the information and the context of a given text.

Legacy systems tend to evolve into behemoths that might get the required task done, but rather slowly. This is especially tedious when the legacy system is a stand-alone system of an organisation - and every user is forced to work in this system. The legacy system analysed in this work is a document management system, called internally Office Information System, used for filing and searching of documents. This document management system (DMS) has, due to natural growth of the document base, outlived the usefulness of its own text-based search as search results tend to deliver unmanageable amounts of data.

Therefore the capabilities of text-based search are seemingly met and a new approach was suggested, which is presented in this paper. We propose a concept for a semantic search for this DMS and we implement a prototype for the users of the legacy system. We will employ tagging-mechanics and constructs of natural language to support search, file and even navigation through the database. We realise a customised triplestore by using open source technologies. Furthermore we use a Folksonomy with semantic extensions to provide qualitative suggestions for categorisation, navigation and search. Finally, we give a short introduction of the metamodel used to model semantic relations between hypernyms and instances.

2. The Legacy Document Management System

The office (Organisational Unit E010 - "Organisation and Coordination") of the Vienna University of Technology is responsible for all incoming documents by mail, the distribution of these documents to the according organisational units and finally for the archiving of these documents for a period of ten years. The existing workflows are supported by a legacy software system named "OIS" (Office Informa-

tion System). The existing system is in its final software lifecycle stage, since it is not capable of meeting today?s requirements and problems in the processing of the existing amount of data arise. The system is in use since approximately 20 years and more than 200.000 files have been entered into the system, averaging at 10.000 files per year.

Examples of problems with the legacy DMS are:

- Lack of support when filing documents - currently the order of the system is maintained by the experience and established conventions of the users.
- No filing across topics - the legacy system can only attach documents to one topic. Content covering multiple topics can not be realised at the moment.
- Traceability of content - the description of content of a document is currently subject to undocumented conventions. These conventions determine which attributes are used to describe the content (e.g. contract-name, paragraph..).
- Limited number of search results - the maximum number of results is currently limited. Due to the nature of the DMS, not all relevant search results are listed by the system.
- Step-wise refining of search criteria - based on a result set, it is currently not possible to step-wise refine the search criteria to get better results.

The existing problems are faced by proposing a design and a prototype realisation as a proof of concept of an innovative and semantic document management system (DMS). By using a semantic approach we hope to improve the search beyond the capabilities of a classical, text-based search engine. To improve acceptance of the new DMS, current system users were heavily involved during design and implementation of the prototype. We integrate domain knowledge of the OIS users to find possible innovations in the area of DMS as the user group is considered as very experienced DMS users.

Finally a prototype of the DMS is implemented that integrates the semantics of the domain into the current workflows. By taking these semantic relationships into consideration, this prototype is capable of assisting during search and filing of documents by giving content and context related suggestions. To be able to give these suggestions, the system needs to derive the knowledge from the domain and from the current usage of the DMS by the users.

3. Design and Implementation of a Semantic Solution

The scenario described earlier is augmented by a number of factors that have to be taken into consideration for the final solution. These are current user-problems, additional requirements beyond the scope of the legacy DMS gathered in stakeholder-interviews and project management input. The boundaries of the new semantic solution are given by current workflows and processes. The search-function is considered a primary factor for the quality of the DMS in the given scenario as it is of central importance for the workflow in the enterprise. Another important factor are standardised descriptions and how to handle them in a user-friendly manner. The integration of semantic aspects into a folksonomy is required for a working tagging system in the context of this work. As it is one of the major problems of the current system and the system continously grows every year, suggestions for navigation through the data sets, but also for tagging have become a key requirement that needs to be addressed.

In the following chapters we show how we addressed these concerns in our concept and we give a short insight into the technical realisation in form of a prototype.

3.1. Improving the Search Beyond the Scope of a String Comparison

A text-based search is capable of returning exact or similar matches This scope however is too narrow for the requirements of the stakeholders because it does not provide accurate search results in the existing database. A semantic factor is missing [3]. Due to this deficiency, semantic relationships between terms won't be recognised and therefore excluded from the search results. To address these issues the system is able to ask the desired meaning of a term, if the user just entered a homonym. Furthermore the system is capable of mapping alternate naming to the same term. By supporting homonyms, synonyms and abbreviations in the DMS a new quality of search results for the user can be achieved.

3.2. Standardised Descriptions

Natural language with its numerous possibilities of expression and different points of view of similar terms represent obstacles in the standardisation of textual descriptions. This lack of standardisation prevents an automated processing of descriptions. To avoid these pitfalls, we employ the use of tags. This concept is being used in the Web 2.0 [10], [11] with big promise. However, using tags does not guarantee standardised description texts. But the simplification of language lowers the risk of complex descriptions and improves the automated processing of these descriptions.

3.3. Folksonomy with Semantic Extensions

A certain degree of freedom for creating tags in the daily usage of the system is a required trade off to increase user-

acceptance of the application. Similar to [9] and the success of Web 2.0, we believe a collective intelligence of the users is more productive than restrictions on the system. This holds especially true considering the collective need to have a usable tool. The focus of the concept therefore lies in the support of the workflows of the users and to create a more efficient work-experience. By using semantics in the processing of the data, the system is capable of supporting the user by proposing meaningful suggestions that are similar in content (and not just textually). Furthermore suggestions build a fundamental design element for navigating the existing datasets. To provide qualitative suggestions for categorisation, the language concept of hypernyms [4] is used in addition to homonyms and synonyms. By using the natural boundaries of the application domain, it was possible to build a metamodel based on the relationships between the generic terms (similar to the ontologies presented in [6]). We use only one metamodel in the application instance for the prototype.

Connections between hypernyms are modelled using only one kind of semantic relation. This relationship is a hierarchical relationship and shows which hypernym is the subordinate of the other (a meronym). Therefore, the focus is on the existence of a relation between two hypernyms and not on a detailed description of the relation itself. The user has to define the kind of relation of the suggested tags with the entered term himself, the system just shows connected tags. The system relies on the associations of the user to the shown combinations of different tags.

The simplified ontology of the user-domain reflected by the metamodel is the key element for semantic extensions. When performing a search with a combination of tags, the result set not only will contain matching tags, but also combinations of subordinate tags of the search tags (meronyms of the search tags). A tag used as a keyword in a search therefore represents a semantic tag space (all meronyms of the tag are included), containing the existing semantically relevant tags in the system.

3.4. Suggestions for navigation and tagging

Each result set of a user search comes with suggestions for further navigation[2]. These suggestions include recommendations derived from the domain knowledge to further constrain the result set of the follow up search and the tags created together with the tags of the search criteria Figure 1. To create the domain knowledge driven recommendations, meronyms of the entered tags are used. To refine the initial search, the user can add meronyms step by step to semantically tune the result set until it fits his expectations. The system also delivers suggestions for creating a tag or tagging documents (see [5]). During tag creation the user gets a suggested list of meronyms related to the created tag after choosing a hypernym. The metamodel is used to find the tags qualified for a relation Figure 2. For tagging documents, the system suggests combinations of tags sorted by frequency of appearance. Thus the user ins informed which sets of tags were used for prior tagging of documents. By showing possible matchings, the system guides the user to place his documents in the proper (best-fitting) filing area. The system supports the user by using the domain knowledge to provide suggestions in every aspect of the application.

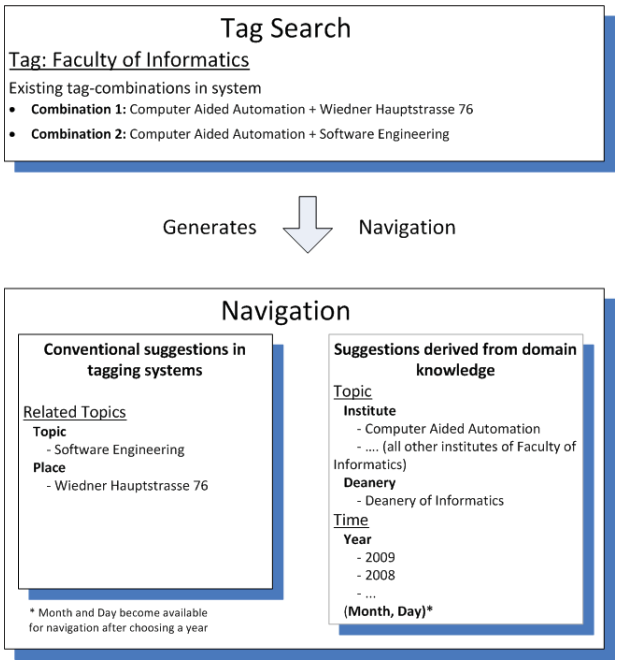

Figure 1. Example of suggestions for navigation

The structure of the hypernyms is built using three semantic axes (based on concepts presented in[12]). These axes are time, place and content. The suggested tags for navigation are grouped according to hypernyms on the semantic axes Figure 1. A strategy for visualisation of the search results is selected depending on the numbers of tags related to the search criterion. If there are less than six entries, the tags are listed consecutively. For more than six and less than 100 tags a combo-box is used. If more than hundred related tags exist, a text field with auto-completion is used together with a list of the top five tags used together with the search criterion.

3.5. Technical Implementation

The concept presented in the earlier sections is implemented in a prototype. The database technology was con-

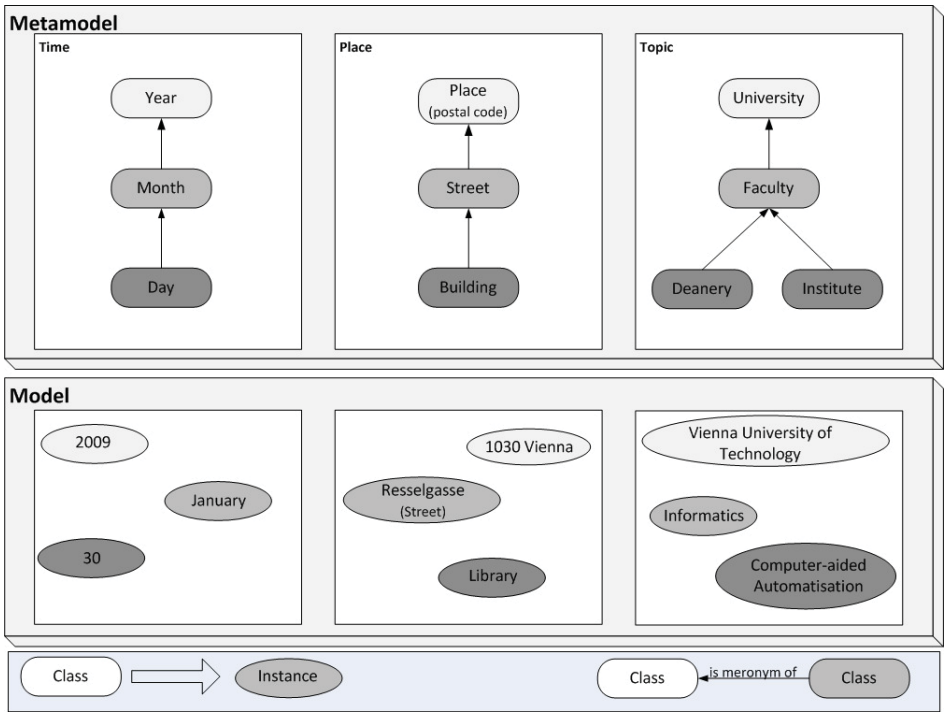

Figure 2. Overview of meronyms, classes and instances structure

strained due to a given software environment of the legacy application. Therefore a relational database system had to be used to create a customised triplestore. Due to the constraints earlier using a stand-alone triplestore or an existing triplestore based ona relational database management system (RDBMS) had to be discarded. The underlying RDBMS of the legacy application is MySQL[1], thus MySQL is the RDBMS on which the customised triplestore is build on. The triplestore is realised by using two tables in the database. The first table holds unique identifiers of the resources (realised as URIs) including the used literals. The second table holds ternary relationships between the resources of the first table and is representing therefore the triplestore. This option for realising the triplestore was not chosen deliberately but to conform to organisational constraints on the prototype.

As there were no such constraints on the choice of the web application framework, we chose "Ruby on Rails"[2]. Development started out swiftly due to numerous Code-Generators and Plugins available. RESTful Routes [3] are used to give access to the existing resources in the system. Every tag has a URL, which is used as unique identifier for the resources in the database. Auto-completion for entering tags is implemented using functionality provided by the "Yahoo! User Interface Library"[4].

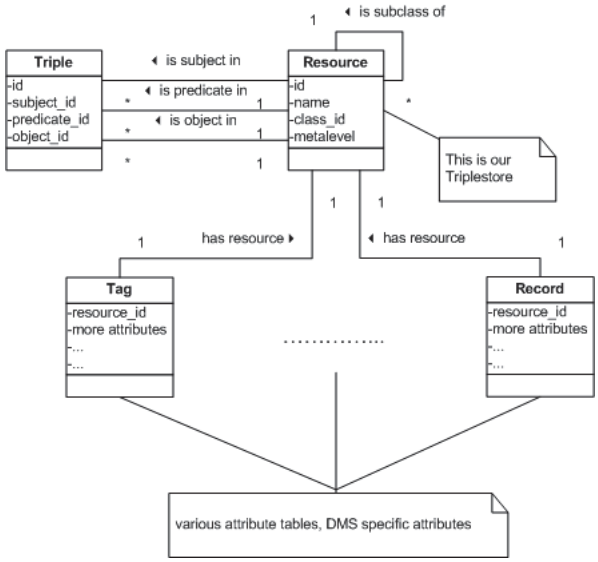

Figure 3. Classdiagram of the triplestore

We use the Metadata Terms of the Dublin Core Metadata Initiative[5] (DCMI) to describe the resources in the triplestore. Every resource of a type has at least a title.

[1] http://www.mysql.com/
[2] http://rubyonrails.org/
[3] http://guides.rubyonrails.org/routing.html#restful-routes
[4] http://developer.yahoo.com/yui/
[5] http://dublincore.org/

The type of the resource is specified by its given hypernym. Synonyms and denominators or abbreviations are optional for the descriptions. The predicates "dcterms:title", "dcterms:identifier" and "dcterms:alternative" are included from the standard to put tags and literals into the relations according to the DCMI Standard[5]. We use "dcterms:hasPart" to express meronym-like relationships between two tags. For reasons of performance additional attributes of resources are stored in conventional database tables. These attribute-tables hold the application-specific, DMS relevant data about the corresponding resources in the triplestore. To improve data queries, statistics about tags and documents are recorded in caching-tables. These tables are constantly updated. Furthermore, to improve performance consecutive queries on the same table are congregated into a single query.

4. Related Work

Folksonomies and the extensions of Folksonomy by using semantic aspects is currently a hot topic due to high activity in this area in the semantic research. Marchetti et al. identify in [8] weaknesses of existing, collaborative tagging-systems. Based on services of Wordnet [6] and Wikipedia [7] a semantic, collaborative tagging-system is implemented. Entries in Wikipedia and Wordnet are used to allow the user to learn more on a concept behind a tag. To connect a resource and a concept the user is able to choose from different relations. The main difference between the system in [8] and our system is that the system in [8] has external dependencies (e.g. Wordnet, Wikipedia, ..). The specification of a semantic statement is the argument for the semantic search, while our system accepts tags as search input. The main focus in [8] is semantic tagging - no semantic navigation for result sets is implemented.

Hope et al. [4] present a semantic tagging-system for blogs. They use hypernyms for their semantic. Compared to our work, Hope et al. chose a simplified approach as they do not rely on meronyms nor do they have a navigation. Similar to [8] they created a prototype using Wordnet to create an ontology of tags.

An interesting approach to generate semantic tag-hierarchies for navigation in an existing Folksonomy is presented in Laniado et al. [7] . In [11], Specia et al. build a semantic tag-hierarchie by using co-occuring tags in folksonomies. Both Specia et al. and Laniado et al. deliver the foundations for approaches to extend Folksonomies with semantic aspects. Our work relied on their research during migration of the data from the legacy system.

5. Conclusion

The proposed design of a semantic search based on a semantic tagging-system is not only restricted to the use in the DMS area. Any resources can actually be described using the tagging system. By supporting aspects of natural language, the way in which users and machines interact with each other can be improved. Applications that incorporate domain knowledge and aspects of natural language are capable of providing a level of service superior to conventional text-based searches. Concrete suggestions to refine the search result set can be directly derived from domain knowledge. The system is capable of asking the user to correctly specify ambiguous entries and actively support the user with semantic suggestions. We only used hypernyms and meronyms out of the number of possible semantic relations to provide the users with tangible, in natural language common relations. Simplicity is a key factor for acceptance of a system, especially in the domain of document management as users working with a DMS tend to be no computer experts. By passing into the semantical web, applications are required to show the user semantic aspects in the processing of information in a simplified fashion [1].

The prototype of the DMS has an improved search functionality over the legacy system and was widely accepted by the current DMS users. Descriptions and categorisations into filing areas were migrated from the legacy system as tags into the prototype to allow a smooth integration for the users.

5.1. Future Work

There are several possibilities to extend the presented method for realising a semantic tagging-system. The realisation of distributed queries across several application instances in different domains might be a possible extension. Using ontologies to transfer domain knowledge seems an obvious, possible next step. The modelled domain knowledge may not only be used for semantic suggestions but also for answering questions a user might pose. New co-workers might be integrated easier by finding proper visualisation techniques of the domain knowledge. A problem that has not been addressed yet is the tracking of changes in domain knowledge. Filing structures in the DMS, terms and semantics all change over time. There is a strong need for mechanisms to reconstruct changes in the domain knowledge.

***Abstract* — Ontologies are an approach for knowledge representation capable of expressing a set of entities and their relationships, constraints, axioms and vocabulary of a given domain. Manual construction of ontologies by domain experts and knowledge engineers is an expensive and time consuming task so, automatic and/or semi-automatic approaches are needed. Ontology Learning looks for automatically or semi-automatically identifying ontology elements like classes, taxonomic and non-taxonomic relationships, properties and axioms from textual resources. This article proposes a process for the automatic extraction of ontology taxonomic relationships from English texts using natural language processing techniques. Some experiments using a legal corpus were conducted in order to evaluate it. Initial results are promising.**

Keywords - Ontology, Ontology Learning, Natural Language Processing, Taxonomic Relationships, Ontology Hierarchies

I. INTRODUCTION

Ontologies are used by modern knowledge-based systems allowing the representation and sharing of knowledge about an application domain [9]. They provide a formal means of knowledge representation capable of expressing a set of entities, their relationships, constraints and rules (conditional statements) of a given domain [10][15].

Ontology Learning looks for identifying ontology elements like classes, taxonomic and non-taxonomic relationships, properties and axioms from textual resources. Manual construction of ontologies by domain experts and knowledge engineers is an expensive and time consuming task so, automatic and/or semi-automatic approaches are needed.

This paper proposes a process for automatic learning of ontologies from text based on Natural Language Processing (NLP) [1][4] techniques. Particularly, the process looks for identifying taxonomic relationships. An experiment conducted to evaluate this the process using a legal corpus is also described.

The article is organized as follows. Section II introduces the ontology definition used in this work. Section III presents an overview of the proposed process. Section IV describes an experiment conducted to evaluate it. Section V summarizes related work and, finally, section VI concludes the article discussing results and future work.

This work is supported by the Brazilian Government agencies: CNPq, CAPES and FAPEMA

II. AN ONTOLOGY DEFINITION

Ontologies are formal specifications of concepts in a domain of interest. Their classes, relationships, constraints and axioms define a common vocabulary to share knowledge [10].

Formally, an ontology can be defined as the tuple:

$$O = (C, H, I, R, P, A) \quad (1)$$

where,

$C = C_C \cup C_I$ is the set of entities of the ontology. They are designated by one or more terms in natural language. The set C_C consists of classes, i.e., concepts that represent entities that describe a set of objects (for example, "Mother" $\in C_C$) while the set C_I is constituted by instances, (for example "Anne Smith" $\in C_I$).

$H = \{kind\_of\ (c_1,c_2) \mid c_1 \in C_C,\ c_2 \in C_C\}$ is the set of taxonomic relationships between concepts, which define a concept hierarchy and are denoted by "$kind\_of(c_1,c_2)$", meaning that c_1 is a subclass of c_2, for instance, "kind_of(Mother, Person)".

$I = \{is\_a\ (c_1,c_2) \mid c_1 \in C_I \wedge c_2 \in C_C\} \cup \{prop_K\ (c_i,value) \mid c_i \in C_I\} \cup \{rel_K\ (c_1, c_2, ...cn) \mid \forall I, c_i \in C_I\}$ is the set of relationships between ontology elements and its instances. For example, "is_a ("Anne Smith", Mother)", "date_of_birth("Anne Smith", 02/12/1980)" and "mother_of("Anne Smith", " Katie Smith")" are relationships between classes, relationships, properties with its instances.

$R = \{rel_k\ (c_1,c_2,..., c_n) \mid \forall i, c_i \in C_C\}$ is the set of ontology relationships that are neither "kind_of" nor "is_a". For example, "mother_of(Mother, Daugther)".

$P = \{prop_K\ (c_i,datatype) \mid c_i \in C_C\}$ is the set of properties of ontology entities and its basic datatype. For instance, "date_of_birth (Mother, mm/dd/yyyy)".

$A = \{condition_x \Rightarrow conclusion_y\ (c_1,c_2,..., c_n) \mid \forall j, c_j \in C_C\}$ is a set of axioms, rules that allow checking the consistency of an ontology and infer new knowledge through some inference mechanism. The term $condition_x$ is given by $condition_x = \{(cond_1,cond_2,\ldots,cond_n) \mid \forall z, cond_z \in H \cup I \cup R\}$. For example, " ∀ Mother, Daughter1, Daughter2, mother_of(Mother, Daughter1), mother_of(Mother, Daughter2) ⇒ sister_of (Daughter1, Daughter2)" is a rule that

indicates that if two daughters have the same mother then, the daughters are sisters.

III. A Process For Acquiring Taxonomic Relationships

Figure 2 illustrates the proposed process for the automatic acquisition of ontology taxonomic relations, that is, the H set of the ontology definition in section II. It consists of four steps: "Tagging", "Extraction of Candidate Classes", "Identification of Hyponyms and Synonyms" and "Identification and Representation of Taxonomic Relationships".

The input of the process is a corpus consisting of a set of textual documents in a particular application domain. The step "Tagging" is intended to identify the tokens, sentences, grammatical classes and lemmas with the application of NLP techniques. Then, the "Extraction of Candidate Classes" phase is responsible for separating the tokens which are likely to be classes of the ontology hierarchy. The step "Identification of Hyponyms and Synonyms" identifies the synonyms and hyponyms of the candidate classes obtained in the previous step. The last stage of the process is the "Identification and Representation of Taxonomic Relations" phase which aims at identifying the final taxonomic relations using heuristic patterns and their representation in an ontology specification language. In the next sub-sections the transformations made at each stage of the process are presented in detail.

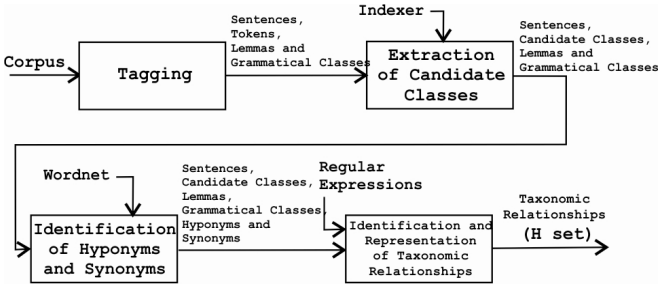

Figure 2. A process for the acquisition of taxonomic relations of an ontology

A. *Tagging*

The step "Tagging" has a corpus as input and aims at transforming them into a model that can be processed computationally. This step consists of the following activities: "Tokenization", "Division in Sentences", "Lemmatization" and "Lexical Analysis" (Figure 3).

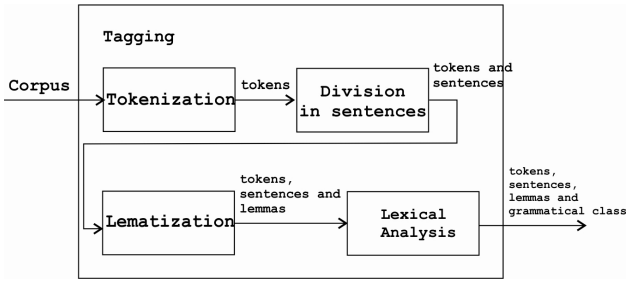

Figure 3. Activities of the "Tagging" phase

The "Tokenization" activity identifies the terms (tokens) in the document. The activity "Division in Sentences" organizes the identified tokens by grouping them into sentences. The activity "Lemmatization" performs the reduction of each token to its basic form . This form generalizes the inflected forms of a token making possible the grouping of tokens. The activity "Lexical Analysis" aims at identifying the grammatical classes for each token selected in the tokenization activity.

The result of this step is the corpus tagged with tokens, sentences, lemmas and grammatical categories. For example, Figure 4 shows the Tagger phase applied to the sentence "Mens have mothers. Mothers are great people!". For example, Figure 4 shows the processing results of applying the "Tagging" phase to the text fragment "*Mens have mothers. Mothers are great people!*".

The first frame shows the terms that were marked as tokens: "Men", "Have", "Mothers", "Mothers", "Are", "Great" and "People". Dots and spaces are also tokens, however, for illustrative purposes, only the terms were shown. The second frame shows the result of dividing the text into sentences: "Men Have mothers" and "Mothers are great people". Next "Lemmatization" is performed on each term. For example, the term "mothers" has "mother" as lemma. The last frame corresponds to Lexical Analysis and shows each token and its corresponding part of speech. For example, the term "mothers" is tagged NNS [14] indicating that this is a plural noun.

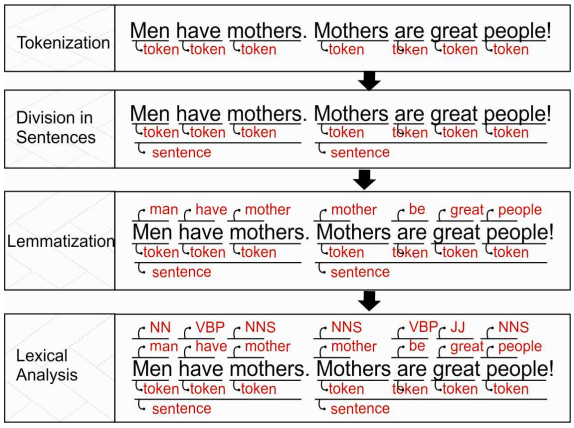

Figure 4. Example of a "tagged" text

B. *Extraction of Candidate Classes*

This phase aims at selecting candidate classes among concrete and abstract nouns.

The hypothesis assumed in this work is that only nouns may be considered classes. Thus, conceptually speaking, we can find two kinds of nouns: concrete nouns and abstract nouns. Concrete nouns are used to represent people names (anthroponyms) or place names (toponyms), which essentially characterizes class instances. Therefore, in the "Extraction of Candidate Classes" anthroponyms and toponyms are ignored and only concrete and abstract nouns are selected.

The products of this step are candidate classes, sentences, lemmas and grammatical classes.

C. *Identification of Hyponyms and Synonyms*

The "Identification of Hyponyms and Synonyms" looks for the identification of synonyms and hyponyms in WordNet [21], a lexical database that contains natural language terms, their definitions and their semantic relationships as synonymy, hyponymy and hypernym. The classes selected in the previous step are located in Wordnet and whenever a synonym or hyponym is found this occurrence in the text is stored. That is, each class is associated with an array of synonyms and hyponyms from the text. The product of this step is the same product from the previous stage plus the relations of synonymy and hyponymy, of each select term, found in Wordnet.

D. *Identification and Representation of Taxonomic Relationships*

The "Identification and Representation of Taxonomic Relationship" aims at discovering taxonomic relationships through the application of heuristic patterns and at representing them in an ontology specification language. Each sentence is analyzed in order to match the patterns. To test the existence of hyponymy relations we apply regular expressions on sentencing patterns with heuristic examples as the Hearst patterns [11]. Regular expressions are a formal method to specify a text pattern [12]. For example, applying the regular expression "([A-Za-z]+,.)+[A-Za-z] + and other [A-Za-z]+" to "*My daughter loves dolls, masks and other toys*", the matched pattern should be "*My daughter loves dolls, masks and other toys*". The tokens "Dolls" and "Masks" are related to "Toys" in a relationship of hyponymy, thus being "Toy" a superior class of "Doll" and "Mask" in the hierarchy of an ontology. This matching represents the pattern (iv) in the table of Hearst heuristics patterns of Figure 5, where NP0 represents a token hierarchically superior to the other NP.

(i) NP0 such as NP1 {, NP2 ... , (and | or) NPi}
(ii) such NP0 as {NP ,}* {(and | or)} NP
(iii) NP {, NP}* {,} or other NP0
(iv) NP {, NP}* {,} and other NP0
(v) NP0 {,} including { NP ,}* {or | and} NP
(vi) NP0 {,} especially { NP ,}* {or | and} NP

Figure 5. Heuristic Patterns of Hearst (Hearst, 1992)

The products of this phase are the taxonomic relationships, the set H of the definition of ontology in Section II, represented in an ontology specification language.

IV. EVALUATION

A case study in the area of Family Law allows for a preliminary assessment of the effectiveness of the proposed process. For that, a prototype tool called T-NLPDumper has been developed for automating the process using Java [13].

A corpus from the Family Law Doctrine [7] has been used in the case study. One hundred sentences randomly selected from the corpus has been manually analyzed by a domain expert, who did the manual identification of taxonomic relationships. These results (Figure 6) were manually compared with the results found on the automatic extraction of taxonomic relationships with the T-NLPDumper tool .

The results were also compared with an adaptation of the precision measure from the Information Retrieval area [5], considering the number of correctly extracted taxonomic relations.

Precision is the ratio between the number of taxonomic relationships extracted correctly (NREC) and number of taxonomic relationships extracted (NRE).

$$P = NREC / NRE \quad (2)$$

The precision value obtained in this experience was 81,57%.

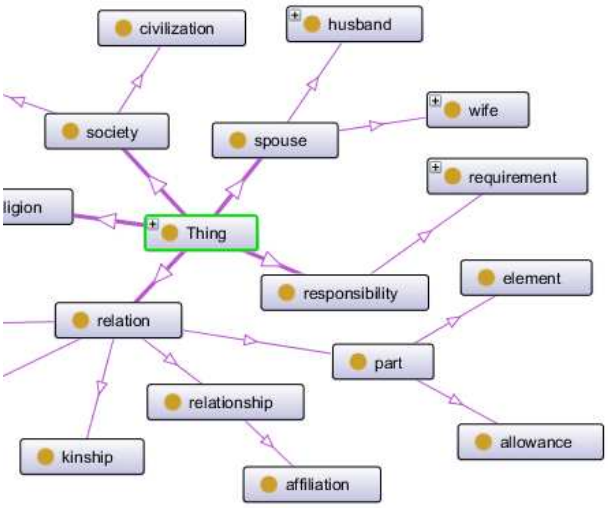

Figure 6. Part of the ontology hierarchy obtained as a result of the experience.

V. RELATED WORK

Table 1 shows the main approaches for automatic and semi-automatic identification of taxonomic relationships.

The main techniques used (second column of Table 1) are based on lexical syntactic patterns [11][19], statistics with Markov Logic Networks (MLR) [6] and Machine Learning techniques (ML) [3][2][16]. More recent works have in common the application of techniques of Natural Language Processing (NLP) in association with other techniques.

The approaches described in [6][16][19] and the one proposed in this article use WordNet as a lexical base for the extraction of hyponyms and GATE [8] to perform the Natural Language Processing tasks. Weka [20] was used as a framework for the clustering tasks in [16], while the tools TreeTagger [18] and Lopar [17] are used in [3] to find grammatical categories and as a parsing tool, respectively.

The effectiveness is shown in terms of the precision obtained for each approach in their experiments. However, these numbers cannot be considered for comparative purposes, because the evaluation of each approach was performed with different corpora and ontologies.

TABLE I. COMPARATIVE TABLE OF THE MAIN TECHNIQUES FOR LEARNING TAXONOMIC RELATIONSHIPS

Approach / Year	Main Technologies	Main Tools	Effectiveness (Precision) / Domain	Level of Automation
Cimiano et al., 2004 [3]	CFA NLP	TreeTagger Lopar	29,33% / Tourism 33,11% / Finance	Automatic
Drumond, 2009[6]	NLP MLN Dictionary PREHE	GATE Wordnet	17% / Tourism	Semi-Automatic
Caraballo, 1999 [2]	ML-Clustering	-	39% / Wall Street Journal	Automatic
Sarmento, 2009 [16]	ML - Clustering NLP Dictionary	WEKA GATE Wordnet	n/a / Tourism	Semi-Automatic
Hearst, 1992 [11]	Lexical Syntactic Patterns	-	63%	Automatic
Ting Wang et al. 2006 [19]	Lexical Syntactic Patterns SVM NLP Dictionary	Wordnet GATE	73,87% /-	Automatic
Correia et al, 2011	NLP Heuristic Patterns Dictionary	GATE Wordnet	81,57% / Family Law	Automatic

The approaches in [2], [3], [11] and the one proposed in this work provide solutions for a fully automatic acquisition of taxonomic relations, while the approaches in [16] and [6] propose just semi-automatic solutions.

Main advantages of the technique proposed here are its domain independency and high precision value (more than 80%).

VI. CONCLUSION

The automatic process for ontology learning proposed in this paper is based on natural language processing and consists of four steps: "Tagging", "Extraction of Candidate Tokens", "Identification of Hyponyms and Synonyms" and "Identification and Representation of Taxonomic Relations".

The process has been evaluated through a case study conducted in the domain of Family Law, showing good results, and demonstrating that the use of techniques of natural language processing represents a promising approach for learning taxonomic relationships of ontologies.

Currently, new heuristic patterns are being developed in order to improve the identification of taxonomic relationships. The development of a tool for implementing all the proposed process is also under construction.

Finally, to improve the results of the proposed tool it is necessary to compare them with concept extractions done manually by domain experts in other domains.

Abstract - **Our society's reliance on a variety of critical infrastructures (CI) presents significant challenges for disaster preparedness, response and recovery. Experts from different domains including police, paramedics, firefighters and various other CI teams are involved in the fast paced response to a disaster, increasing the risk of miscommunication. To ensure clear communication, as well as to facilitate CI software interoperability, a common disaster ontology is needed.**
We propose using the knowledge stored in domain glossaries, vocabularies and dictionaries for the creation of a lightweight disaster management domain ontology. Glossaries, vocabularies and dictionaries are semi structured representations of domain knowledge, where significant human effort has been invested in choosing relevant terms, determining their definitions, acronyms, synonyms and sometimes even relations. We use that knowledge built into semi formatted documents for ontology learning. In particular, we look at five glossaries/vocabularies from the disaster management domain and analyze their content similarity and structure. A lightweight disaster ontology is created exploiting the structure of the semi-structured source documents.

Keywords- Ontology, Glossary, Disaster Management, Ontology Learning

I. 1. INTRODUCTION

Today we rely heavily on a variety of critical infrastructures (CI) such as electrical systems, water supplies, telecommunications, transportation, emergency services and others. Each of these systems is highly complex with their daily operation, maintenance and repairs requiring specialized domain knowledge. On the other hand, there exists significant interdependency between these systems: water distribution systems rely on electricity to power water pumps and emergency response teams rely on a variety of telecommunication methods. The significance of the cascading effects caused by interdependencies of CI has been recognized and significant efforts have been made in attempts to understand and manage them better [1] [2].

The variety of infrastructure systems involved, together with their interdependencies, demand an interdisciplinary approach to disaster management. Involvement of experts from different domains, and the need for exchange of information across domains (between people, as well as between machines), represent significant challenges in achieving successful communication. A word in common to two or more domains may have different meanings; or, conversely, different terms may represent the same concept. In fast paced emergency response situations, this may cause misunderstandings and possibly result in severe consequences.

The importance of having a common understanding within the disaster management field has been recognized; consequently, different glossaries, vocabularies and dictionaries have been created by multiple agencies involved in the disaster prevention, response and recovery processes [3] [4] [5] [6] [7]. Depending on the main focus of the agency, these glossaries, vocabularies and dictionaries vary with regards to the terms they include as well as term definitions. Furthermore, because they are mainly created to be used by people, they are in text form (PDF or text files) that cannot be easily read and understood by computers. As such, these glossaries, vocabularies and dictionaries cannot be used in the information systems that are becoming an integral part of any disaster response process. The way of making this knowledge available for use by computers is through ontologies.

An ontology is a formal, explicit specification of a shared conceptualization [8] that provides a common understanding of information. Additionally, ontologies provide a way of representing human knowledge, making it readable and understandable for machines. This, in turn, represents the basis for achieving semantic interoperability.

In this paper we look at five glossaries and vocabularies each from a different Canadian or American disaster management agency, analyze their differences and propose the creation of an ontology from these glossaries, vocabularies and dictionaries. In the remainder of the paper, the term glossary will be used to represent glossaries, vocabularies and dictionaries.

This paper is organized as follows: Section II reviews related work including ontologies in disaster management and ontology learning. Emergency management glossaries are presented in Section III together with comparative analyses. Section IV describes ontology creation from glossaries and the conclusions and future work are presented in Section V.

II. Related Work

The main directions of research efforts related to CI interdependencies are: research dealing with analyzing past incidents that involved CI interdependencies [1] [2], studying infrastructure interdependencies through the use of simulators [9] [10] [11] and ontologies in disaster management [12] [13]. Particularly relevant to our work is the work on ontologies.

Peng et al. [12] propose the Emergency Case Ontology Model (ECOM) as a way of organizing the emergency case knowledge by taking into consideration relations among emergency cases. The proposed model handles heterogeneity among different earthquake disasters, but it is earthquake specific and does not consider other emergencies.

Castorini et al. [13] propose the Knowledge Base System (KBS) founded on ontologies with the main goal of modeling CI and their interdependencies. The proposed framework consists of: MKIONT (Meta Knowledge Infrastructure ONTology) which defines a template for conceptualization; IONT (Infrastructure ONTology) which represents knowledge of a specific CI domain (e.g. water distribution or telecommunication); FONT (Federation ONTology) which describes interactions between infrastructures and the Gateway which provides a connection between the KBS and simulators.

Another field relevant to this work is ontology learning, which is the process of building an ontology from scratch by enriching, or adapting an existing ontology in a semi-automatic fashion using distributed and heterogeneous knowledge and information sources. The majority of research efforts in ontology learning focuses on learning from unstructured sources [14] [15] [16], primarily text documents, as a significant portion of today's knowledge is stored in such form. Gómez-Pérez and Manzano-Macho compared different ontology leaning methods from unstructured text [17], and presented advantages and disadvantages of each method. Other possible sources of information for ontology learning are structured sources such as databases and semi-structured documents including XML schemas, web pages, glossaries, dictionaries and vocabularies. Since semi-structured sources have various structure elements, the structure can be exploited to extract concepts and/or relations

Zhao and Li [18] propose ontology learning from the hierarchy structure of organization websites. The approach is motivated by the observation that the organization web site is organized in a hierarchical sitemap that reflects a shared view of the organization structure. Consequently, they use the sitemap hierarchy to create the lightweight organizational ontology.

Karoui et al. [19] combine exploiting the structure of the HTML documents with natural language processing techniques for ontology learning. They propose the Contextual Concept Discovery (CCD) algorithm based on K-means clustering and guided by a structural context. In HTML documents they observe physical links, such as heading-paragraph links that represent the structure of documents and logical links that represent links between tags, such as keyword tags. When terms appear in the same context, within the same block tag or within linked elements, it indicates their co-relation. This structural context drives the incremental use of K-means algorithm in identification of ontology concepts.

Davulcu et al. [20] use taxonomy-directed web sites to bootstrap the ontology population task of extracting instances of concepts and their classification into ontology concepts. OntoMiner detects HTML markup and turns it into hierarchical structures that are in turn used for ontology population. Shinzato and Torisawa [21] use itemization and listing in HTML documents to extract hyponym relations.

Navigli and Velardi [22] enrich the CIDOC CRM cultural heritage core ontology using the Art and Architecture Thesaurus (AAT). Descriptions of the meanings of the terms from AAT are processed using NLP (Natural Language Processing) techniques, annotated with CIDOC properties and formalized. The core ontology is enriched from formalized term definitions.

García-Silva et al. [23] propose a methodology for creating ontologies by reusing and re-engineering non-ontological resources. Their proposed patterns for re-engineering define a process to transform non-ontological resources into ontologies. While [23] is concerned with the transformation process, we explore to which extent the structural elements of glossaries can be used in ontology creation.

III. Emergency Management Glossaries and Vocabularies

Glossaries and vocabularies play a significant role in emergency management due to the importance of clear communication during disaster response. Misunderstandings could lead to severe consequences, even the loss of life. Therefore government and private agencies involved with disaster management often create and publish dictionaries of relevant emergency terms. Depending on the focus of each agency, the included terms and their definitions may be significantly different.

We have analyzed five glossaries/vocabularies readily available from the web. Two are from Canadian sources: the Emergency and Crisis Communication Vocabulary from Government Services Canada [3] and the EMO (Emergency Management Ontario) glossary [4] from the Ontario provincial government. The remaining three sources are American: NIMS (National Incident Management System) glossary [5], ICDRM (The Institute for Crisis, Disaster and Risk Management) glossary [6] and ICS (Incident Command System) glossary [7]. The five listed glossaries were chosen since they are relatively generic nonspecific management glossaries dealing with generic disasters and are not disaster (i.e. flood or earthquake) or responder type (i.e. firefighters or CI teams) specific. The ICS glossary is somewhat specific since it deals with command and control in particular, but its main goal is coordination among the different actors in emergency situations which is not highly dependent on disaster or responder type. The two Canadian sources contain English and French terms and definitions, but for the purpose of this analysis, due to the need to compare to American glossaries

which are only available in English, we have considered only the English terms of the glossaries. The same approach can be applied on the French part of those glossaries, or even glossaries in different languages.

A. Glossary Content Comparison

All five observed glossaries describe the same domain and therefore it is expected that the terms included in them are similar and that a high number of terms is defined in most glossaries. Some discrepancy between Canadian and American dictionaries may exist due to the slight differences of American and Canadian English. As a first step, we looked into the five glossaries to see if, and to which degree, our expectations of content similarity were correct.

From the five observed glossaries, four are relatively close in the size (Table I) and include between 115 and 167 term definitions, while ICDRM is significantly larger, including 572 term definitions. As opposed to the other four glossaries that are intended to be used in practice, ICDRM is established for the purposes of emergency management education and practice. ICDRM was created by the Institute for Crisis, Disaster, and Risk Management, at The George Washington University.

Table II depicts the overlap between the observed glossaries. Even though all five glossaries are relatively generic emergency glossaries, there is very little overlap between them. Only seven terms are defined in all five glossaries: *emergency, hazard, mitigation, preparedness, recovery, response* and *threat*. And only five terms appear in four glossaries: *communications, incident, incident management team, prevention* and *public information officer*. Some terms that could be considered significant disaster management terms, such as *risk assessment, disaster, crisis* and *alert*, are defined in only two glossaries. This demonstrates that a single glossary does not fully cover the domain and cannot be used as a standalone source for the creation of a disaster ontology. The high number of terms appearing in only one glossary is in part caused by the fact that the ICDRM glossary contains significantly more terms than the remaining four.

To further investigate the commonalities among glossaries, we observed the number of overlapping terms between pairs of glossaries. Table III shows the number of overlapping terms in pairs of glossaries and the percentage of relative overlap. The relative overlap is calculated as:

```
Relative overlap = (2 x number of overlapping
terms) / total number of terms in the pair of
glossaries x 100%.
```

The overlap between the Canadian (Emergency and Crisis Communication and EMO) and the American glossaries is relatively low – 10% or less. However, overlap between the two Canadian glossaries is still only 14%. A high number of term overlap occurs between the different American glossaries, with the highest between NIMS and ICS at 52%. This high term overlap can be explained by the fact that both ICS and NIMS are created by Federal Emergency Management Agency (FEMA).

TABLE I. GLOSSARY SIZE

	Emer. and Crisis Com	EMO	NIMS	ICDRM	ICS
# of terms	115	129	167	572	153

TABLE II. TERM OVERLAP BETWEEN GLOSSARIES

Number of glossaries term appears in	Number of terms
1	638
2	84
3	67
4	5
5	7

TABLE III. NUMBER OF OVERLAPPING TERM IN PAIRS OF GLOSSARIES AND RELATIVE OVERLAP.

	Emer. and Crisis Com	EMO	NIMS	ICDRM	ICS
# of terms	115	129	167	572	153
Emer. and Crisis Com		17 (14%)	13 (9%)	30 (9%)	10 (7%)
EMO			14 (9%)	34 (10%)	9 (6%)
NIMS				93 (25%)	84 (52%)
ICDRM					81 (22%)

There is a significant overlap of 25% between NIMS and ICDRM caused by the fact that ICDRM is developed with NIMS as its basis; moreover, a high number of ICDRM terms cite NIMS' definitions.

Among the five glossaries, we expected significant term overlap due to their shared domain and purpose, but the findings are on the contrary. Only high overlap is found between glossaries created within the same agency, ICS and NIMS glossaries. Overlaps between other pairs are generally low, and somewhat higher between pairs of glossaries from American sources.

Even for terms defined in all glossaries, definitions are often quite different across the glossaries; this is illustrated in Table IV with *Threat* as an example. In the five glossaries, there are five different definitions of term *Threat*. ICDRM gives two definitions of the term *Threat*, with one being the same as the definition in ICS.

In some situations, different terms have similar meanings. If we look at definition of the term *Hazard* in the ICDRM and NIMS glossary, 'Something that is potentially dangerous or harmful, often the root cause of an unwanted outcome,' it is very similar to the definition of the term *Threat* in the EMO glossary. The EMO glossary defines a *Threat* as, 'A person, thing or event regarded as a likely cause of harm or damage.' The two terms, *threat* and *hazard*, are defined as distinct terms in all five glossaries, but some of their definitions make it hard to distinguish between the meanings.

This analysis shows that even though the five glossaries deal with the same domain and have the same purpose, they are very different in the terms that they define as well as in term definitions.

TABLE IV. TERM *THREAT* IN DIFFERENT GLOSSARIES

Glossary	Term Definition
Emerg. and Crisis Comm.	The combination of the presence of a hazard and an exposure pathway.
EMO	A person, thing or event regarded as a likely cause of harm or damage.
NIMS	Natural or manmade occurrence, individual, entity, or action that has or indicates the potential to harm life, information, operations, the environment, and/or property.
ICDRM	An indication of possible violence, harm, or danger.
ICDRM	The possibility of a hazard occurrence; something that has the potential to cause harm.
ICS	An indication of possible violence, harm, or danger.

Therefore, the creation of a domain ontology needs to use a variety of domain glossaries to encompass vocabularies of different domain members and to achieve better domain coverage.

B. Glossary Structures used for Ontology Creation

Glossaries, as semi-structured documents, have structure and formatting that can be used to facilitate ontology creation. The typical structure of a glossary is a term or label followed by the term's definition. For example, '**Communications:** The process of transmission of information through verbal, written, or symbolic means.' In all five observed glossaries, the term label is distinguished from the rest of the text by bold font; for example, '**Hazard:** Something that is…'. In three sources, the term is separated from its definition by a colon, while the other two use new lines. Glossary terms are concepts significant for a domain of interest. Therefore, we extract glossary terms using source document formatting and create initial ontology concepts.

Acronyms are typically included in glossaries. In [3], acronyms are separated from the term by using a semicolon: '**business resumption planning; BRP**'. In the remainder of the observed glossaries, acronyms are in brackets following the term: '**Emergency Operations Center (EOC):**…**'**. This is used to extract properties of the concepts for the ontology. Some of the documents, such as EMO, NIMS and ICS also have a separate section for lists of the acronyms, where only the acronym and its meaning are listed. Often, this is a duplication of the acronym listed with the term definition.

Redirection is commonly used to lead from one term to another one: '**Action Plan:** See Incident Action Plan'. If the term does not have definition, but it only has redirection, redirection is used to lead to a synonym term where the description is specified. In the observed documents, redirection is performed through the use of the 'See' word preceding a redirecting term. Therefore, if the term does not have a description and it is followed by a redirecting 'See' word, the two terms are considered synonyms. For the identification of synonyms, EMO also uses the 'synonym' word in formatting such as '**full-scale exercise** (synonym: **field exercise**)'.

Some terms are described and also contain a redirecting 'See' word; for example: '***Competency***: A specific knowledge element… See "Proficiency"'. In this case, description of a redirecting term c*ompetency* and a redirected *proficiency* term are not the same, and therefore the terms are not synonyms. In this situation 'See' indicates a related or similar concept. In the presented example, 'See' indicates that term c*ompetency* is related to term *proficiency*. EMO uses 'See also' in lieu of 'See' from the presented example to indicate related terms: '**Incident Action Plan (IAP):** An oral or written plan ... See also "Action Plan."'. These two patterns are used for the creation of relations between ontology concepts. In the Emergency and Crisis Communication Vocabulary, relations among terms are given more significance than in the other observed documents. The abbreviation 'cf.' is used to identify a cross-reference to a related concept, each being separated by a semi-colon; for example, '**mitigation** … cf. emergency management; preparedness; recovery; response; resumption'. Of the 115 terms defined in this document, related term(s) are specified for 91. Commonly, several related terms are specified for a single term, bringing the total number of relations specified in this way to 242. Even though this pattern appears in only one of the observed glossaries, it is a significant resource for the creation of relations in an ontology.

Some glossaries distinguish among different meanings of a single term. The emergency and Crisis Communication Vocabulary uses number superscripts to indicate different meanings, while EMO uses numbers in brackets following the term: '**hazard (1)** A risk that is a threat. **hazard (2)** An event ...'. ICDRM uses bullets to specify different definitions, as in:

'Hazard:
- A potential or actual force, …
- Something that is …'

ICDRM has formatting features indicating taxonomic hierarchies. For example, the term *volunteer* is in the ICDRM, but its definition is not specified. The term *volunteer* is followed by bulleted list where each bullet specifies definitions of a specific kind of volunteer, such as *Accepted volunteer*, *Affiliated volunteer*, *Recruited volunteer* and others. This pattern defines a hyponym (is-a) relation where one concept is a subconcept of another concept; for example, *Affiliated volunteer* is a special kind of *Volunteer*. This is the only structural pattern in observed glossaries that we use for the extraction of hyponym relations.

IV. DISASTER ONTOLOGY

A glossary, in general, contains explanations of concepts relevant for certain field. Domain experts' knowledge was used in the process of the glossary creation and it is built into the glossary itself. Terms defined in the glossary are identified as relevant terms by the people and organizations that created the glossary. Other elements, such as synonyms, related terms, acronyms and subconcepts, are extractions of domain

knowledge as well. The structures of the glossaries represent a strong foundation for the creation of an initial domain ontology.

We use the formatting aspects of glossaries described in subsection III.B as a source of information for the ontology's creation. We use only the formatting elements to extract an ontology, without the use of any natural language processing techniques. Fig. 1 depicts the use of the formatting elements of glossaries in ontology learning. The left column shows the structural elements observed in one or more glossaries. It is followed by the example of each pattern from one of the observed glossaries. Those formatting patterns identify fragments of the glossaries that are translated into different ontology elements as shown in the ontology element column of the Fig. 1. Patterns used in the ontology creation process are only those found in the five disaster management dictionaries analyzed. The use of other glossaries, dictionaries or vocabularies may demand different or additional patterns depending on the structure of the source document.

Using a single glossary for ontology creation would limit the ontology to the view of the domain described by the glossary creator; this single view is likely to not be shared by other participants in the same domain. The coverage of the domain would also be limited. To alleviate this, we use the multiple glossaries described in Section III for the ontology creation.

Fig. 2 illustrates a fragment of the ontology created from the five observed glossaries using only their formatting elements without the use of any natural language processing techniques.

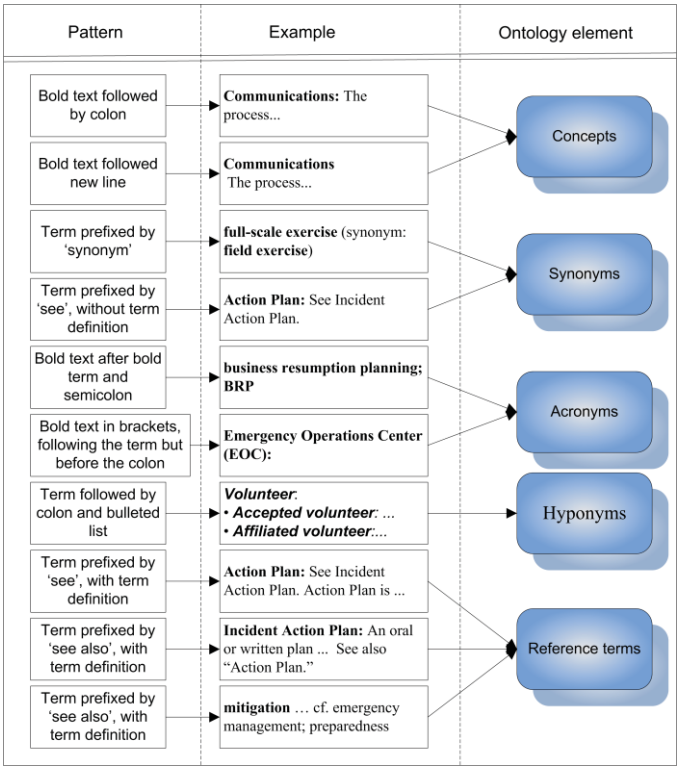

Figure 1. From formatting element to ontology component

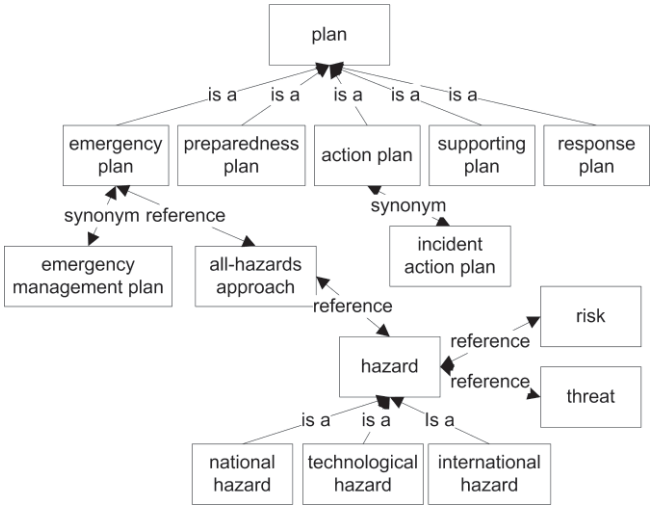

Figure 2. Fragment of ontology created from glossaries

The concepts *hazard* and *threat* appear in all five glossaries. The concept *Plan* is defined only in the ICDRM glossary, while the other glossaries contain definitions of more specific plans, such as *preparedness plan* and *response plan*. *Emergency management plan* is identified as a synonym of *emergency plan* and *action plan* is a synonym of *incident action plan*.

For use by machines and software systems, the created ontology can be represented in an ontology language of choice, such as OWL (Web Ontology Language), OIL (Ontology Interchange Language) or others. The choice of representation language does not change the ontology learning process, but it only changes how the ontology is represented for automatic processing.

V. Conclusions and Future Work

In disaster management, involvement of various teams with different views of the domain presents a significant challenge in achieving a successful communication process. A way of achieving a common understanding among teams is through ontologies. Even though this work focused on disaster management, similar situations exist in other fields where different views of the domain are expressed through a variety of glossaries.

We explore the use of glossaries as semi-formatted stores of domain knowledge for ontology creation. Domain experts' knowledge was used in the process of glossary creation and is built into the glossary in the form of content and formatting.

Not only do glossaries contain a list of terms that may be used for ontology creation, but they also contain additional structural patterns that we propose may also be used. In addition, we investigate the discrepancy between different views of the same domain expressed in domain glossaries. As a case study, we observe five glossaries from the disaster management domain; however, is it expected that glossaries from other domains will demonstrate similar properties. Even

though the five observed emergency management glossaries are relatively generic, their content overlap is very low, with only five terms appearing in all five. Even between two glossaries created by the same emergency management agency, term overlap is only 52%. This indicates that for ontology creation, it is preferable to use multiple domain glossaries from different sources. This will lead to better domain coverage and facilitate a true shared conceptualization.

Formatting of the documents is similar across observed glossaries. All five glossaries use similar formatting to distinguish between terms and their definitions, and similar methods to identify synonyms, acronyms and related terms. We use the formatting of documents to extract terms, synonyms, acronyms, hyponyms and referenced terms to create an initial ontology. The main advantage of this approach is the use of domain knowledge built into domain glossaries and the relative simplicity of the processing. The initial ontology created using this approach is lightweight, without considerable detail, but the quality of included terms and relations is high due to the high reliability of the source document. The created lightweight ontology can be enriched by applying further processing using statistical methods or natural language processing methods, such as the approach proposed by Navigli and Velardi [22].

The direction of the future work is towards fully utilizing the structure of semi-formatted documents for ontology learning. A rule engine that will enable specifying custom rules for the extraction of concepts and relations from generic semi-formatted documents needs to be created. This rule engine will enable the user to specify how formatting should be used in ontology learning. Because this approach creates lightweight ontologies, we want to integrate it with other ontology learning mechanisms from un-structured text. Also, a way of distinguishing between the significance of different source documents is needed; that is, a method that will account for source relevance and reliability.

Abstract

A body of knowledge in Software Engineering requires experiments replications. The knowledge generated by a study is registered in the so-called lab package, which must be reviewed by an eventual research group with the intention to replicate it. However, researchers face difficulties reviewing the lab package, what leads to problems in share knowledge among research groups. Besides that, the lack of standardization is an obstacle to the integration of the knowledge from an isolated study in a common body of knowledge. In this sense, ontologies can be applied, since they can be seen as a standard that promotes the shared understanding of the experiment information structure. In this paper, we present a workflow to generate lab packages based on $_{EXPER}Ontology$*, an ontology of controlled experiments domain. In addition, by means of lab packages instantiation, it is possible to evolve the ontology, in order to deal with new concepts that may appear in different lab packages. The iterative ontology evolution aims at achieve a standard that is able to accommodate different lab packages and, hence, facilitate to review and understand their content.*

Keywords: Controlled Experiment, Experimental Software Engineering, Ontology, Knowledge Representation.

1. Introduction

Controlled Experiment in Software Engineering (SE) attempts to assess methods, techniques and tools applied on software development activities [5, 4]. By using a similar model of practitioners building software, subjects apply methods, techniques and tools under controlled environment, producing data that allow evaluating, measuring and comparing their performance under pre-defined conditions. The collected data set leads to conclusions that are meaningful on controlled conditions, considering the population from which subjects are representative. However, results from a single experiment cannot establish definitive facts about a phenomenon due to variations introduced by different system domains, personal background and experience and cultural environments [6, 21, 23, 27, 20]. Gaining insight into such variations requires running multiple independent studies on a topic [26, 20] – for example, varying the subjects profiles, the adopted procedures or even the experimental design help on establish knowledge about a topic [22, 20]. So, by executing multiple experiments that address these variations, researchers build knowledge on SE discipline, as well as help the practitioner understand how to build software systems better [4].

In this sense, the *International Software Engineering Research Network* (ISERN) was formed with researchers that promote SE research in an experimental context. According to the ISERN Manifesto [17], in order to build basic models and components on SE discipline, it is important to consider characteristics from specific environments, since each one imposes variations in the effects of technologies.

Replications of a study that investigates a technology by different research groups can deal with those execution variations, allowing to draw conclusions that reach a broader context and, thus, consolidating knowledge in SE. Replicate a study depends on the effective review of its lab package, to understand the adopted procedures and guarantee process conformance with the previous experiment [6, 28]. The description of a study – including the procedures, the results and conclusions – is registered in the lab package [26]. The lab package carries the knowledge to be transferred among researchers in order to enable replications and to report the experimental findings, aimed to contribute to the advance of the discipline and the application in industry.

However, knowledge sharing problems among research groups arise, such as difficulties in reviewing lab packages [26] and integrating this knowledge in a common body [18],

mostly because the lack of standardization of lab packages. Dealing with such problems minimizes the risk of an experiment being isolated. Noticing how those problems have influenced on replications, Mendonça et al. [20] presented the *Framework for Improving the Replication of Experiments* (FIRE). The FIRE suggests standardizing packages and evolving knowledge repositories in order to share knowledge, which should be available in a common body and also understandable to researchers willing to execute a replication.

In this direction, Garcia et al. [14] elaborated the $_{EXPER}Ontology$: an ontology of controlled experiments domain, with the purpose of formally describe concepts that compose a lab package. Ontologies have already been applied in Software Engineering aiming at the standardization of the concepts of a domain and knowledge reuse and share [12, 13, 2, 7, 3].

The packaging of information about a study can incorporate the ontology as a standard in order to deal with the complications in integrating and transferring the knowledge from experiments, considering that knowledge representation and sharing is a recurring application to which ontologies are designed for [15, 29]. According to Amaral and Travassos [1], packaging should be done phase by phase, throughout the experimental process [31]. So, in this context, it is proposed a workflow that suggests this packaging based on the concepts defined in $_{EXPER}Ontology$. And, since its definitions are not necessarily static, the ontology can absorb new concepts, as lab packages containing different sets of information are instantiated.

The remainder is organized as follows. In Section 2 is given an overview of replications importance and is presented the problem in knowledge sharing among research groups. With the purpose to address such problems, in Section 3 is argued about the use of an ontology to represent the knowledge from a study. In Section 4 is presented the proposed workflow that applies and evolves the ontology as a standard to lab packages. Finally, in Section 5, the contributions and future work directions are summarized.

2. Replications, Knowledge Transfer and Integration

Several issues involved in running an experiment present sources of variations that limit the generalization to apply the conclusions. The participants may be from different cultural environments or imposed to a different set of conditions during the execution [22, 20]. Therefore, in order to generalize the conclusions, these variations should be explored and dealt with in replications of the study.

To effectively attend to the conditions variation, different research groups might execute replications in their own laboratory environment. Thereby, if obtained results confirm previous conclusions, it is demonstrated that they are applicable to a broad context. Conversely, if the results do not confirm the conclusions of the previous study, the influence of the variations can be identified and produce other relevant conclusions on the topic. Therefore, the knowledge about a technology can be consolidated across replications based in the study that investigates it. Besides, the selected variables to model the phenomenon or the adopted procedures in the realization may not be ideal. In this sense, similar replications, accomplished by the original experimenters or not, can build confidence in the procedure and the result [8].

Replicating a study, in a not completely independent way, depends on the effective review of its original execution, to understand the procedures and the experimental design of the previous study for process conformance sake [28], that is, to produce comparable results. The lab package is the tool that carries study information. Thus, replications can be encouraged with the availability of lab packages [26]. And, given the amount of effort required to conduct an experiment, it is reasonable to facilitate the reuse of experimental artifacts by providing a lab package [8]. From its review, researchers have access to how the previous study was conducted.

However, the review of lab packages by researchers presents difficulties [26], what can be considered an obstacle in knowledge transfer among research groups. Noticing knowledge transfer problems as barriers to the conduction of replications, Mendonça et al. [20] proposed the *Framework for Improving the Replication of Experiments* (FIRE), which is composed by the two cycles of activities, as illustrated in Figure 1. The internal cycle represents the execution of a study by a research group. The external cycle (inter-group) represents the activities whose purpose is to integrate the knowledge generated by running a study (internal cycle) in a common body of knowledge. In that sense, the lab package can be effectively reviewed by eventual replicators from a different research group aimed to set the experiment (replication) goals. One might observe in Figure 1 that *criate/evolve package* influences the external activity *share knowledge*. Likewise, in the other point that the cycles intercept, *understand lab packages* is crucial to *set experiment goals* of a new replication.

It can be considered, therefore, that the lab package represents the output of the internal cycle carrying out information about an isolated study, and also the input of the internal cycle of a possible replication, considering that researchers should review and understand the original experiment lab package. So, with regard to *share knowledge* and favor better understanding of lab packages (in the external cycle), the way which the lab package information must be represented is important, what is endorsed by the activity of *standardize packages*.

In the other hand, activities of the external cycle of FIRE

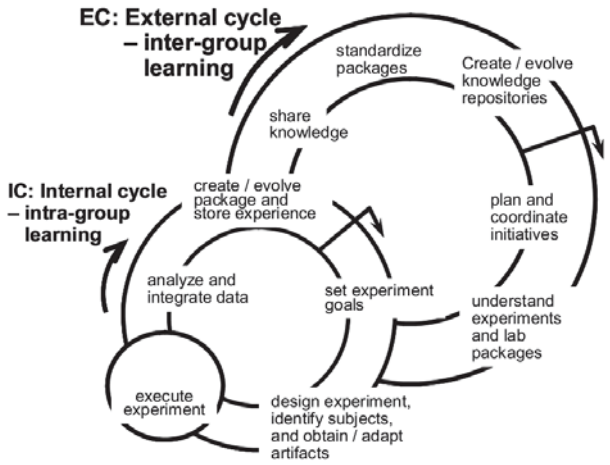

Figure 1. The FIRE [20]

also suggest to integrate the knowledge generated by an isolated study in a common body. This established body of knowledge may support decision making to practitioners in software development process [18] and the available lab packages should supply an experimental infrastructure to support future replications as well [26], whose results can sustain the progress of such body of knowledge. However, a major problem for this integration is the heterogeneity in the way that experiments are reported [18], which present different sets of information or level of details [9]. Accordingly to FIRE, to integrate the knowledge or to *evolve knowledge repositories*, it is necessary to *standardize packages* (see Figure 1). Indeed, Carver [9] highlights the importance of standardization to deal with this heterogeneity.

3. Ontologies as the Common Solution

Shull and his partners have pointed out that lab packages are important tools for supporting replications (easy-available designs and materials facilitate replications by reducing the amount of effort required from independent researchers), but well-designed lab packages are crucial for facilitating better and comparable replications [28]. Therefore, it must be promoted well-defined knowledge representation into the lab packages. Additionally, there is not a broadly adopted standard to report experiments in Software Engineering, even though guidelines have been proposed [19, 18]. So, those issues suggest the establishment of a structure for lab packages, that also support a better understanding to reviewers. In this sense, an ontology can be used to describe the model of information that compose a lab package, aiming at provide a standard and favor a better understanding.

Ontologies are means to formally represent the structure of a specific domain, by defining explicitly entities and their relationships that emerge from its observation [16]. The concepts interpretation is restricted by axioms, and thus the ontology-based information carries embedded meaning, allowing agents from different contexts to interpret it consistently.

Considering the role of ontologies in knowledge representation and sharing [15, 24], and problems related to knowledge integration and transfer in Experimental Software Engineering, Garcia et al. have proposed an ontology for the controlled experiments domain: the $_{EXPER}Ontology$ [14]. Basically, this ontology helps to elucidate concepts and relations concerning controlled experiments. Garcia et al. [14] presented the conceptualization in two levels of refinement and axioms to formalize it. Concepts like *controlled experiment*, *replication*, *experiment validity* and *lab package* are defined in the first level. The second level comprises the refinement of concepts on the first one. The main aspect is a more accurate definition of lab package, which defines and relates concepts from the experimentation process [31], that is, concepts whose instances are information of the lab package.

The main goal on using the $_{EXPER}Ontology$ is to incorporate the benefits that ontologies provide to the knowledge transfer by organizing lab packages: the shared understanding of information [24], what is essential to allow transferring effectively the knowledge embedded into a lab package. Besides, the ontology itself – with concept definitions – can be considered as standard of information organization that the lab package has to include.

4. The Proposed Evolutionary Approach Based on Ontology

Several experiments have been conducted and their results published, but each researcher publishes what considers most important in the experiment report [18]. There is not a broadly adopted standard to lab packages. In this context, the $_{EXPER}Ontology$ was proposed to deal with the necessity of a established standard, that also eases the understanding of lab package information. With the purpose to apply $_{EXPER}Ontology$, initially was proposed the instantiation of lab packages information based on $_{EXPER}Ontology$ concepts, according to the experimental process [31, 1]. To support this initial approach, the $_{EXPER}Ontology$ was implemented using OWL (Web Ontology Language) and, then, a tool was developed to instantiate the concepts [25]. However, during the tool validation, it was faced the lack of standardization problem, what leads to the difficulties in knowledge integration, as stated in Section 2.

Thus, not only the use of $_{EXPER}Ontology$ in packaging experiment data set should be considered, but also the current reporting practice, since it is usual lab packages con-

taining different sets of information. For example, details about treatments might be missing, becoming unable to apply ontology concepts straightly. So, it is necessary to deal with different sets of information to accommodate them according to $_{EXPER}Ontology$.

Despite problems found during instantiation using the tool [25], the ontology-based packaging proved itself to be appropriate, since the lab packages were generated in a format that makes explicit the meaning of the information represented, what enables machine processing – the ontology is expressed in a language with formal semantics [30]. However, considering the need for a standardization that complies with the inconsistency of published experiments [9], the $_{EXPER}Ontology$ should address the different manners in which an experiment execution is registered. This suggests that the initial ontology should evolve, incorporating new concepts.

In this direction, we propose a workflow, which includes the evolutionary approach to the lab packages instantiation using the $_{EXPER}Ontology$. As illustrated in Figure 2, the inputs of the workflow are the lab package to be instantiated and the $_{EXPER}Ontology$ – the concepts descripted and their relationships are used as parameters to instantiate the lab package. Each phase of experimental process has its own goal and concepts defined in $_{EXPER}Ontology$. Following experimental process, the concepts are used as parameters to a mining process aimed to match corresponding information, which is initially presented without a standard. Thereby, it is possible to instantiate information in the OWL lab package.

To describe the workflow activities, the concepts defined to Planning and Definition phases in the ontology for Lab Packages are presented throughout the experimentation process, highlighted in the following. At first, the **initial hypothesis** of a controlled experiment is established. It is composed by the **object of study**, in agreement with a **purpose**, under a **quality focus**, and in a specific **context**. The *Definition* phase is the basis for the *Planning* phase and the **initial hypothesis** generates the **hypotheses formalized**. These hypotheses have **null hypothesis** and the **alternative hypothesis**, as attributes. From the **hypothesis formalized**, the experimenter defines the experiment variables – **dependent** and **independent variables**. During the planning phase s/he also defines the **experiment objects**: **technologies** to be studied (**techniques**, **methods** or **tools**) and **artifacts** (**documents**, **tools** or **forms**) to be used. Each **subject** has his/her **profile** recorded to characterize his/her background. Capturing the subject background aims at identifying possible influence on results. For instance, previous knowledge about experiment objects or domain application might influence the results obtained. The subjects' profile must be considered to create the **experimental design**, which is built combining experiment objects, independent variables and subjects, in agreement with the hypothesis under investigation. In addition, the subjects' profile must be considered in analysis. Based on the experimental design, an **execution plan** must be elaborated in order to describe the entire controlled environment to conduct the experiment.

For instance, conducting the mining process focusing on Definition phase, the concepts Purpose and Context are essential to compose the Initial Hypothesis (parameters to mining process). And considering the experiments published by De Lucia et al. [11] as data set (lab package), after mining process we obtained "Compare ER and UML class diagrams in data modeling" and "Academic" as information corresponding to **Purpose** and **Context**, respectively.

Additionally, the mining process might fail: or the mining do not match meaningful values to concepts; or do not match at all. This situation might be consequence of missing data in the lab package, what indicate to experimenters that s/he should handle during the activities of FIRE internal cycle. Also, this situation might be consequence of missing concept, i.e., the $_{EXPER}Ontology$ have to be updated in order to evolve it. Considering the same experiment from the previous example [11], the researchers applied feedback questionnaires after tasks execution. The information of subject feedback analysis did not match properly to the concept Questionnaire, since Questionnaire concept is defined in the $_{EXPER}Ontology$ to represent subject profile, and its relation with feedback analysis was missing. This mechanism of discover and insert missing concepts automatically is facilitated by the ontology formal description, which enables machine processing.

The instantiation of several lab packages following the proposed workflow allows capturing missing concepts and, consequently, evolve the $_{EXPER}Ontology$. This can be accomplished similarly as the tool validation, by using information extracted from published experiments [10], but only after a comprehensive review of the literature. As the lab packages are instantiated through the workflow, the ontology approximates to the semantic standard that allows to accommodate variations on lab packages, and thereby, the $_{EXPER}Ontology$ evolution improves its application on packaging experiments as well.

5. Conclusions

In this paper we propose a workflow to apply and evolve the $_{EXPER}Ontology$ to package controlled experiments in Software Engineering. The use of an ontology as a standard to instantiate experiment information was already implemented [25] aiming at improve the understanding of lab packages, since problems concerning their review by researchers were pointed out [26].

The validation of such approach has shown that its main

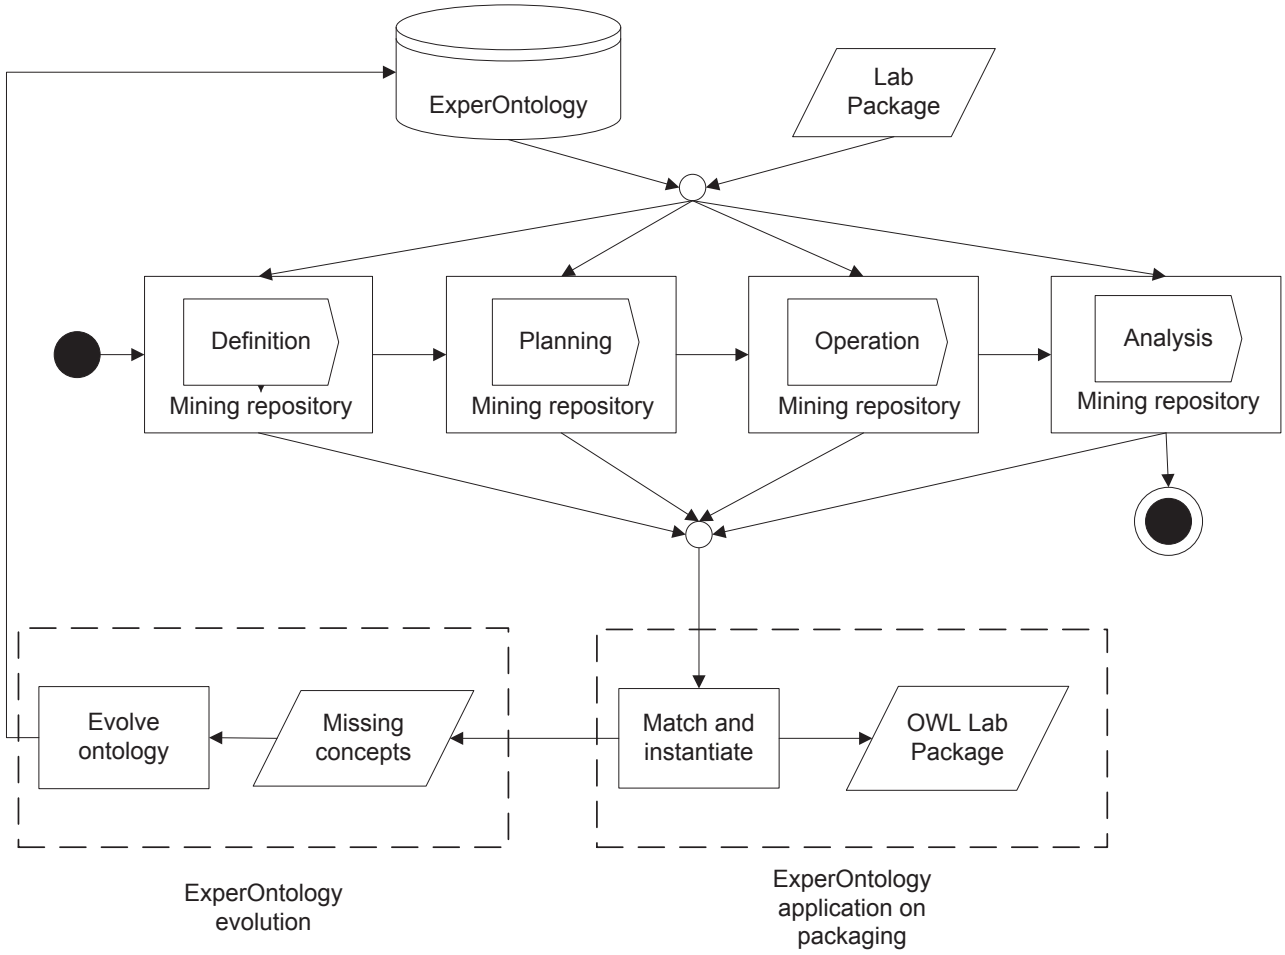

Figure 2. The evolutionary approach proposed for Packaging Controlled Experiments

contribution is the creation of lab packages according to a structured and organized way that makes explicit and meaningful the represented information. Also, ontologies enable machine processing, since are expressed in a language that presents formal semantics [30]. As pointed out by Jedlitschka et al. [18], experiments reports in practice contain different sets of information, what produced the requirement to evolve the ontology, in order to accommodate variations on the sets of information that lab packages can present. This heterogeneity entangles the integration of the knowledge generated by each isolated study in a common body [18]. In this sense, the $_{EXPER}Ontology$ can be seen as a unifying model, in which lab packages are instantiated, therefore enabling integration. Also, *create/evolve package* activity proposed on FIRE (see Figure 1) suggests that the initial ontology should evolve, incorporating new concepts, what is addressed by the proposed approach. Consequently, a semantic standard that deal with the heterogeneity issue can be accomplished.

As input to the workflow we consider the lab package as the data set describing an experiment. In this sense, any experiment description might be used: for example, an experiment description found in literature. In this case, the workflow should be applied in parallel with a literature review, in order to apply the information extraction from papers describing experiments [10]. Through this mechanism, it is also possible to assess the new concepts being inserted.

***Abstract*—This paper presents knowledge engineering work for building a knowledge-based system (KBS) for the amine-based CO_2 capture process system at International Test Center for CO_2 capture (ITC) located in Regina, Saskatchewan of Canada. The knowledge acquisition process was conducted for building knowledge base for the CO_2 capture process system. The knowledge base includes static and dynamic knowledge. The static knowledge includes the information on constructive components of the reaction instruments, fluids, and the control devices in the CO_2 capture system. The dynamic knowledge specified operation tasks of the CO_2 capture process system, which are expressed as the control strategies for dealing with 25 critical process parameters when a fault condition emerges. The knowledge obtained is represented in the knowledge table. In this paper, we present our work in knowledge engineering and how the knowledge table provided the foundation for developing an expert system for automatic monitoring, control, and fault diagnosis of the CO_2 capture process system at ITC and for implementing the ontology for the CO_2 capture process system.**

Keywords-knowledge engineering; ontology; knowledge-based expert system; CO_2 capture

I. INTRODUCTION

Combustion of fossil fuels in power generation and in various industrial processes such as cement manufacture and hydrogen production emits large amounts of CO_2. It is reported that CO_2 is a primary greenhouse gas and causes enhanced global warming. Due to increasing public concern about environmental pollution and climate change, the technology of amine-based carbon dioxide (CO_2) capture has been widely adopted for reducing industrial CO_2 emissions and mitigating global warming. The amine-based CO_2 capture process system is a complicated chemical process system which involves over a dozen reaction instruments and a number of control devices such as pumps and valves. The operators of the CO_2 capture process system are required to detect the abnormal condition in a timely manner and to fix the problem promptly so as to ensure reliable performance of the process system. Therefore, developing a systematic knowledge depository which collects both the domain and operation knowledge of the CO_2 capture process system is useful. A KBS can help the novice operators in monitoring and diagnosing the system. This paper discusses the process of knowledge acquisition (KA) and development of the knowledge base for the CO_2 capture process system. As a result of the KA process, a knowledge table was generated, which formed the basis for the conceptual model of the KBS as well as an implemented ontology of the domain.

The paper is organized as follows: Section 2 gives a brief description about the CO_2 capture process system at ITC. Section 3 describes the knowledge acquisition process and presents the conceptual structure of the developed knowledge base. Section 4 discusses the mapping of the elements of the knowledge base to the structure of DeltaV Simulate (a trademark of Emerson Corp., USA). Section 5 presents a case study of the expert system developed on DeltaV Simulate. Section 6 describes the development of the implemented ontology for the CO_2 capture process system based on the conceptual knowledge base. Section 7 gives a conclusion and includes some discussion about future work.

II. PROBLEM DOMAIN

In the amine-based CO_2 capture process, an amine solvent is used to absorb CO_2 from the flue gas, and CO_2 is subsequently extracted from the amine solvent, which can then be regenerated and reused. The amine-based CO_2 capture technology has been implemented at the International Test Center for CO_2 capture (ITC); the CO_2 capture process system is the problem domain for the KBS. More details of the CO_2 capture process system can be found in [6].

III. KNOWLEDGE ACQUISITION

The objective of the knowledge acquisition process is to obtain systematic knowledge about the CO_2 capture process system, and identify the knowledge needed for performing monitoring and diagnosis. Knowledge acquisition for this project lasted six months and involved discussions with the experts during interviews, observation, and field studies on site. During the interviews, the expert provided illustrations, answered questions, and verified the acquired knowledge. The result of the knowledge acquisition process was analyzed based on the Inferential Modeling Technique (IMT) [1], and the knowledge base of the CO_2 capture process system was developed. The knowledge base includes two parts: static knowledge and dynamic knowledge. The static knowledge defines the constructive components of the CO_2 capture plant

and specifies the reaction instruments, process parameters, and control devices. The dynamic knowledge was developed by representing the problem-solving skills of the experienced process operators, which included the diagnosis and remedial control actions for the 25 critical parameters when an abnormal condition is detected.

A. Static Knowledge

The static knowledge includes three classes: reaction instruments, process parameters, and control devices; they are discovered as follows.

1) Reaction Instruments

There are in total 16 reaction instruments in the CO_2 capture process. Each reaction instrument carries out a specific function and produces different output fluids. The sixteen reaction instruments are divided into three subclasses of objects according to their functions: (1) Pre-treatment section, which includes the steam boiler, micro turbine, inlet-gas scrubber; (2) Absorption-based CO_2 section, which includes the absorber, off-gas scrubber, lean amine storage tank, lean amine cooler, rich amine vessel, lean/rich amine exchanger, stripper, reboiler, and reclaimer; (3) Post-conditioning section for product purification, which includes the reflux condenser, reflux accumulator, CO_2 wash scrubber, and CO_2 dryer unit.

2) Process Parameters

The fluids circulating in the system include: flue gas containing CO_2, off gas free from CO_2, CO_2, steam, amine solvent, and water. They go through and undergo changes in different reaction instruments. The attributes of the fluids are defined as the process parameters which reflect performance of the plant, and there are in total over one hundred process parameters in the CO_2 capture plant. The values of the attributes are constantly changing in the process, even for the same type of fluid. The design decision was made to divide the attributes of each fluid into groups based on their locations, or which reaction instrument they have gone through. Therefore, the attributes of fluids have been defined as the attributes of the reaction instrument from which it flows. In this way, over one hundred process parameters in the plant can be grouped into 16 reaction instrument based groupings.

3) Control Devices

The control devices include the two classes of pumps and valves, which are used to regulate the flow of fluid. The pumps can be either opened or closed, and the valves can be opened, closed, or partially closed. Manipulating the pumps and valves can regulate the flow of fluids and change their attributes, or the process parameters. As the process parameters are divided into 16 classes according to the reaction instrument to which they belong, the control devices can be divided in the same way based on the process parameters that they regulate, i.e., 16 groups of control devices based on which reaction instrument they control.

As a result, the entire system can be viewed in terms of sixteen reaction components, their relevant attributes, and the relevant control devices. The relationships among these classes of the CO_2 capture process system are illustrated in Figure 1. The objects are denoted with the square boxes, and their respective attributes are denoted with the ellipse boxes. The object of reaction instrument processes some input fluids and produces the output fluids. The attributes of its output fluid are specified as this reaction instrument's attributes, which are represented by the dotted arrows. Also, the reaction instrument has its own attribute of fluid level, which is represented by the solid arrows. These attributes can be divided into the subclasses of temperature, pressure, flow rate, and level. The arrows pointing from the attributes of reaction instrument to the control devices indicate that these process parameters are directly controlled by the pumps and valves. The pumps and valves can be further classified by their own attributes. These attributes include: (1) type, which defines control mechanism of the valve/pump; (2) fluid, which specifies what fluid the valve/pump controls; (3) state, which specifies the status of a 2-state control device, it has the values of On and Off; (4) location, which indicates where the valve/pump is installed; and (5) name, which is a brief description of the valve/pump.

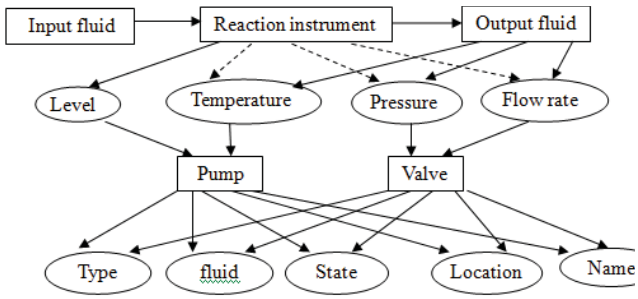

Figure 1. Relationship among the classes of the CO2 capture process system

Dynamic Knowledge

The dynamic knowledge represents the tasks of monitoring each reaction instrument, which includes the subtasks of monitoring its related attributes, or process parameters. During knowledge acquisition, twenty five critical process parameters, their desirable operating ranges, and the control actions when an abnormal condition emerges are specified.

The domain knowledge was analyzed based on the IMT, which emphasizes decomposition of the information into knowledge elements. The knowledge elements were then represented in the table format, which became the knowledge table. Table 1 provides a segment of the table that shows the knowledge element of inlet gas scrubber.

The table consists of 8 columns, the first four columns describe the static information, namely, the reaction instrument to which the attribute belongs, the attributes' number, tag, and name respectively. The fifth and sixth columns together describe the attribute's range of normal operation. For example, for the parameter of inlet-gas scrubber water level control (LC-410), the high limit of its desirable operating range is 65%, and the low limit is 60%. The "low low" limit indicates the critical condition which causes safety concerns. If the actual value of the attribute exceeds the limit value, the corresponding control action is executed. The seventh and eighth columns present the control action and diagnosis or explanation for that control

action, respectively. For inlet-gas scrubber water level control (LC-410), the valve ED-420 should be open when its value exceeds the high limit of 65% to increase water drainage of the tank; the valve EV-300 should be open if its value drops below the low limit of 60% to increase make-up water supply to the scrubber. However, if the remedial action is not taken in time and the attribute falls to the critical level of 30%, the pumps of P-420 and B-200 should both be shut off immediately to stop the wash water circulation and cut off the gas supply to the absorber.

TABLE I. SAMPLE SEGMENT OF KNOWLEDGE TABLE

Object Name	Attribute Number	Attribute Tag	Attribute Name	Operate Limit	Limit Value	Controlling Decision	Diagnosis & Explanation
C3. Inlet-Gas Scrubber	C3A1	DPT-200	Flue Gas Scrubber Differential Pressure				
	C3A2	LC-410	Inlet-Gas Scrubber Water Level Control	High	65.0	Open up EV-420	To increase wat drainage
				Low	60.0	Open up EV-300	To increase mal up water supply scrubber
				Low Low	30.0	Shut off P-420 & B-200	To stop the was water circulatin scrubber and st pumping flue g

IV. MAPPING KNOWLEDGE TABLE TO DELTAV STRUCTURE

The knowledge represented in the knowledge table is mapped into knowledge representation constructs in DeltaV Simulate. The DeltaV Simulate has a five-level hierarchical structure, which includes from top to bottom: (1) plant area, (2) module, (3) algorithm, (4) function block, and (5) parameter. The mapping from the knowledge table to the DeltaV system is presented as follows.

The plant areas are logical divisions of the process control system, which can be based on physical plant locations or main process functions. A plant area consists of modules, and each module is a logic control entity responsible for configuring the control strategies. It contains algorithms, alarms, and other characteristics that define the process control. Algorithms define the logic steps that describe how the module behaves and how the tasks are accomplished. In this intelligent system, the function block diagrams (FBD) were used to continuously execute control strategies. The basic component of a FBD is a function block, which contains the control algorithm and defines the behaviour of the module. Each function block contains parameters which are the user-defined data manipulated by the module's algorithm in its calculations and logic. The structure of DeltaV Simulate is shown in Figure 2, and the details of each hierarchical component are explained from the top to bottom level as follows.

Level 1: as the plant area is the logical division of the process based on the location or the function, each reaction instrument is defined as a plant area for two reasons. Firstly, every reaction instrument has its particular function. Secondly, the process parameters and the control devices are classified by which reaction instrument they belong to, i.e. the location. Therefore, defining 16 reaction instruments into 16 plant areas properly divides the entire plant into 16 functional and structural areas. It also can be observed from Figure 1 that the reaction instruments, the process parameters and the control devices are interrelated in a top-down hierarchy. Therefore, defining the reaction instruments as the top level logically supports the construction of the lower hierarchical components in DeltaV Simulate.

Level 2: modules are at the next level in the structural hierarchy of DeltaV Simulate, and a module is a logic control entity responsible for configuring the control strategies. These control strategies indicate the manipulation of the control devices, i.e., pumps and valves, to adjust the process parameters. The attribute of type of the control devices reflects that primarily two mechanisms of PID control and 2-state control are used to manipulate pumps and valves. Corresponding to these two types of control strategies, there are two types of modules: PID control modules and 2-state modules. The PID control modules configure the control strategies for the PID valves; the 2-state modules configure the control strategies for the control devices with two states, i.e., the pumps and solenoid valves.

Level 3: function block diagram (FBD) is a diagram that contains multiple interconnected function blocks. It generally contains input signal function block, control function block, and output signal function block. Different control function blocks are used and the choice depends on what control mechanism the module deploys. The control function block is the item that contains the most critical parameters.

Level 4: a function block defines the behaviour of an algorithm for a particular module. Two types of function blocks of 2-state function block and PID control function block are used for the control function block. Since the PID control valves are used to control the attributes of the reaction instruments, the attributes of reaction instruments and their relative PID control valves are combined into the PID control function blocks, which enable the present values of the attributes to approach their desired values by controlling the PID valves. The pumps and solenoid valves manipulate the attributes of the reaction instruments by switching between the ON/OFF states, i.e. between the current state and desired state. Therefore, the pumps and solenoid valves are represented by two-state control function blocks.

Level 5: parameters define the values of the attributes of the reaction instruments. As mentioned earlier, a PID function block controls a PID valve, so as to enable the present value of an attribute of the reaction instrument to approach its desired values. Therefore, the critical parameters of a PID function block include the present values of the attribute, the high/low values that specify the operating limits beyond which an alarm is activated, and the set-point value which represents the desired value. For the 2-state function blocks, the critical parameters are the current and desired states of the 2-state control devices.

The knowledge table developed based on knowledge about the CO_2 capture system clarifies the domain knowledge and supports encoding the knowledge into the hierarchical structure of DeltaV Simulate using a top-down approach. The knowledge table also supports a more efficient design of the expert system implemented on the DeltaV Simulate; the developed system involves a mapping of the knowledge table constructs to the DeltaV Simulate mechanisms. The reaction instrument of inlet gas scrubber and its related PID valve PCV-901 is used as an example to explain how each hierarchical

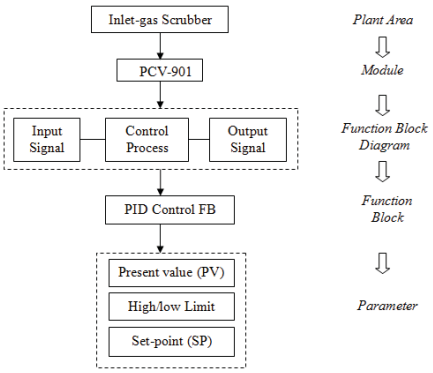

Figure 2. Hierarchical structure of sample component in DeltaV Simulate

level is developed on DeltaV Simulate based on information in the knowledge table. The components are shown in Figure 2 and the details are described below.

The reaction instrument of inlet gas scrubber is defined as a plant area. Its related PID valve PCV-901 together with the attribute it controls, i.e., the pressure of off gas (PT-901), are combined into a PID control module. The module is represented in a function block diagram, which consists of function blocks for input signals, output signals, and most importantly, for the control strategy. As shown in Figure 2, the function block for the control strategy conducts PID-control. The key parameters contained in this PID function block include: the present value of the off gas pressure, the set-point value of the off gas pressure, and the high and low limit values of the off gas pressure. If a value is beyond the range defined by the high and low limit values, the alarm function embedded in the PID function block is activated. A sample scenario is present in the next section.

V. Expert System on DeltaV Simulate

A sample interface of the expert system developed on DeltaV Simulate describes the scenario in which the inlet-gas scrubber wash water flow rate (FT-420) is in an abnormal condition. The interface is shown in Figure 3. The current value of FT-420 shown on the panel of FC-420 is 0kg/min, which is lower than its normal low limit of 5kg/min and indicates the water circulation between the inlet gas scrubber and water tank has stopped because the pump is shut. The alarm is activated and displayed on the interface, as a result, the panel for FC-420 turns to the blue color. The diagnosis and control suggestions are sent to a message board on the user interface: "If P-420 is on, open up FCV-420 to increase water returning from the scrubber to water tank; if P-420 is off, turn on P-420." The red color of pump P-420 indicates its closed status. Therefore, according to the control suggestion, P-420 should be opened so the water circulation will restart.

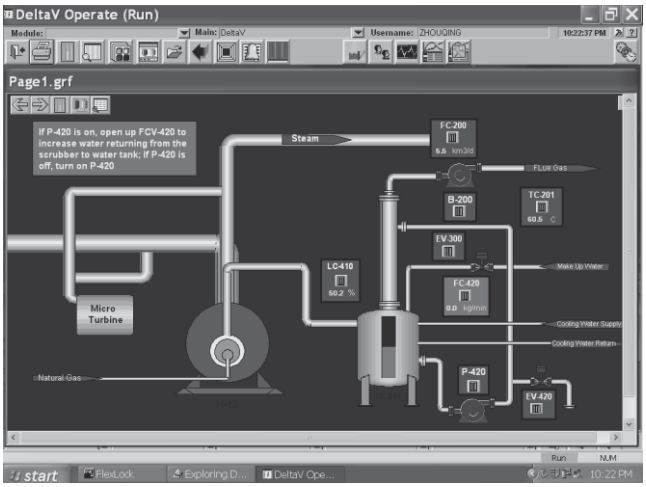

Figure 3. Interface of Expert System

VI. From Knowledge Tables to Implemented Ontologies

In addition to being used as the basis for development of the expert system, the knowledge tables were also used as the basis for building an implemented ontology of the domain. An implemented ontology can serve as the shareable and reusable knowledge base for supporting development of diverse KBS's. The implementation was conducted using both Protégé and Dyna [2]. Protégé is a freely available open source ontology editor and knowledge base framework implemented in Java. It supports constructing OWL ontologies as well as creating add-ons for other ontology or knowledge based applications. Dyna [2], is one such add-on. It is for the specification of dynamic knowledge. Being an add-on to Protégé allows Dyna to access the OWL ontology directly in the Dyna environment. This means that a dynamic action (or task) specified in Dyna can be linked to the OWL class in Protégé.

The static knowledge in the knowledge table was implemented using the OWLClasses of Protégé, and the dynamic knowledge was implemented with a Protégé add-on called Dyna. The conversion of knowledge elements specified in the knowledge table to the implemented ontology is explained with the knowledge element of CO_2 wash scrubber shown in the knowledge table segment in Figure 4 and discussed as follows.

TABLE II. Knowledge Table: Example of O15_CO2_Wash_Scrubber

Object Name	Attribute Number	Attribute Tag	Attribute Name	Operate Limit	Limit Value	Controlling Decision	Diagnosis & Explana
C15.	C15A1	DPT-700	CO_2 Wash Scrubber Differential Pressure				
CO_2 Wash Scrubber	C15A2	LC-710	CO_2 Wash Scrubber Level Control	High	95.0	Open EV-720	To increase water drain and lower the scrubber water level
				Low	5.0	Open EV-303	To increase make-up w supply to scrubber
				Low Low	0.0	Shut off P-720	To stop the wash water circulation in the scrubl

The class of CO_2 wash scrubber has the two attributes of the CO_2 wash scrubber differential pressure, and CO_2 wash scrubber level control. In the table shown in table 2, the class of CO_2 wash scrubber is referred to as "Object C15". Implicitly, there were two kinds of relationships among the classes. Firstly, an inheritance relationship exists among parent and child classes, e.g. the relationship between SC_3_Post-Conditioning_Unit_for_Product_Purification_Parts and O15_ CO_2_Wash_Scrubber is an inheritance relationship. The two classes are specified in Protégé and shown in Figure 4.

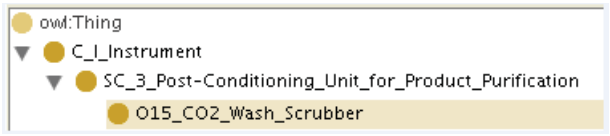

Figure 4. O15 Class Hierarchy Specified in Protégé

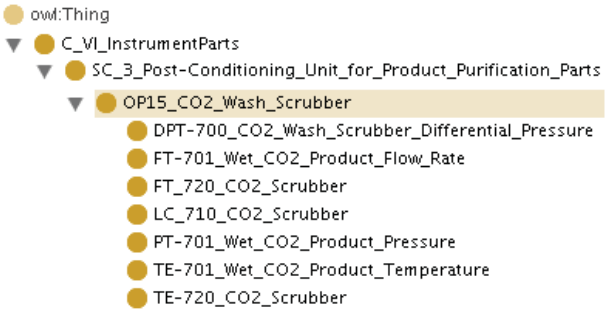

Figure 5. OP15 Class Specified in Protégé

The second kind of relationship is an aggregate relationship in which one class is a composite of several component classes, e.g. the relationship between O15_ CO_2_Wash_Scrubber and its component objects of FT_720_CO_2_scrubber and LC_710_ CO_2_scrubber, which are shown in Figure 5. Protégé converts the parent-child relationship in the first relationship into the OWL statements about the class of CO_2 wash scrubber, its parent class, and the other classes which are disjoint from it. These OWL statements are shown in Figure 6.

```
<owl:Class rdf:about="#O15_CO2_Wash_Scrubber">
  <rdfs:subClassOf rdf:resource="#SC_3_Post-
Conditioning_Unit_for_Product_Purification"/>
  <owl:disjointWith rdf:resource="#O16_CO2_Dryer_Unit"/>
  <owl:disjointWith rdf:resource="#O14_Reflux_Condenser"/>
  <owl:disjointWith rdf:resource="#O13_Reflux_Accumulator"/>
 </owl:Class>
```

Figure 6. OWL Statements on the Class of CO2 Wash Scrubber

The aggregate relationship among the classes shown in Figure 6 is converted into the OWL statements about the class of CO_2 product flow rate; it is a subclass of CO_2 wash scrubber, and the classes from which it is disjoint. The OWL statements are shown in Figure 7.

```
<owl:Class rdf:about="#FT-701_Wet_CO2_Product_Flow_Rate">
  <rdfs:subClassOf rdf:resource="#OP15_CO2_Wash_Scrubber"/>
  <owl:disjointWith rdf:resource="#DPT-
700_CO2_Wash_Scrubber_Differential_Pressure"/>
  <owl:disjointWith rdf:resource="#LC_710_CO2_Scrubber"/>
  <owl:disjointWith rdf:resource="#FT_720_CO2_Scrubber"/>
  <owl:disjointWith rdf:resource="#TE-720_CO2_Scrubber"/>
  <owl:disjointWith rdf:resource="#PT-701_Wet_CO2_Product_Pressure"/>
  <owl:disjointWith rdf:resource="#TE-701_Wet_CO2_Product_Temperature"/>
 </owl:Class>
```

```

Figure 8. XML file dyna produced describing C15's behaviour

According to the IMT, the dynamic knowledge is decomposed into the knowledge elements of objectives and tasks, which are specified in the knowledge table. An example of this representation is given in section B *Dynamic Knowledge* Dyna performs two functions in converting the knowledge table into an implemented ontology. First, it converts the information into OWL statements, and secondly, it tests the specified behavior to ensure that the representation is correct. Based on the knowledge specified in the columns of Operate Limit, Limit value, Controlling Decision, and Diagnosis and Explanation of the knowledge table shown in Table 2, Dyna converts this segment of dynamic knowledge related to the attribute of level control of the class of CO_2 wash scrubber level control (C15A2_LC-710) into the OWL statements shown in Figure 8.

The testing function of Dyna requires the user to make up a test case for each behaviour that is specified in the knowledge table. The test case for the same knowledge element involves specifying three different values of 9.5, 5.0, and 0.0 for the attribute which would trigger the corresponding "print" statements. The test case is shown in Figure 9.

Decomposition of domain knowledge into its discrete elements facilitates knowledge sharing and reuse because an ontology that has a particular class, e.g., a pump class would enable it to link with other ontologies that also have that particular class of a pump. While the current version of the implemented ontology does not link to any other ontologies, it is possible that such a link can be established. For example, Ontocape [5] is a large ontology on the chemical process system domain that includes useful classes of knowledge on substance and measurement. It is an item on the future research agenda to see if some components of knowledge clarified and represented in Ontocape can be incorporated into the implemented ontology developed.

VII. Conclusion and Future Work

The objective of the work is to clarify and represent the domain knowledge of the CO_2 capture process system as the basis for building the ontology of this chemical process system. Knowledge engineering for the CO_2 capture process system based on the IMT resulted in documentation of the elicited domain expertise in a knowledge table. The domain knowledge was decomposed and clearly specified in the knowledge table. The explication was helpful because it clarified for the knowledge engineer the roles and relationships among the roles of the different knowledge elements. An expert system developed based on the represented knowledge can serve as a decision-support tool for the novice operator. When any fault occurs in the CO_2 capture process system, the time for diagnosis can be greatly shortened and the effective remedial control action can be deployed in a timely manner. This would help enhance efficiency the CO_2 capture process system. Also, the clarified knowledge about the constructive and reactive components facilitates understanding of the process system and construction of the expert system for automatic monitoring, control and diagnosis of the CO_2 capture process system. As well, it supports conversion of the knowledge table to an implemented ontology, which can be reused or extended in the future for building other knowledge based systems. Developing the ontology contributes to realization of the semantic web, which aims to structure data found on the internet by means of ontologies. Therefore, semantic web technology such as ontologies would enhance the ability of computers to search for information on the internet and support widespread use of agent technology for performing complex online tasks.

Maintainability Predictors for Relational Database-Driven Software Applications: Results from a Survey

Mehwish Riaz, Emilia Mendes, Ewan Tempero
Department of Computer Science, The University of Auckland
Auckland, New Zealand
mria007@aucklanduni.ac.nz, emilia@cs.auckland.ac.nz, e.tempero@cs.auckland.ac.nz

***Abstract*—Software maintainability is a very important quality attribute. Its prediction for relational database-driven software applications can help organizations improve the maintainability of these applications. The research presented herein adopts a survey-based approach where a survey was conducted with 40 software professionals aimed at identifying and ranking the important maintainability predictors for relational database-driven software applications. The survey results were analyzed using frequency analysis, and results suggest that maintainability prediction for relational database-driven applications is not the same as that of traditional software applications. The results also provide a baseline for creating maintainability prediction models for relational database-driven software applications.**

Software maintainability, relational database-driven software applications; survey; predictors; frequency analysis

I. INTRODUCTION

Software maintainability is the ease with which a software system or component can be modified to correct faults, improve performance or other attributes, or adapt to a changed environment [6]. It is inherently associated with the process of software maintenance which has long been known to have the major amount of software costs associated to it [12]. In order to manage these costs, it is important to understand, predict and improve software maintainability [12]. Software maintainability prediction involves proposing and validating predictors that have a bearing on software maintainability [1] and then employing these predictors to create software maintainability prediction models [13]. With the help of a maintainability prediction model, software organizations can better manage their maintenance resources and adopt a defensive design [11].

Database-driven applications have gained much popularity in modern software development [4] with relational databases as the most used and most successful type of database [15]. Relational databases are different from and more formalized than other types of databases and persistence mechanisms [2]. Database-driven applications consist of a database, a Database Management System (DBMS), and a set of applications that interact with the database through this management system [7]. Relational database-driven applications are therefore, those database-driven applications that have a relational database backend. The change in requirements cause these applications to undergo maintenance resulting in storing increased number of data sources and relationships; increased database complexity; and increased coupling between the database and application [9]. This suggests that the maintainability of these applications is also impacted by database specific factors in addition to application specific factors [13].

Given the importance of relational database-driven software applications in modern software development, it is important to investigate the factors that impact upon their maintainability in order to enable maintainability prediction. This paper is a step towards predicting maintainability of relational database-driven application by providing a validated list of predictors that have an impact on the maintainability of relational database-driven applications. This list of predictors was initially gathered with the help of twelve interviews conducted with software professionals [13]. The interviews' analyses resulted in the identification of 120 predictors. The focus of the work presented herein is to rank these predictors, with respect to the strength of their impact on the maintainability of relational database-driven applications, via another survey conducted with a larger sample of software professionals. The main contributions of this paper are therefore to:

- Further validate the predictors of maintainability identified by Riaz et al. [13] within the context of relational database-driven software applications.
- Rank the maintainability predictors for relational database-driven software applications in terms of their relative importance to predicting maintainability.
- Establish whether the predictors presented by Riaz et al. [13] positively or negatively impact the maintainability of relational database-driven applications.
- Present evidence on the type of applications and DBMS used the most in practice.

The remainder of the paper is organized as follows. Section II gives an account of the related work. Section III details the research methodology. Section IV presents the results. A discussion on the results and threats to validity are given in Section V, followed by conclusions in Section VI.

II. RELATED WORK

The research presented herein is informed by the results of: (1) a Systematic Review (SR) conducted on the topic of 'Software maintainability prediction and metrics' [12]; and (2) twelve interviews conducted with software professionals [13]

aimed at gathering evidence relating to the maintainability prediction of relational database-driven applications.

The results of the SR revealed very little evidence on maintainability prediction. The total number of studies selected in the SR was 15. These studies were further analyzed to assess if the datasets used in these studies completely or partially comprised relational database-driven software applications. Only three of these studies [3] [5] [8] had used relational database-driven software applications for the purpose of their research evaluation. However, only one of these studies [5] presented a maintainability prediction model but did not provide its prediction accuracy; the other two studies only presented measures [3] and factors [8] that impacted upon software maintainability, without any associated maintainability prediction model. Further analysis of these studies revealed that although they used relational database-driven applications, none of their proposed predictors or factors related specifically to a back-end database or to the interaction between a back-end database and the front-end application.

To further investigate maintainability prediction in the context of relational database-driven applications, interviews with software professionals were conducted to gather evidence from practice [13]. The results from the interviews revealed that a formal prediction model, or approach to predicting the maintainability of relational database-driven applications is not used in practice. The practitioners rely on expert judgement when assessing maintainability of relational database-driven applications. The analysis of these interviews also resulted in a list of factors that impact upon the maintainability of relational database-driven applications and may be used as their maintainability predictors.

III. RESEARCH METHODOLOGY

A. Survey-based Questionnaire

In order to determine which maintainability predictors are the most relevant and stand out the most from the list of predictors compiled with the help of SR and interviews' results, a survey was conducted with software practitioners. The list used in the survey comprised a total of 120 predictors [14], and the survey was informed by the results from the SR and the conducted interviews. It aimed at ranking these predictors in terms of their relative impact on the maintainability of relational database-driven software applications.

The survey questionnaire had 3 parts: The first part related to the respondents' characteristics, such as job function at the company, highest qualification, and total experience in years; and companies' characteristics, such as the year it was established, whether it is involved in developing relational database-driven applications, and the DBMS used most often.

The second part related to maintainability predictors. There were a total of 120 predictors, which belonged to one of the 10 categories below:

1. Database design
2. Relational database-driven applications
3. Design aspects of relational database-driven applications
4. Size, scope, and complexity of relational database-driven applications
5. Quality, quality assurance, and testing of relational database-driven applications
6. Change and maintenance of relational database-driven applications
7. Development and deployment environment of relational database-driven applications
8. Web applications with relational database back-end
9. Organizational culture and policies
10. Team communication and project management.

The possible responses against each of the factors, in relation to their impact on the maintainability of relational database-driven applications, were recorded on a 7-point bi-polar scale. The responses could be one of 'high decrease', 'medium decrease', 'low decrease', 'no impact', 'low increase', 'medium increase', and 'high increase'. The scale was designed such that both the direction of the factors' relationship (positive or negative i.e., whether a given factors increase maintainability or decreases maintainability, respectively) and the strength of the relationship with maintainability could be determined.

The third part of the questionnaire recorded opinions on which aspect of a relational database-driven application, from interface, data model, or algorithm objects/computation intensive modules, was hardest to maintain; asked of any additional predictors of maintainability; and recorded information on how a judgment is made on the maintainability of relational database-driven applications in a company (for which the option supplied was the amount of time to carry out a maintenance task). Refer to Riaz [14] for the complete survey questionnaire.

The survey was tested with a pilot run of four practitioners. Based on the feedback from the pilot, the survey was improved where the predictors from the SR, especially those that corresponded to various software metrics, were described using a simpler language in order to be clearly understandable by the practitioners.

B. Survey process

In order to conduct the survey, approval from the University of Auckland Human Participants Ethics Committee was obtained (Ref. 2009/527). The process prescribed by UAHPEC was to contact the competent authorities within the companies which would then extend the invitation to their employees. The invitations were sent to more than 50 companies in New Zealand and more than 25 companies in Pakistan through email. The email addresses were obtained through companies' listings on the Internet. In addition, a mailing list of the University of Auckland's Center of Software Innovation and authors' own contacts were also used to make contact with the companies. The email invitation explained the purpose and nature of the survey, provided the Web link to the survey, and asked the companies' competent authorities to request participation by those employees within their companies that had experience with developing and/or maintaining relational database-driven software applications.

The survey and the relevant UAHPEC documents were made available online and were filled out via a Web interface [14]. Some respondents also downloaded the questionnaire and returned an e-copy. The survey was conducted between June 2010 and September 2010.

C. Data Source

The data source used herein comprised responses of a total of 40 software professionals - 13 from 8 different software companies in New Zealand and 27 from 15 different software companies in Pakistan, where one respondent was self-employed. The roles of the participants varied from 'Software Developer' to 'Head of Development'. The participants had at least 2 years of experience with software development and/or maintenance, and had an average experience of 7.8 years with a minimum of 2 and maximum of 28 years of experience.

The two countries, Pakistan and New Zealand, were chosen for the following reasons: i) the interviews of which this research is informed were also conducted in New Zealand and Pakistan; ii) the results of the interviews established that the context of this research was not culture-sensitive as the focus was on software applications in general and not specific aspects related to people or their way of carrying out their work; and iii) the first author is originally from Pakistan and research is being carried out at the University of Auckland, New Zealand to which all the three authors are affiliated.

In terms of the participating companies, only 3 companies, from which only one respondent each participated, were created 1, 2 and 5 years ago. All the other companies were at least 10 years old. In addition, all companies except two were engaged in development or maintenance of applications where 90% or more of their applications had relational database backend. The other two also were involved in developing or maintaining relational database-driven applications; however, most of their work did not involve this type of development. In relation to the use of DBMS, all the participating companies used either Oracle or Microsoft SQL Server.

D. Data Analysis

Prior to analyzing the data, it was consolidated from two different sources, a database residing on Microsoft SQL Server used for the online survey and e-copies of the survey forms filled by some respondents for which the data was manually entered. Frequency analysis was the technique used for data analysis. It was well suited to the purpose as the intention was to see how many respondents thought of a predictor as having an impact 1 to 7 (high decrease to high increase) on the maintainability of relational database-driven software application.

During the frequency analysis, initially only the predictors that were reported to have an impact of 'high decrease' or 'high increase' on the maintainability of relational database-driven applications were considered. However, the frequency values did not stand out when only the extreme ends of the bi-polar scale were considered. For instance, for most of the factors the proportion of the respondents (out of 40) that chose one of the extreme ends of the scale (1 and 2 OR 6 and 7) were half or less than half i.e., between 15 and 20 (out of 40 respondents) and the proportion of the respondents that chose other options 'medium decrease' to 'medium increase' was equal or higher to those that selected one of the values at the extreme ends of the scale. Therefore, for final analysis, the sum of the frequencies for 'high decrease' and 'medium decrease' (1 and 2 on the bi-polar scale), and 'medium increase' and 'high increase' (6 and 7 on the bi-polar scale) were considered. The sum of the frequencies for the two ends of the bi-polar scale presented a better choice and represented better insights into the data.

IV. Results

A. Maintainability Predictors

The results of the survey data analysis corresponding to the second part of the survey are presented in Figure 1, and show only those maintainability predictors for relational database-driven applications that had frequency values of 21 or higher i.e., those predictors that were reported by more than 50% of the respondents as having a high impact on the maintainability of the mentioned applications. Note that, the predictors presented in the table are all those predictors that had an impact of 'medium increase' or 'high increase' on the maintainability of relational database-driven applications. None of the predictors that had an impact of 'medium decrease' or 'high decrease' on maintainability were selected as a result of the frequency analysis. This shows that all the predictors listed in Figure 1 have a positive relationship with the maintainability of relational database-driven software applications i.e., they all result in an increase in the maintainability of relational database-driven applications whenever they also increase.

The number of selected predictors for each category (as defined in the survey questionnaire and mentioned in Section III-A) against the total in that category are given in Table I. Note that predictors belonging to categories 'Size, Scope, and Complexity of Relational Database-Driven Software Applications' and 'Web Applications with Relational Database Backend' were not selected during frequency analysis and are therefore not presented in the results discussed further.

It is also worth noting that the best predictor relates to the relational database schema. In addition, other predictors, such as good database design, optimal use of DBMS features, are also among the top predictors of maintainability for relational database-driven software applications. Note that these predictors were not reported in the studies selected in the SR yet these rank higher than the predictors that were identified both by SR and interviews.

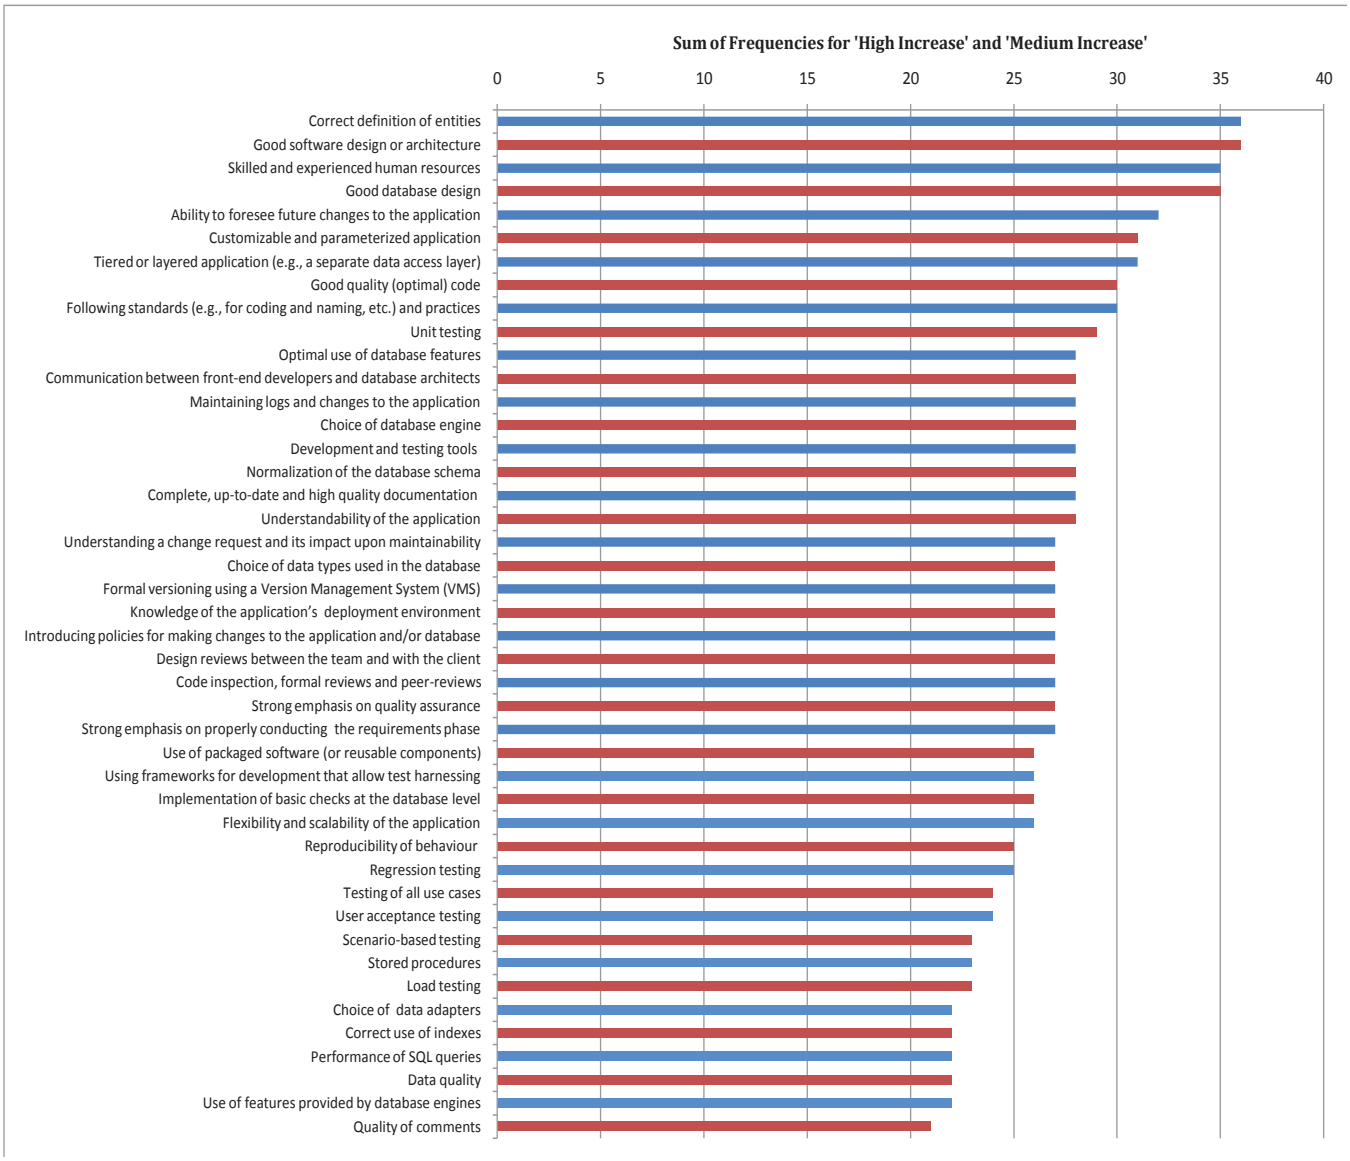

Figure 1. Predictors of maintainability for relational database-driven software applications

The percentages of predictors selected for each category presented in Table I.

TABLE I. PERCENTAGE OF MAINTAINABILITY PREDICTORS PER CATEGORY

Category	Frequency	Total in Category	Selection Percentage
Database Schema	4	19	21%
Relational Database-Driven Applications	7	15	47%
Design Aspects of Database-Driven Applications	4	9	44%
Quality, QA, and Testing	17	20	85%
Change and Maintenance	4	10	40%
Development and Deployment Environment	4	7	57%
Organizational Culture and Policies	2	4	50%
Team, Team Communication, and Project Management	2	7	29%

The results given in Table I show that the most important category of predictors was 'Quality, Quality Assurance, and Testing', both in terms of total number of predictors selected for overall analysis and number of predictors selected from the total number of predictors within the category. The second important category, perhaps not in terms of the percentage of factors selected from the category, but the number of factors contributing to maintainability prediction is 'Relational Database-Driven Applications'. Other important categories relate to 'Development and Deployment Environment' and 'Organizational Culture and Policies'. The results clearly indicate that the factors related to quality, database schema, relational database-driven application play an important role in predicting maintainability. However, the results also indicate that the factors related to development environment and organizational culture are also considered important by

practitioners in order to determine the maintainability of relational database-driven applications.

B. Ranking of the Aspect of Relational Database-Driven Applications for Ease of Maintenance

The first section of the third part of the survey asked the respondents to assign a ranking of 1(easiest) to 3(hardest) to each of three listed aspects of the relational database-driven applications i.e., application's interface, application's data model, and application's algorithmic objects or computation intensive modules. The results (see Figure 3) show that the application's interface was considered the easiest to maintain by 33 respondents, followed by the application's data model (24 respondents) and algorithmic objects (23 respondents). As such, there was not too much difference between the number of respondents for second and third rankings, which suggest that the data model of a relational database-driven software application can be as difficult to maintain as algorithmic or computation intensive objects.

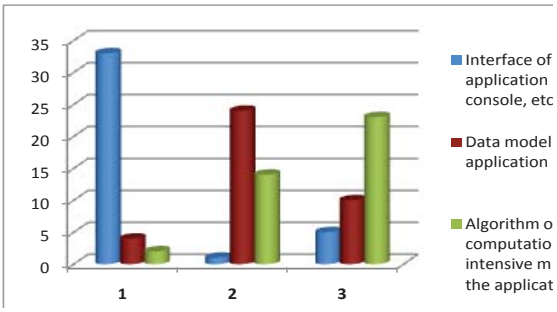

Figure 2. Ranking of the aspects of relational database-driven applications as per ease of maintenance

In addition to the ranking against the application's aspects, this part of the survey also asked if the respondents wanted to report any other factors they believed were important for predicting maintainability of relational database-driven applications. Only three respondents added their responses, which included software development process level used in an organization; non-technical aspects related to customer behavior which drives the timelines for performing maintenance tasks; and conformance of DBMS to standards, reliability of WANs, and impact of other software installed on the system such as anti-virus, operating system etc. As such, these factors were not considered significant as part of the analysis as each of these were reported by only one respondent and would have ultimately been eliminated from the list of top maintainability predictors.

C. Measures of Maintainability for Relational Database-Driven Software Applications

The second section of the third part of the survey was aimed at recording the most used measure of maintainability among time to carry out a maintenance task, own experience and judgment, and an equation or a more sophisticated method. Thirteen respondents provided no answer to this question. Among the 27 responses received, 20 favored expert judgment, 4 favored time to carry out a maintenance task, 1 favored a more sophisticated method, and two reported a combination of time to carry out a maintenance task and their judgment. The one respondent who mentioned an equation or more sophisticated method also added a note to indicate that there is no use of an equation or model but the company uses mature practices so it has its own parameters to assess maintainability.

Overall, their own experience and judgment was the measure reported by most surveyed practitioners to measure the maintainability of relational database-driven applications. This suggests that maintainability of relational database-driven applications is determined by subjective assessment in practice.

V. Discussion

This paper presents the results of a survey conducted with software professionals. The survey was informed by a previously conducted SR [12] and the results of interviews conducted with software professionals [13]. It was aimed at identifying maintainability predictors that had the highest impact on the maintainability of relational database-driven software applications. A list of 120 predictors belonging to 10 different categories was used on which expert opinions from software professionals were recorded. The survey results suggest that the top 5 predictors related to 'Database Design', 'Design Aspects of Relational Database-Driven Applications', 'Team, Team Communication and Project Management', and 'Change and Maintenance'. The number of predictors selected by more than 50% respondents was highest for the category 'Quality, Quality Assurance, and Testing' followed by the predictors related to 'Relational Database-Driven Application'.

The main contribution of this paper is that it identifies the top predictors of maintainability for relational database-driven applications. Other contributions include establishing and supporting by evidence that the type of applications most developed in software organizations have a relational database backend, as discussed in Section III-C; interface of a relational database-driven application is considered easiest to change by software practitioners whereas data model and computation intensive modules are considered equally difficult to maintain in comparison to interface; and maintainability in practice is measured using expert judgment.

The results of the survey presented some interesting findings in terms of the factors considered important by software practitioners. From the results of the SR, the most frequently mentioned predictors related to coupling, complexity and size related measures. However, the survey results suggested that the factors related to 'Size, Scope, and Complexity of Relational Database-Driven Applications' were not ranked higher than predictors belonging to other categories by the surveyed software practitioners. In fact, the list of predictors ranked higher by more than 50% of the respondents does not include any factor from this category. This is a very important finding suggesting a huge gap between research and practice with regards to the perception of maintainability predictors in the context of relational database-driven applications. The possible reasons for this can be that most research experiments reported in literature are not performed in an industrial setting and the applications used in research experiments are generally small in scope. This makes it easier to gather metrics and experiment on these applications whereas

in practice there is lesser room for experimentation due to tight deadlines. In addition, in practice no sophisticated techniques for maintainability prediction are used and therefore, practitioners rely more on the visible factors on which that they can more easily formulate a judgment on maintainability. Also, the sample size for this research is not large so there is also the possibility of lack of external validity. We believe that irrespective of the reasons, there is a need to further investigate maintainability predictors of for relational database-driven applications. In this regard, our work in progress involves gathering project specific data on the predictors identified herein and creating maintainability prediction models based on the gathered data. This, in addition to providing prediction models, will also be a means to validating the predictors and will suggest a need to consider predictors other than the ones selected herein.

The maintainability predictors for software applications suggested in the literature involved measures related to coupling, complexity and size of the application. The results of the survey suggest that size related measures are not important predictors whereas predictors related to database design are very important for maintainability prediction of relational database-driven applications. This suggests that the maintainability of relational database-driven applications is different from that of the software applications.

It may appear that the data analysis method used is not very sophisticated and rigorous. However, the purpose of this survey was to identify top predictors from the list of 120 predictors such that these could be used for future work involved in this research. The analysis technique used perfectly suited the purpose and the use for a more sophisticated technique was hence, not required. Moreover, there are examples in the literature on software prediction where frequency analysis has been used to rank the predictors to be used further for the creation of prediction models [10].

The possible limitations of this research are related to unequal number of respondents from the two countries and smaller sample size. While equal number of respondents from both countries would have provided better opportunity for data analysis and comparison of results, the research itself was context free as established by the results from the interviews [13]. Therefore, we believe that the unequal number of respondent in this case is not a threat to the validity of the research. In regards to small sample size, we believe that it poses threats to the external validity of the research as the chances of obtaining different results from a larger sample size cannot be ignored. However, considering the number of companies to which invitations to participate were emailed, the length of the survey, and the time frame within which the survey had to be completed; we believe that the sample data is of a considerable size to derive valuable conclusions.

VI. CONCLUSIONS

This paper presents the results of a survey conducted with software professionals. The survey was informed by the results of a previously conducted SR and interviews conducted with software professionals. The aim of the survey was to rank the 120 maintainability predictors of relational database-driven applications belonging to 10 different categories for their strength in predicting maintainability. Out of 120 total factors, 44 factors were found to have an impact of either 'high increase' or 'medium increase' on maintainability, as per more than 50% of the respondents. The most important category of predictors was 'Quality, Quality Assurance' and Testing' whereas the top predictor ‘Correct definition of entities’ belonged to the category 'Database Design'. Our results also suggest that the practitioners measure maintainability using expert judgment and consider computation intensive modules of relational database-driven applications as easy or difficult to maintain as the data models.

Future work involves creating maintainability prediction models for relational database-driven software applications. In this regard, the work on gathering project related data on the predictors is already in progress.

How Annotations are Used in Java: An Empirical Study

Henrique Rocha*, Marco Tulio Valente*

*Department of Computer Science
Federal University of Minas Gerais (UFMG)
Email: henrique.rocha@gmail.com, mtov@dcc.ufmg.br

***Abstract*—Since 2004, Java provides support to general purpose annotations (also known as metadata) that allows developers to define their your own annotation types. However, seven years after their inception in the Java language, we still do not have empirical evidence on how software developers are effectively using annotations in their systems. Therefore, this paper presents an empirical study on how annotations are used on a corpus of 106 open-source Java systems. On total, we have evaluated more than 160,000 annotations that have been applied to the source code of such systems. Our main findings can be summarized as follows: (a) the so-called annotation-hell phenomena affects many of the evaluated systems; (b) developers are using both pre-defined annotations and annotations defined by external frameworks, mostly annotations dedicated to persistence and testing; (c) most of the evaluated annotations have been employed to annotate methods (more than 90%); (d) although Java does provide not support to annotations for anonymous classes, several programs from our corpus have applied annotations to such classes.**

***Index Terms*—Annotations, Empirical Studies, Qualitas Corpus.**

I. Introduction

Annotations have been one of the features introduced in J2SE 5.0 released in 2004 [3], [1]. Annotations are a metadata feature that provides the ability to associate additional information to Java elements (like classes and methods). Annotations have no direct effect on the code they annotate, and they do not change the way in which the source code is compiled. There are at least the following possible uses for annotations [3], [1], [6]:

- Compiler information (using compiler annotations) to suppress warnings and to detect errors. For example, developers can use the `@SuppressWarning("unchecked")` annotation to suppress the unchecked warning that can be raised when using an old code written before J2SE 5.0.
- Generation of additional files such as source code, XML, help files, and so on. For example, developers can annotate some system's functions with `@Help("...")` and later an annotation processing tool can read this metadata and generate a help file.
- Source code documentation by javadoc and similar tools (using the `java.lang.annotation.Documented` annotation).
- Since annotations can be processed at runtime, they can be used for logging, testing and other utilities.
- Some APIs (like Java Persistence API) relies on annotations as a declarative way to provide their services. Instead of calling methods or declaring objects, an annotation is placed in the program elements that the developers want to be annotated. For example, to define a class as a `JPA` entity, we just need to put the `@Entity` annotation on the class.

Although annotations have several useful applications, their use could massively contribute to code pollution. This phenomenon is usually called *annotation hell*, i.e. the source code becomes cluttered with so many annotations leading to poor code readability and understandability.

The ultimate goal of our research is to empirically investigate the use of annotations in Java programs. Annotations have been a part of the Java language for almost seven years, and now it is reasonable to assume that they are being used in most Java applications. We are particular interested in providing answers to the following questions: (a) Which are the most used annotations? (b) Which program elements (i.e. methods, classes) are annotated more frequently? (c) Are there many systems suffering from the *annotation hell* phenomenon?

In order to answer such questions, we present the results of an in-depth empirical study including the inspection of annotations in 106 open-source Java systems that are a part of the Qualitas Corpus. The Qualitas Corpus is a collection of open-source Java sytems designed to help code analysis in empirical studies [9], [8]. Basically, we developed two approaches to extract the annotation data from the Qualitas Corpus. The results from both approaches are shown and compared, providing a better analysis to the use of annotations and even showing some tendencies that programmers are following.

The remainder of this paper is organized as follows. In Section II, we provide an introduction to the use of annotations in Java, explaining their most recomended uses and underlying syntax. Section III describes the methodology used for the empirical study, including the two approaches we have followed to retrieve annotations in Java systems. Section IV analyzes and discuss the obtained results. In Section V we present this study's threats to validity. Section VI discusses related work and Section VII concludes the paper, summarizing its main

contributions and outlining future work.

II. Annotations

Annotations are a metadata feature that does not directly affect the code they annotate. As mentioned in the Introduction, they can be used for several purposes like runtime testing, generating additional files, providing information to compilers, and providing a simple and declarative form to use API features [3], [1], [6].

In terms of implementation, annotations can be considered a special kind of interface [3], [1]. To distinguish an annotation declaration from an interface, annotations are declared using the `@interface` keyword. Listing 1 shows a code fragment that declares an annotation called `Author`. Annotations can make use of access modifiers just like interfaces (`public`). In the example, the `Author` annotation has the *element* `name` which has a `String` type and by default has the `"[unassigned]"` value. Annotations *elements* are a special kind of method declaration.

```
1 public @interface Author {
2     String name() default "[unassigned]";
3 }
```

Listing 1. Code fragment declaring an Annotation

Listing 2 shows how the `Author` annotation can be used to annotate a class. This code also shows some `JPA` annotations. For example, the `@Entity` denotes that the `Customer` class will be made persistent by `JPA`. The `@Id` annotation is used to define the entity's primary key.

```
1 @Author{name="Henrique"} @Entity
2 class Customer implements Serializable{
3
4     @Id
5     public Integer getCustomerId(){
6       ...
7     }
8 ...
```

Listing 2. Annotations Example

Annotations can be divided based on their retention policy into three types: Source, Class and Runtime annotations [3]. Source annotations are processed during compilation (usually by a compiler plug-in), but they have no effect on the generated code. Class annotations are also processed during compilation and they are stored in the generated class files. Runtime annotations are stored in class files and can be recovered at runtime through the Java Reflection API.

There are some predefined annotations in Java, including the following compiler annotations: `@Deprecated`, `@Override`, and `@SuppressWarning`. The `@Deprecated` annotation indicates that the marked component is deprecated and should no longer be used. The `@Override` is an annotation for methods only, and it indicates that the method is supposed to override a superclass method. Finally, the `@SuppressWarning` annotation disables a specific warning the compiler would otherwise generate.

The additional data provided by annotations can be processed by the compiler, other tools or, in the case of runtime annotations, they can be examined at runtime using reflection. The most common tool to work with annotations is the annotation processing tool (`apt`) provided in the Java development toolkit. The `apt` retrieves annotations in source files, using custom factories and visitors so that programmers may process annotations according to their needs.

III. Methodology

In this section we describe the target systems used in the study (Section III.A) and the methodoly we followed in the research (Section III.B).

A. Target Systems

We defined the scope of our study to be the systems contained in the Qualitas Corpus [9]. The Qualitas Corpus is a *curated* collection of open-source Java systems whose ultimate goal is to reduce the effort in finding, obtaining, and organizing code sets to be used in empirical studies [9]. We used the Qualitas Corpus version `20101126r`, that contains only the most recent versions of the 106 systems.

B. Study Design

To retrieve the annotations used by the systems in the Qualitas Corpus, we implemented a factory class for the `apt` tool, that is a part of the Java SE Development Kit (JDK) version 1.6.0 update 24. The `apt` parses the source files and provides to the factory class each annotation found, as well as details about the annotation. Basically, our factory class saves all the relevant information about the annotations in a relational database for latter analysis.

Since `apt` is the official Java tool to process annotations, our original plan was to use it to examine all annotations used by the systems included in the Qualitas Corpus. However, the `apt` tool has stopped with runtime errors while trying to process 15 systems – Table I shows the name of these systems. The errors occurred on the tool itself, and even bug report information has been raised to contact the manufacturer.

TABLE I
Qualitas Corpus systems the APT has not been able to Process

System	System	System
Castor	javacc	nakedobjects
Cayenne	jboss	netbeans
gt2	jrefactory	springframework
Hibernate	maven	struts
jFin_DateMath	myfaces	tapestry

Due to the `apt` errors, we created a textual search program to find annotations in source files. Originally, this textual search approach has been used on the systems that the `apt` tool has not been able to process. Latter we expanded the textual search to analyze all the systems to better compare the differences between both approaches.

IV. RESULTS

In this section we present the results from our study. Table II shows the systems, their Kilo non-comment Lines of Code (KLOC), the total annotations found and the annotation density as retrieved by the `apt` tool and by the textual search. The annotation density is calculated by dividing the number of annotations by the KLOC. Therefore, this density represents an average of how many annotations are present in every one thousand lines of code. As mentioned, the `apt` tool crashed with an internal bug on 15 systems, these systems are shown on the table with a "–".

Two more aboservations should be made about the data in Table II, first the table shows that the size of the evaluated systems has no impact on the runtime errors raised by the `apt` tool. For example, the `castor` system has 115.543 KLOCs and caused a crash in the `apt`, while the `Eclipse_SDK` system has 2,282.490 KLOCs and has been sucessfully processed.

Second, Table II also shows a slight difference between the number of annotations found by the `apt` and by the textual search. Investigating further, we discovered that Java does not support annotations in the scope of anonymous classes. Because of that, the `apt` has completely ignored those annotations. On the other hand, the implemented textual search has count such annotations.

To better inspect the different measurements regarding annotations in anonymous classes, we will use the `jhotdraw` system as an example. As can be observed on Table III, the measurements have a difference of 427 annotations in their count. Table III also shows the particular annotations present in the `jhotdraw` system. As we can observe, the main difference is in the `@java.lang.Override` annotation, followed by the `@java.lang.SupressWarning` annotation. In fact, this seems to be case not only for the `jhotdraw`, but for every system in the Qualitas Corpus with a different annotation count between the `apt` and the textual search.

TABLE III
JHOTDRAW ANNOTATIONS

Annotation	APT	Textual Search

@java.lang.annotation.Target	2	2
Total	**3143**	**3570**

From all the 106 analyzed systems, 41 did not have a single annotation – Table IV shows these systems and the year of their release date. Analysing the years on this table, we can

conclude that seven systems were release before 2004 (i.e. before the introduction of annotations in Java) and another seven systems have been release in 2004.

Finally, Table V shows the top ten Qualitas Corpus systems with annotations using both measurements. Based on this table it is possible to conclude that some of the systems the `apt` was not able to process have a large number of annotations, for example, `netbeans`, `spring framework` and `hibernate`.

In the remainder of this subsection we first discuss the results using the `apt` tool (Section IV.A). Second, we show the results provided by the textual search approach (Section IV.B). And finally, we discuss both results in order to clarify our main findings (Section IV.C).

A. APT

Table VI shows the top ten analyzed systems with the highest annotation density. For example, the `htmlunit` system – the system that presented the highest annotation density – has a 147.01 density, which means that on average on each one thousand lines of code there will be 147 annotations.

Table VII show the total number of annotations from all systems processed by the `apt` classified by program element. In this classification, a type denotes packages, classes, enums or interfaces. As we can see, more than 92% of the annotations are used to annotate methods.

TABLE VI
TOP TEN QUALITAS CORPUS SYSTEMS WITH HIGHEST ANNOTATION DENSITY AS PROCESSED BY THE APT

System	KLOC	Annotations	
		Total	Density
htmlunit	40004	5881	147.01

@org.jgroups.annotations.Property	290	0.51
@BeforeClass	279	0.49

B. Textual Search

Table IX shows the ten analyzed systems with the highest annotation density, as processed by our text-based search approach. By comparing Tables VI and IX, it is possible to conclude that some systems the `apt` has not been able to process have a high density value and they appeared on the textual search (`tapestry`, `spring framework`, `nakeobjects`, `hibernate`). The system that presented the highest and second highest densities were respectivelly the `htmlunit` and `jchempaint`.

Due to limitations inherent to the textual search approach, we could not determinate to which program element the annotations belong to. Finally, Table X presents the most used annotations in all systems. We can observe that, as in the `apt` tool based results, the compiler annotations are widely used.

TABLE IX
TOP TEN QUALITAS CORPUS SYSTEMS WITH THE HIGHEST ANNOTATION DENSITY AS PROCESSED BY THE TEXTUAL SEARCH

System	KLOC	Annotations	
		Total	Density
htmlunit	40.004	5959	148.96

@Id	951	0.59

C. Analysis

Based on the results presented on this paper we can present some interesting findings about the use of annotations.

First, by inspecting Tables VI and IX, we can observe that the annotation density values for these systems (specially those on Table IX) are a strong indication they might be suffering from *annotation hell*. For example, when we analyze the `htmlunit` system, it scored the highest density in both approaches, having almost 150 annotations per KLOC (or approximatly one annotation at 7 lines of code).

A second interesting finding is about the annotations used on the systems. We initially expected that all three compiler annotations to be amongst the most used ones. But the second most used annotation was the `@Test` annotation. The `@Test` annotation is used to test methods dynamically through reflection. Apparently, this has become a popular standard used by several programmers.

Moreover, we can see on Table X that the annotations `@Column`, `@Entity` and `@Id` are used very frequently. These annotations are used by the Java Persistence API to map Java classes to relational database tables.

Another annotation used frequently, as presented on Tables VIII and X, is the `@org.jruby.anno.JRubyMethod`. This annotation is used by the `jruby` system to specify methods signatures using Java code and to use them as method calls in Ruby code. To illustrate the use of `@JRubyMethod`, Listing 3 shows an example of a `readchar` method marked with this annotation. As mentioned, the goal is to mark this method callable from code within Ruby.

```
1 @JRubyMethod(name = "readchar")
2 public static IRubyObject readchar(
      ThreadContext context, IRubyObject recv)
      {
3 ...
```

Listing 3. JRubyMethod Annotation Example

A third interesting finding comes from the observation of Table VII. As we can see, most annotations were used to annotate methods (over 90%), which is a huge difference to the second most used annotation, the types annotations with almost 5%. Very few annotations have been used to mark constructors, fields and parameters.

Finally, another interesting finding was that although Java does not support annotations for anonymous classes, many programs are using it. The reason why the annotation count differ from the `apt` and the textual search is mainly because of those anonymous class annotations. Analyzing the table we can see that in 38 out of 50 systems evaluated by both approches we have anonymous class annotations.

Investigating this occurence further, we discovered another reason for such form of use. Some programming IDEs warn the programmer to use annotations or even generates code with annotations, regardless they are located in anonymous class. We tested this feature using the `Eclipse` IDE build ID 20110218-0911 to generate the code for an anonymous inner class for a button event, and the IDE generated the method with an `@Override` annotation.

V. THREATS TO VALIDITY

Two main factors can impact on the validity of the results presented in this paper. First, our chosen systems might not be representative of all annotations used by the entire Java community. To minimize this threat we used the Qualitas Corpus that has 106 open-source systems from which 65 had annotations.

The second threat is related to the `apt` bugs. We were not able to determine what caused the bug that made the `apt` to crash while processing 15 systems from the Qualitas Corpus. To minimize this threat we developed a second approach based on a textual search. In this way the results obtained by the `apt` could be compared and validated to the results obtained by the textual search. However, using the textual search approach it was not possible to extract the annotations' full qualified name, nor which Java program element have been annotated.

VI. RELATED WORK

Annotations can be considered a relative new feature in the Java language. Probably because of that, there is not many works related to studying the use of annotations in existing systems. However, there are studies related to creating tools to verify the correct use of frameworks and APIs annotations. One of those efforts presents the AnnaBot tool [1], that demonstrate its usefulness using Java Persistence API examples. Another proposed tool to verify frameworks and

APIs annotations is the ModelAn [6], which is a model based approach, and uses the Fraclet as a case study.

On the field of empirical studies about Java constructions and abstractions, there are many related work. First, there is an empirical study of UpgradeJ [10] which is a variant of the Java language. UpgradeJ is a language that allows multiple versions of classes to co-exist, thus supporting dynamic software updatings. The empirical study has evaluated different versions of classes on open-source Java applications and estimated how many of the classes changes could be handle by UpgradeJ dynamically. The results show that most changes could be supported without a significant code rewrite.

There is also a work aiming to evaluate the use of non-private fields in Java applications since there is little empirical evidence to this practice [8]. This study has relied on 100 open-source Java applications (that we could consider to be an ancestor to the Qualitas Corpus [9]). The study has concluded that it is not uncommon for systems to declare non-private fields and do not take advantage of that access.

Another empirical study that uses a Qualitas Corpus release aims to find how programmers are overriding methods [7]. This work relies on a set of metrics to analyze the systems and how well their overriding implementation is. This study found that most subclasses override at least one method. It also found some questionable uses of overriding in the Qualitas Corpus systems.

The analysis of class coupling and the choice of refactoring (or removing) them in latter releases of the systems is the topic of another empirical study [5]. This study shows that the size of the source code does not affect the redesign choices, and a strong tendency that some classes have towards their removal.

Annotations have also been investigated in the scope of aspect-oriented software development. For example, annotations are often mentioned as an alternative to design more robust pointcuts. Kiczales and Mezini recommend using annotations when: (i) it is difficult to write a stable regular expression or enumeration-based pointcut; (ii) the name of the annotation is unlikely to change; (iii) the annotation denotes a well-defined semantic property (and not properties that are only true in some configurations of the system) [4]. Eaddy and Aho propose using annotations at the statement level for exposing join points needed by heterogeneous concerns and for enabling fine-grained advising [2]. However, their proposal can lead to a widespread use of annotation and thus can increase the code scattering and tangling phenomenon usually associated to Java annotations.

VII. Conclusions

We have presented a large empirical study on the use of annotations in open-source Java systems. Our motivation for this work was mainly because as a new language feature, it is difficult to find studies analyzing the use annotations. After analyzing the systems using the official Java annotation processing tool, we had to develop a textual search program to process the systems where the `apt` hast failed. Using the `apt` we were able to process 50 systems with 56,330 annotations; and using the textual search we processed 65 systems with 160,570 annotations.

We have also shown that some systems have a very high annotation density. Moreover, some of the discoveries found by our analysis from both approaches confirm that the most used annotations are the compiler ones. Also that methods are the most annotate element, and that the `JPA` annotations are popular. We also found that programmers are using the `@Test` as a standard annotation to mark methods that will be dynamically tested by reflection.

Finally, although the Java language does not support annotations inside anonymous classes, programmers are still annotating them. Some programming IDEs generate code with annotations even in anonymous classes. This indicates a tendency that maybe should be included on latter versions of the Java language.

As future work we hope to inspect even further the annotations on Java applications, processing and analyzing more annotated data.

***Abstract*—Database application is one of the most common types of systems. Grounded on the simple concept of data lifecycle—any data in database is created from insertion, used via selection and modification and terminated at deletion—this paper proposes a novel approach to reverse engineer the data lifecycle automatically from the source code of database applications. The extracted information can be used for the selection of open-source database applications for adaptation. It can also be used for maintenance and verification of database applications. A tool has been developed to implement the proposed approach for PHP-based database applications. Case studies have also been conducted to evaluate the use of the proposed approach.**

Keywords-data lifecycle; extraction; reverse engineering; maintenance; verification

I. INTRODUCTION

Due to the complexity of software development and absent or incomplete associated documentation through most stages of the whole software development life cycle, recovery of system inner features automatically from program source code is important in system comprehension, verification and maintenance. Reverse engineering is the process of analyzing a subject system to create representations of the system at a higher level of abstraction [1], and is a suitable approach for this purpose.

During the past decades, much effort has been focused on this area. Michael L. Nelson conducted a survey on the reverse engineering and program comprehension in [2]. He presented various approaches to automating reverse engineering including syntactic analysis, graphing methods and execution and testing method. In 2000, H. A. Muller.et al [3] presented a roadmap of reverse engineering building on the program comprehension theories. They discussed the code reverse engineering and explored the spectrum of reverse engineering tools.

Database application is one of the most common types of systems, it is important to provide support to analyze the code of the database applications automatically. The specific characteristic of database applications is data manipulation and the data maintained in the database is always dynamic. The flow of data processing, from insertion to being used to finally deletion, indicates a lifecycle of data in the database, which can be a representative aspect of database applications.

Based on the basic concept of data lifecycle, this paper proposes a novel approach to reverse engineer the data lifecycle automatically from the source code of database applications. This basic but representative information is an easy to use and understand indicator that benefits the selection, maintenance and verification of database applications.

The paper is organized as follows. Section 2 depicts the data lifecycle. Section 3 discusses the proposed approach. Section 4 reports our evaluation. Section 5 presents the related work and Section 6 concludes the paper.

II. DATA LIFECYCLE

Data maintained in a database is usually dynamic. Once the data is created from insertion, the data should be used, updated, and finally removed once it becomes obsolete. This implies that an attribute and table defined in the schema have a lifecycle that starts from being inserted, via being used as and when needed, and optionally being updated in any number of times, to being deleted. We call such characteristics data lifecycle of attribute and table respectively. Fig. 1 depicts the data lifecycle using state transition diagram.

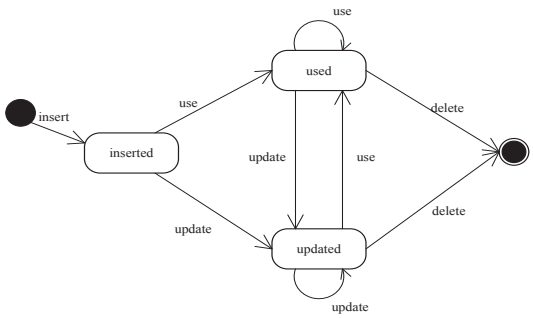

Figure 1. Data lifecycle of attribute and table

The property of the data lifecycle implies directly that any database application must include related operations to support the data lifecycle of attribute and table. Any missing of database operation for supporting the data lifecycle is very serious. Programs in database applications provide support to data lifecycle by performing four database operations: INSERT, SELECT, UPDATE and DELETE.

TABLE I. TYPES AND CLASSIFICATION OF DATA LIFECYCLE SUPPORT

SELECT	INSERT	UPDATE	DELETE	Category	IMPLICATION
T	F	T	T	Undefined	Data is updated, used and deleted without defined
T	F	T	F	Undefined	Data is updated and used without deleted and defined
T	F	F	T	Undefined	Data is used and deleted without updated and defined
F	F	T	T	Undefined	Data is updated and deleted without used and defined
T	F	F	F	Undefined	Data is used without updated, defined and deleted
F	F	T	F	Undefined	Data is updated without used, deleted and defined
F	F	F	T	Undefined	Data is deleted without updated, used and defined
F	T	T	T	Redundant	Data is defined, updated and deleted without used
F	T	F	T	Redundant	Data is defined and deleted without updated and used
F	T	T	F	Redundant	Data is defined and updated without used and deleted
F	T	F	F	Redundant	Data is defined without used updated and deleted
T	T	T	F	Undeletable	Data is defined, used and updated without deleted
T	T	F	F	Undeletable	Data is defined and used, without updated and deleted
T	T	F	T	Non-modifiable	Data is defined, used and updated without updated
F	F	F	F	Reserved	Data is specified without defined, used, updates and deleted
T	T	T	T	Complete	Data is specified then defined, used, updates and deleted

In a database application, most of the attributes and tables should be provided with a complete data lifecycle. That is, there are programs in the application which perform insertion, selection, updating and deletion for these attributes and tables. However, we should note that there are some special cases on updating and deleting the data, e.g., the application of initial public offer of a company stock. The record can't be updated or cancelled when it is confirmed.

Table I shows all the sixteen possible combinations of data lifecycle support provided in a database application with SELECT, INSERT, UPDATE and DELETE operations. We can classify the sixteen possible combinations according to their implications. For example, if insertion, selection, updating and deletion are all provided for an attribute, then the data lifecycle for that attribute is basically complete. If none of these database operations is provided, then basically the attribute or table is just to be reserved for future use. In addition to the details of data lifecycle support types, Table I also shows the classification of data lifecycle support provided in a database application.

III. EXTRACTION OF DATA LIFECYCLE SUPPORT

In this section, we give detailed description on the extraction of data lifecycle support from the source code of database applications.

Considering different purposes, our approach extracts data lifecycle support of the attribute and table respectively. The data lifecycle support of attribute provides detailed information about the lifecycle support of each attribute and its category. The data lifecycle support of table is the combination of data lifecycle of attributes within the table and provides detailed information about the lifecycle support of each table and its category. Next, we describe the extraction process.

In the extraction, for each SQL query, we need to identify: the operation type (SELECT, UPDATE, INSERT or DELETE); attribute names and table names that are involved. In practice, an SQL query is usually formed as a string literal or more often a string variable, and is then passed to some specific query functions, e.g. mysql_query in PHP if MySQL is used. Based on our observation, the value of the SQL string variable commonly varies according to some conditions, i.e. the actual value taken by the query function is subject to different program paths chosen during execution. Fig. 2 shows a simple snippet of PHP code as an example for this.

```
1. <?php
2. if (…)
3.     $attr = 'col1';
4. else
5.     $attr = 'col2, col3';
6. mysql_query('SELECT ' . $attr . ' FROM table');
7. ?>
```

Figure 2. A PHP code snippet

From Fig 2, it can be observed that the SQL query in line 6 is constructed by concatenation of three strings, the second of which is a variable with different execution values under different conditions. For the extraction, first, we compute the control flow graph and then perform control and data dependency analysis.

A. Construction of Control Flow Graph and Control Dependence Analysis

All SQL query function call sites in the source code should be identified, and parameters they take can then be evaluated. We compute standard control flow graph (CFG) for each program. Fig. 3 shows the CFG for the code in Fig. 2.

Starting from the entry block, the control flow graph is traversed and each basic block encountered is checked to see whether it contains query function calls. We can locate one such function call in the node 5 in Fig. 3 representing line 6 in the code in Fig. 2. The parameter which contains the SQL query is extracted. For each query, it would be either one single

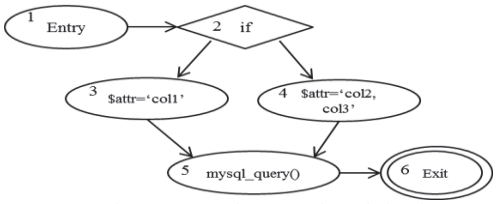

Figure 3. CFG for example code in Fig. 2

variable, or the concatenation of several string literals and variables. In Fig. 2, the parameter only includes one variable: $attr. The actual value of the variables vary according to different condition values taken in the predicate nodes before the function, whose different successive paths would assign different values to the variables that are used directly or indirectly by the query function. To include all possible values for the variables for the precision of the extraction process, we need to further adopt data dependence analysis.

B. Data Dependence Analysis

For each basic node in CFG that contains one or more SQL query function calls, we extract paths in the CFG starting from the entry node and passing through the function call node. For example, from the CFG in Fig. 3, we obtain two paths for node 5. One is 1 –> 2 – >3 –> 5 and the other is 1 –> 2 –> 4 –> 5.

For each such path, data dependence analysis is performed for every variable that is used in the function call. We trace each variable's direct or indirect definition from the function call node backward along the path, until either 1) a constant assignment is encountered, for example: $attr = 'col1'; 2) assignment with values that are unable to be determined, such as return value of user input functions. If the string value of one variable can be determined, this variable is replaced by its actual value; otherwise it is replaced by an empty string. All these strings are concatenated in the same order as they are listed in the function call. By this way, the string value of the parameter used in SQL query function is extracted.

In this way, for the above example, from the first path, we generate the SQL query: "SELECT col1 FROM table"; from the second path, we produce "SELECT col2, col3 FROM table". These queries are put into a set for further analysis.

C. Data Lifecycle Generation

After the possible values of the SQL string variable used in the query function are retrieved, the set of SQL query strings are formed. When we parse each SQL query, the operation type of the query, i.e., either SELECT, UPDATE, INSERT or DELETE, is first determined. Next, the attribute names and table names are obtained from the strings according to the standard SQL grammar specification. For some set of SQL queries, the operation type, attribute names and table names are identical, and the changing part is the values that are used by the attributes, for example, values in the conditions in WHERE clause. In our approach, these different SQL queries are treated as duplicated and we only keep one of them.

For the example in Fig. 2, we finally extract two selection operations, the first one selects attribute "col1" from table "table"; the second one selects attributes "col2" and "col3" from the same table. We count the two operations into the corresponding data lifecycle information for the attributes and the table.

Finally, with these retrieved attribute operations and their occurrence sites, we integrate them together to count operations on each attribute in each table. Based on these, data lifecycle for attributes and tables as described above can be generated accordingly. Fig. 4 shows the above mentioned data lifecycle extraction process.

```
Algorithm extractDataLifecycle:
Input: source code files of one software system
Output: Data lifecycle information
Begin:
for each source code file F do:
    Generate control flow graph G for F;
    Traverse G and identify query function invocations;
    for each invocation node I do:
        Extract parameter list from I;
        for each variable V do:
            for each path p in G that passes I do
                Perform data dependency analysis for V on P;
                Trace definitions backward along P;
                if the last traceable definition is string
                    literal then:
                    Replace V with the string value;
                else:
                    Replace V with empty string;
                endIf;
            endFor;
        endFor;
        Generate a SQL query by concatenation of string
            values of all variable;
        Parse the SQL query and record
            operation type, attribute names and table names;
    endFor;
endFor;
Integrate all extracted information for each attribute of each
table;
Generate data lifecycle;
End.
```
Figure 4. The pseudo-code of data lifecycle extraction

IV. EVALUATION

In this section, we evaluate our proposed approach for the selection, maintenance and verification of database applications with case studies. We start by first giving a description of our prototype tool.

A. Prototype Tool

Many database applications are developed using PHP. Hence, we implemented a prototype tool in Java for PHP applications in order to verify our proposed approach. PHP is the widely used scripting language for developing web application. We used Pixy [4], an open-source PHP analyzer to parse the PHP source code.

The tool analyzes the source code and extracts the data lifecycle support automatically. It works in the following steps: first it scans through the PHP system and finds all the PHP source code files; second, it parses each file to generate corresponding control flow graph, and then identifies the query

execution functions; third, the tool computes data dependency for the variables involved in the query functions, and based on that possible SQL queries are generated, the operation types and table and attribute names involved are determined; finally, according to the information extracted, the data lifecycle support is generated automatically. Though some variables' values cannot be decided during data dependency analysis, we observed that these variables are mostly used as the values of attributes, and in most cases the operation types, attribute and table names involved in the queries can be resolved from string literals.

Fig. 5 shows a diagram depicting the workflow of the prototype tool.

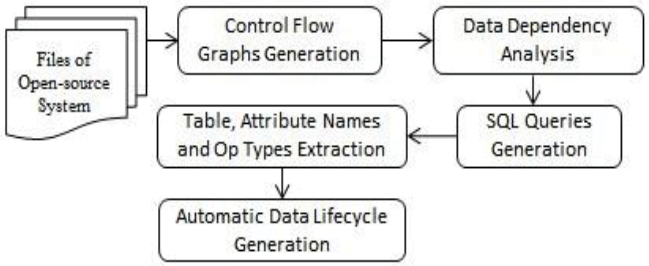

Figure 5. The workflow of the prototype tool

B. Case Studies

1) Selection

Due to the lack of documentation, selection of an appropriate open-source database application for use from the huge repository is not an easy task. Our approach extracts easy to use and understand lifecycle support information automatically to assist the users in the selection process.

To aid the selection process, we give summarized information of the system. With this information, one can assess the quality of the whole system directly from the analysis of data lifecycle completeness. Furthermore, with the information of data lifecycle of attributes and tables, the user can look into detailed information of implementation and be clear about the data lifecycle for each attribute and table.

For the selection process, we evaluated our proposed approach on four real-world PHP DB applications from sourceforge.net. They are School Mate (v1.5.4, a PHP/MySQL school administration and management), Open-School (pre-alpha release, a web-based School Management Software), LAMP School (v0.3 beta, an online school register system) and School Admin (v0.3, a web-based software for schools and colleges). The four systems provide similar functionalities, but differ in their completeness and maturity. Our tool is applied to analyze them and discover their data lifecycle support information.

Due to the space limit, summarized information of two systems is shown in Table II. From the experiment, we know that the percentage of complete category is highest for School Mate (45.3%) followed by LAMP School (42.0%) whereas School Admin has the lowest percentage (1.2%) of complete attributes. The percentage of undefined attribute of School Mate is the lowest (21.3%) while that of Open-School's is the highest (46.0%). Besides, the percentage of the reserved attributes of School Mate (4.3%) is lower than that of the other three (12.4%, 28.0% and 35.3% for Open-school, LAMP School and School Admin respectively). It also has no undeletable attribute in it. Both the Open School and Lamp School have no redundant attributes or tables while School Admin and School Mate have 8.2% and 6.8% redundant attributes respectively. Furthermore, only in School Admin, the percentage of undeletable category is 17.6% while there are no undeletable attributes and tables amongst the other three.

TABLE II. SUMMARIZED DATA LIFECYCLE SUPPORT

School Mate	**Table**		**Attribute**	
	#	**%**	**#**	**%**
Complete	11	73.3	53	45.3
Redundant	0	0	8	6.8
Non-modifiable	2	13.3	26	22.2
Undeletable	0	0	0	0
Undefined	2	13.3	25	21.3
Reserved	0	0	5	4.3
Total	15	100	117	100
School Admin	**Table**		**Attribute**	
	#	**%**	**#**	**%**
Complete	1	6.3	1	1.2
Redundant	3	18.8	7	8.2
Non-modifiable	1	6.3	6	7.1
Undeletable	3	18.8	15	17.6
Undefined	1	6.3	26	30.6
Reserved	7	43.8	30	35.3
Total	16	100	85	100

The above mentioned information suggests that each system has some advantages against others as well as some disadvantages. Usually a more complicated and better established system would have more complete data lifecycles. On the contrary, systems that have not been fully developed may have poor data lifecycles.

The empirical results can facilitate the user when selecting a suitable database application for adaptation. Considering the huge amount of open-source systems available on the Internet, the data lifecycle support is a good way to start and help the selection process.

2) Maintenance

The data lifecycle support for attributes and tables is also useful in database application maintenance since it reveals the completeness of functions from inside the source code. In this section, we demonstrate how the data lifecycle support can be used in the maintenance process for cases of undefined, non-modifiable, undeletable, redundant and reserved respectively. We use Table III and Table IV for demonstration.

- *Undefined*

If the data lifecycle support information provided for an attribute or table in a database application is classified as undefined, it is certainly not adequate and additional programs must be coded to address this flaw.

TABLE III. DATA LIFECYCLE OF ATTRIBUTE FOR SCHOOL ADMIN*

Attribute	Table	S	U	I	D	Category
admid	admission	T	F	T	T	Non-modifiable
cls	classes	T	F	T	F	Undeletable
reasonofrej	admission	F	T	T	T	Redundant
email	emp	F	T	F	F	Undefined
empid	emp	F	F	F	F	Reserved
statid	admission	T	T	T	T	Complete

* S = Select, U = Update, I = Insert, D = Delete. This is only a part.

TABLE IV. DATA LIFECYCLE OF TABLE FOR SCHOOL ADMIN*

Table	S	U	I	D	Category
assign	F	F	F	F	Reserved
rght	F	F	F	F	Reserved
rolerght	F	F	F	F	Reserved

* Only a part of the table is shown.

From Table III, we found that the attribute "email" in table "emp" is undefined, which means there is no insertion for this attribute, but there is an update operation for it. Although there is a case that an attribute has a default value and its insertion is not compulsory, we note that this might still be a flaw in design. However, by manual inspection, we found that in the project School Admin, the attribute "email" in fact has no default value, so this is actually an error or incompleteness of implementation. An additional function for this is thus needed.

- *Non-modifiable/Undeletable*

If the data lifecycle support information provided for an attribute or table in a database application is classified as non-modifiable or undeletable, then its adequacy depends on the application characteristics or the requirements; developers can examine whether additional programs are needed be coded for the adequacy of data lifecycle.

It can be seen from Table III that attribute "admid" in table "admission" is non-modifiable. This indicates that once a record is inserted, its attribute "admid" can never be changed. After investigation, we found that this attribute is not an attribute that requires special control to disallow from changes. The value of this attribute can be changed from time to time.

Besides, the attribute "cls" in table "classes" is undeletable. It is also possible that some attributes are not allowed to be deleted, but it is not the case for this attribute either.

Hence, additional functions should be added to the application to enable the users to modify or delete the values of the two attributes.

- *Redundant*

If the data lifecycle support information provided for an attribute or table in a database application is classified as redundant, a developer should examine whether it is really needed for the application. This may lead to the introduction of additional programs to use it or removal of unnecessary attribute or table.

As can be seen from Table III, the attribute "reasonofrej" in table "admission" is redundant for it is never used. According to this information, developers can decide either to add functions that use this attribute, or remove it and its other operations correspondingly.

- *Reserved*

If the data lifecycle support information provided for an attribute or table in a database application is reserved, a developer can decide whether he still wants to retain the reserved attribute/table.

From Table III, we learnt that attribute "empid" in table "emp" is reserved. Also from Table IV that, tables "assign", "rght" and "rolerght" are reserved. This is resulted from that there is not any operation on them. Consequently, whether to delete the attribute or tables from the schema depends on the real adaptation and developers. We found that these tables could be retained because the system is not fully developed yet and further enhancement and extension could be made.

As the above cases demonstrated, data lifecycle information reveals overall status and defect or incompleteness of implementation. Problems with the code could thus be located more easily and quickly. Since software maintenance could often be costly and time-consuming, especially when a new developer tries to have a broad picture of the existing system, data lifecycle can thus be a cost-effective facilitation for the maintenance process.

3) Verification

Software verification seeks to provide objective evidence that the design outputs of a particular phase of the software development life cycle meet the specification for that phase. When development reaches a stage, e.g. a milestone, developer would like to check the correctness of the specified programs in that stage. We show a simple example to demonstrate the use of data lifecycle in database application verification.

TABLE V. DATA LIFECYCLE OF ATTRIBUTE IN LAMP SCHOOL

Attribute	Table	S	U	I	D	Category
idalunno	alunni	T	F	F	T	Undefined
idcattedra	cattedre	T	F	F	T	Undefined

As is shown in Table V, the attribute "idalunno" in table "alunni" is undefined, i.e. there is no insertion operation for it. However, in the source code file "alu_conf.php", we found the following SQL query:

```
"SELECT * FROM alunni WHERE idalunno='$c'"
```

It can be seen that the attribute "idalunno" in table "alunni" is used as the condition in WHERE clause. However, since its value has never been defined, the result of this selection would be always empty and thus this operation would be inappropriate. This indicates design flaws or incompleteness of implementation against the original design.

Besides, there is another SQL query in a different source code file "del_cat.php" shows the same flaw:

```
"DELETE  FROM cattedre WHERE (idcattedra=
$_GET[idcl])"
```

The cases above are only two similar flaws example among all in the source code files. Data lifecycle support helps expose

such flaws with straightforward information. Reviews can thus be conducted to draw these problems.

V. Related Work

Software reverse engineering plays a critical important role in many aspects such as software maintenance and software comprehension. Over the past decades, a large number of studies have been conducted and quite a number of tools have been developed. In [1], Elliot J. Chikofsky and James H. Cross II et al provided taxonomy of software reverse engineering, in which six definitions of terms were given. Bellay and Gall reported an evaluation of four reverse engineering tools that analyze C source code [5]. They used a number of assessment criteria derived from Brown and Wallnau's Technology Delta Framework [6].

Reverse engineering has long been employed in software maintenance process. Rainer Koschke surveyed software visualization in software maintenance, reverse engineering and re-engineering in [7], where several representations for both software and specification were described. H. A. Müller presented using reverse engineering approach to aid subsystem identification, which could be used to provide better understanding and maintenance of a large software system [8]. P. Benedusi et al showed the use of hierarchical data flow diagrams in reverse engineering for software maintenance [9]. They focused on methodology at different levels of abstraction. Roger H. L. Chiang et al proposed extraction of ERR model from a relational database through data schema and data instance analysis [10]. However, we focus on extraction of data lifecycle from source code analysis.

Reverse engineering can also be used to enhance the understanding of software systems, and better understanding can result in better maintenance. S. Rugaber gave introductions of methodology, representation and tools in this area of research [11]. In [12], the authors described the results of the use of Rigi project in reverse engineering, which builds mental models from the discovered abstractions. Eleni Stroulia employed dynamic behavior analysis in reverse engineering to understand the system's process and uses [13]. Instead, our approach uses static analysis. J. Henrard et al described techniques in database reverse engineering [14]. However, they focused on generic methodology for construction of representation from different patterns, while our approach focuses on data lifecycle usages.

VI. Conclusion

Though the proposed approach is simple and useful, to the best of our knowledge, no such approach has been proposed in the literature. For a database application, there are four database operations supporting the data lifecycle: INSERT, UPDATE, SELECT and DELETE. We classify the possible sixteen combinations from these four operation types into six categories. We propose an approach to reverse engineer the data lifecycle automatically from the source code of the database applications. To verify the proposed approach, we developed a tool for PHP database applications and conducted case studies to evaluate the proposed approach using the tool.

The first benefit of our approach is the automatic data lifecycle extraction can lighten the burden of analyzing the code manually when the users try to understand the systems' database usage and behavior. Users can infer design flaws and completeness of the database from the extracted data lifecycle support directly. Secondly, the straightforward information provided by our approach can facilitate the selection, maintenance and verification of database applications.

Acknowledgment

We would like to take this opportunity to express our thanks to the developers of Pixy for releasing their tool as open source software, which helps a lot in our prototype tool development.

Abstract— **Quality requirements can constrain many aspects of a software system and have a strong influence on its success. Therefore, they play a major role in the development of any software system. As software systems are designed to achieve various goals and perform different functions, the order of importance of quality requirements may vary depending on these goals and functions. Within this context, this paper aims to gain new insights into how industry deals with quality requirements. More specifically, its purpose is to analyze the importance of different types of quality requirements. An empirical study has been performed in order to determine practitioners' perspectives on this issue. The paper reports on a survey in which product managers, project leaders and programmers with different backgrounds have participated. Consequently, the paper provides further evidence about the perceived importance of types of quality requirements and how the importance may be different depending on the practitioners' roles, the types of project, the orders of magnitude of the requirements or the application domains.**

Keywords- requirements engineering, empirical study, survey, quality requirement, non-functional requirement, industry.

I. INTRODUCTION

The requirements of a software system can be considered the main indicators of its success [16] and of its quality [10]. As a result, the requirements engineering (RE) process has been widely recognized as the most important development stage. Not adequately addressing it can lead a software system to failure and increase its development time and cost [7].

Among the types of requirements for a software system [14], quality (aka non-functional) requirements (QRs) specify restrictions on a software system and how well it shall perform its functions. Some typical examples of types of QRs are usability, performance and security. The influence of these requirements on the success of a software system has been acknowledged both in academia [5] and in industry. Organizations can face many problems when dealing with QRs [4], and they can strongly constrain decisions related to important aspects of the development of a software system such as its architecture [23], planning [19] and evolution [8].

An important issue about QRs is that the importance of the types of QRs is not always the same. For example, it can vary among stakeholders' roles [11], types of project [2] and application domains [8]. If practitioners disregard this issue, then they may develop software systems whose quality is insufficient and/or does not meet the actual needs of its stakeholders. As a consequence, a project or a system may fail.

This paper aims to gain new insights into the importance of QRs in industry. For this purpose, an empirical study in the form of a questionnaire-based survey is presented. 31 practitioners from 25 organizations participated in the survey and determined the most important types of QRs for them and the rationale behind their decisions. The respondents also indicated their role, the types of project in which they participate, and the order of magnitude of the requirements [20] and the application domain of the projects.

The results of the study provide novel empirical evidence about the perceived importance of types of QRs in industry and how it may vary. Results are presented and analyzed for: a) product managers, project leaders and programmers; b) development of internal, contract-driven and market-driven software; c) small, medium and large-scale RE, and; d) public administration, telecommunications and software development application domains. The value of the results is twofold. First, they can help practitioners to determine the types of QRs that may be more important for a given software system and possible conflicting priorities on the QRs. Second, they can be very useful for academia to formulate hypotheses for new studies and to identify areas for further research.

The paper is organized as follows. Section II presents background and related work. Section III explains the research methodology that was followed. Section IV presents and discusses the results of the study. Finally, Section V summarizes our conclusions and future work.

II. BACKGROUND AND RELATED WORK

Gaining insights into RE practice has been and is an important goal for the RE research community [17], and empirical studies are essential to achieve it. Important contributions have been made up to date, but more studies are necessary yet. The first significant empirical study on RE practice [6] was published in 1988. Since then, many issues of RE in industry have been analyzed, including QRs.

This work has been developed with the support of the Spanish Government under the project PROS-Req TIN2010-19130-C02-02 and the program FPU AP2006-02324, the Valencia Regional Government under the project ORCA PROMETEO/2009/015, and ERDF.

Several facets of QRs such as elicitation, dependencies, metrics, cost estimation and prioritization have been addressed in empirical studies. A systematic literature review on them is presented in [3]. Among the studies listed in the systematic review and others published after the search of the systematic literature review was performed, we have found publications that addressed priorization and/or focused on the importance of types of QRs in industry. These works are the following ones.

Haigh [11] performed the existing survey with the largest sample. 318 students and alumni of a MBA ranked the importance of types of QRs on the most important software system in developing their work responsibilities. The factors analyzed were the stakeholders' role and the type of system. In a similar line, Berntsson Svensson et al. [2] examined how QRs of embedded systems were handled. They interviewed product managers and project leaders from five organizations, and analyzed the importance, interdependencies, quantification, dismissal, challenges and non-challenges of QRs.

Leung [15] conducted a user survey on QRs of intranet applications for which he obtained 30 valid responses. Another study on specific products was presented in [22]. A process framework for customization of software quality models was proposed and validated with two software products. The importance of types of QRs in the products was determined.

A survey with respect to cost and lead-time impact in development of software platforms is presented in [12]. This study analyzed 34 responses from two organizations and addressed the architect, system designer and marketing roles. Ameller and Franch [1] also analyzed QR-related practices of architects. 60 subjects participated in a web survey, and they indicated the importance of types of QRs in their projects.

Finally, Ernst and Mylopoulos [9] studied the importance of QRs along project lifecycle and the interest on them in different projects. They analyzed mailing list discussions, bug reports and commit logs of eight open-source products.

The contribution of this paper on understanding the perceived importance of QRs in relation to these works are that 1) it provides new insights about factors and treatments that have been studied previously (e.g., importance for project leaders), and 2) analyzes factors and treatments that have never been addressed (e.g., order of magnitude of requirements and software for public administration). With regard to the results of these works about common factors, they are used in Section IV for comparison with the results of this paper.

III. Research Methodology

The empirical study that is presented corresponds to a part of a survey on RE practices and perspectives in industry (hereafter referred to as wider survey). It was performed using a mixed research approach [21], i.e., there are parts of the study that correspond to quantitative (fixed) research whereas others correspond to qualitative (flexible) research.

On the one hand, some parts of the study and its analysis were pre-specified, e.g., overall rating of the importance of the types of QRs on the basis of the percentage of respondents that selected the types. These parts aimed to obtain quantitative data for comparison of variables and corresponded to the fixed side of the study. On the other hand, analysis of other parts evolved during the research process, e.g., analysis of some factors was not initially intended but was later decided. In addition, we aimed to investigate and understand phenomena within its real context and to seek new insights, ideas and possible hypotheses for future research. These conditions allowed us to regard the study as qualitative [18].

The following two subsections present the research process that was performed and discuss the validity of the survey.

A. Research Process

The study was performed through 6 stages [13].

Objectives definition: The first stage of the study involved brainstorming and meetings to identify the areas of interest. Of all the objectives of the wider survey, this paper addresses further understanding of the importance of QRs in industry. The research questions analyzed are: **RQ1:** What types of quality requirements are considered the most important ones by practitioners? **RQ2:** Is there any difference in the perspectives about their importance among roles, types of project, orders of magnitudes of the requirements or application domains?

Survey design: The survey was cross sectional [13] and explorative [25], and was administered by means of a web-based self-completion questionnaire. As explained above, a mixed approach was followed.

Development of a survey instrument: Relevant literature has been presented in Section II. The survey instrument was created with inspiration from [2]. We defined 21 types of QRs on the basis of Lauesen's comparison between ISO 9126 and McCall quality factors [14]. In addition to background information (about the possible factors and treatments to analyze), respondents were asked to indicate 1) the top five most important types of QRs, 2) the most important type, and 3) why they regarded that type as the most important one. Before listing the questions, a description of the survey was provided. It must also be indicated that more questions were asked for the wider survey.

Since the first and the fourth authors were initially responsible for data collection, it was expected that most of the respondents worked in Spain. Nonetheless, it was also planned to obtain responses from other countries. As a result, a Spanish version and an English version[1] of the (same) questionnaire were created. The expected time for completing the questionnaire (wider survey) was between 10 and 15 minutes.

Instrument evaluation: Four pilot studies were conducted for pre-testing, two for each version of the questionnaire. Time for completion was within our expectations, and some minor changes were made in question wording.

Data collection: Respondents were selected through a combination of maximum variation, convenience and snowball sampling [18] within our industrial collaboration network. We mainly aimed to obtain responses from product managers, project leaders and programmers of different organizations,

TABLE I. SUMMARY OF RESPONSES AND RESULTS

Factor	Treatment	n	Top 5 types			#1 type	
			SEL	N_SEL	J_SEL	SEL	J_SEL
Role	Product manager	6	PERF (1), USAB (2), STAB (2)	MAIN	-	-	-
	Project leader	14	USAB (1), MAIN (2), SUIT (3) FLEX (3), SECU (5)	-	-	SUIT (1), USAB (2)	SUIT
	Programmer	11	MAIN (1), PERF (2), USAB (2)	-	-	-	-
Type of project	Internal software	6	MAIN (1), USAB (2), RELI (2), SUIT (2)	STAB	-	-	-
	Contract-driven	9	MAIN (1), USAB (2), PERF (3), CORR (4)	-	-	-	-
	Market-driven	10	PERF (1), USAB (1), RECO (3), RELI (3)	-	RECO	USAB (1)	-
Order of magnitude	Small	11	MAIN (1), USAB (2), PERF (3), FLEX (4)	-	-	USAB(1)	-
	Medium	8	USAB (1), MAIN (2), RELI (2)	-	ANAZ	MAIN (1)	MAIN
	Large	7	USAB (1), MAIN (1), PERF (3), SECU (4)	-	-	-	-
Application domain	Public admin.	9	USAB (1), MAIN (2), RELI (3)	-	CORR	-	-
	Telecom.	4	PERF (1), FAUL (2)	-	-	-	-
	Sw. development	4	USAB (1)	-	-	-	-

Types of QRs: analyzability (ANAZ), correctness (CORR), fault tolerance (FAUL), flexibility (FLEX), maintainability (MAIN), performance (PERF), recoverability (RECO), reliability (RELI), security (SECU), stability (STAB), suitability (SUIT), usability (USAB).

Perspectives: selected in the treatment (SEL), not selected just in that treatment of the factor (N_SEL), just selected in that treatment of the factor (J_SEL).

thus we focused on potential respondents' role for sampling. The role was the only treatment for the people contacted that we knew for all of them before analysis. They worked for regional, national and multinational organizations.

Analysis: This stage was performed by the first and the fourth author. 35 responses were obtained, but four were rejected because of inconsistent or lack of information. One was modified because the respondent indicated software testing as application domain ("other" option), which was considered to be part of software development. Therefore, we finally analyzed 31 valid responses (data points), 22 from the Spanish version of the questionnaire and 9 from the English one. The respondents worked for 25 different organizations[2]. Three responses from two organizations, two from two organizations and one from the rest of organizations were obtained. One respondent worked for several organizations, but it was regarded as a single organization for analysis.

After overall rating of the types of QRs, partition of responses involved determination of the factors (e.g., respondents' role), treatments of the factors (e.g., project leader) and perspectives in a treatment (e.g., usability is a top five type) that should be reported and thus analyzed according to the scope of the paper. Some criteria for determination of results to report and analyze were defined (Table II).

Criteria for respondent's perspectives aimed to determine selections and no selections of perspectives to analyze. P1 is related to the importance of a perspective in a treatment in general. P2 is related to the non-importance of a perspective in comparison to other treatments of a factor, and P3 in comparison to other perspectives of a treatment. P4 is related to the importance of a perspective just for a treatment. T1 and T2 aimed to determine the treatments to analyze, and F1 to determine the factors. These criteria apply to the whole questionnaire. Some extra ones for analysis and report of specific questions are described in Section IV.

Table I shows a summary of the data points (n) of the treatments (twelve) of each factor (four) that was considered for analysis. Most of the factors had less than 31 data points due to answer exclusions, i.e., the rest of data points until 31 correspond to answers that were not part of any of the treatments defined. Finally, it must be indicated that statistical tests [25] were not used for analysis. We did not use probabilistic sampling methods, thus statistical inferences could be made in the survey [13].

TABLE II. CRITERIA FOR DETERMINATION OF RESULTS TO ANALYZE

Criterion	Description
T1	A treatments is not analyzed if it has less than four data points (less than 10% of the sample)
P1	A perspective in a treatment that fulfils T1 is analyzed if at least three participants of the treatment (75% of the smallest sample for a treatment) selected the perspective
P2	A perspective in a treatment that fulfils T1 is analyzed if no participant selected the perspective but P1 is fulfilled in the perspective for all the other treatments of the same factor
P3	A perspective in a treatment that fulfils T1is analyzed if no participant selected the perspective but P1 is fulfilled in all the other perspectives of the same treatment
P4	A perspective in a treatment that fulfils T1 is analyzed if it fulfills P1 and P1 is not fulfilled in the perspective for all the other treatments of the same factor
T2	A treatment that fulfils T1 is not analyzed if it does not have any perspective that fulfils P1, P2, P3 or P4
F1	A factor is not analyzed if it all its treatments fulfill T1 or T2

B. *Validity*

This section discusses how threats to validity were addressed. We consider the four perspectives proposed in [25].

Construct validity: This validity is concerned with the relationship between a theory and its observation. Mono-operation bias was avoided by collecting data from respondents with different backgrounds, and evaluation apprehension by guaranteeing anonymity and confidentiality when publishing the results. A remaining validity threat was the provision of lists for determination of background information and selection of types of QRs. It may have been easier for respondents to use the list items provided than to propose others.

Conclusion validity: This validity is concerned with the relationship between a treatment and the conclusions drawn from it. For reliability of measures, pilot studies were

[2] Although identification of respondents' organization is not necessary for analysis in this paper, it is for some parts of the wider survey.

conducted and all the types of QRs and concepts that may have been unknown to the respondents (e.g., small-scale RE) were briefly described in the questionnaire. Reliability of treatment implementation was achieved by providing the same questionnaire to all respondents. We also consider that the criteria defined for analysis increased the possibility to draw correct conclusions. A remaining validity threat is the fact that the treatments determined for each factor have different data points. The influence of this fact on overall rating of the types of QRs is further discussed in Section IV.

Internal validity: This validity is concerned with the causal relationship between a treatment and its results. Maturation was addressed by designing an instrument whose completion should take between 10 and 15 minutes. Pilot studies and development of the questionnaire with close reference to literature and influence of an administered and validated existing instrument reduced instrumentation threats.

External validity: This validity is concerned with the generalization of the conclusions. Given the exploratory and qualitative nature of the study, it does not aim to generalize conclusions beyond its actual setting, but to explain and understand the phenomena under analysis. Nonetheless, understanding the phenomena may help in understanding other cases. Interaction of selection and treatment was avoided by just contacting product managers, product leaders and programmers for data collection. In addition, many results and conclusions coincide with the studies outlined in Section II.

IV. Results and Interpretation

This section describes and discusses the results of the study. They have been divided into selection of the set of top five types of QRs and selection of the most important type.

A. Top Five Types of QRs

This section presents the results that were obtained when respondents selected the top five types of QRs for them. When reporting the results (in Table I and in the text), the ranking of the types is put in brackets. The ranking was determined by ordering the types of QRs on the basis of the percentage of respondents that selected them. It must be noted that the respondents did not rank the types when selecting the top five ones, but just selected the five types of QRs that according to them were the most important ones.

Figure 1 shows the overall rating of the types of QRs as top five types in the survey. Usability (1), maintainability (2), performance (3), reliability (4) and flexibility (4) are the five types with the highest overall frequencies. Therefore, they are the overall top five types of QRs in the survey.

The number of times that these types were selected as top five in the twelve treatments is: eleven times for usability, nine for maintainability, seven for performance, four for reliability, and two for flexibility. This order is equal to the overall rating except for flexibility. Just security (sixth type) and suitability (eighth type) were selected the same number of times (two treatments in total) than some of the overall top five types. Therefore, we consider that the threat related to not having balanced data points did not strongly affect the overall rating.

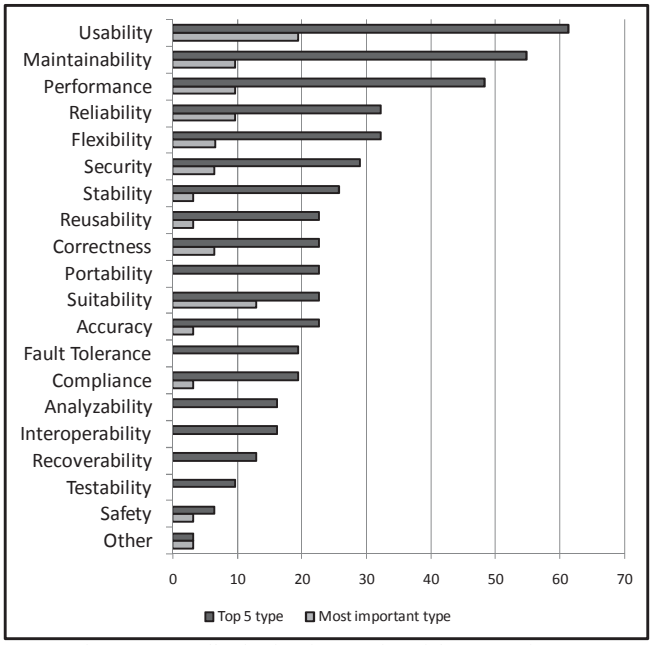

Figure 1. Overall selection frequencies of the types of QRs.

No respondent selected installabilty or replaceability, and one selected the "other" option. He specified *"hard core performance (speed and uptime, 99.999)"*, what we consider a specialization and combination of performance and reliability. This indicates that the types of QRs used in the survey can be combined when specifying requirements, and suggests that a clear cut between the types may not always exist in industry.

The overall rating is in line with related work. The most different results were the high ranking of accuracy and the low rankings of performance and flexibility in [11], and the low ranking of usability in [12]. The focus on software systems that respondents used and software platforms, respectively, may be the reasons. The results of [15] have not been considered for comparison because it just studied users' perspectives.

Table I shows a summary of the results for the treatments of each factor. The "SEL" column corresponds to perspectives that fulfill the criterion P1 (see Section III), the "N_SEL" column to perspectives that fulfill P2, and the "J_SEL" column to perspectives that fulfill P4. Less than five types of QRs are reported if P1 is not fulfilled (e.g., just one respondent selected the fifth type) or if more than five types should be reported (e.g., the fourth and seventh types have the same frequency).

When analyzing respondents' role, we can see that usability is a top five type for the three roles, and performance and maintainability for two. The difference in the selection of other types of QRs indicates that perspectives may vary among stakeholders. In relation to related work, performance, usability and stability were top five types of QRs for product managers in [2], and usability, maintainability and flexibility were for project leaders. In [11], maintainability and usability were top five types for developers, and maintainability and stability were for managers of development. The most different result is that no project leader selected suitability in [2].

For types of project, again just usability is ranked as a top five type for all the types of project, whereas maintainability,

performance and reliability are for two. Four types of QRs are top five types in several types of project, thus it seems that there is less variation in this factor than in others. Nonetheless, this factor is the only one in which the criteria P2 and P4 are fulfilled. The high importance of usability, performance and reliability for market-driven development was reported in [2][9][12]. However, recoverability was lowly ranked in [2].

With regard to the order of magnitude, maintainability and usability are top five types in all the scales, and performance is in two. The impact of the order of magnitude of requirements on the importance of QRs has not been previously analyzed. Therefore, no comparison is possible. Nonetheless, we think that the results suggest that it is a factor that can have influence, although the coincidences in perspectives may indicate that the influence of the factor is lower than of others.

Concerning specific application domains, we can see that just usability is a top five type for more than one domain. This is the factor with the lowest number of coincidences between treatments. Although the low number of data points of the treatments and of perspectives reported affects them, the results suggest that this factor has a higher influence on the variation of the importance than others. The importance of performance and fault tolerance in telecommunications was acknowledged in [8], and usability was reported as a top five type of QRs for development tools in [11].

In summary, the results provide new evidence about the fact that some types of QRs are more important than others in industry and that their importance can vary depending on stakeholders' roles, types of project, orders of magnitude of requirements and application domains. It also seems that some factors may have more influence on variation than others, and that the types of QRs used in the survey can be combined for specification. Finally, many hypotheses can be formulated from these results and could be tested in new studies. For example, that the importance of recoverability is higher in market-driven development than in other types of project.

B. Most Important Type of QRs

This section presents the results that were obtained when respondents were asked to select the type of QRs that was the most important one for them and to justify the selection. The first question allowed us to further analyze the results about the top five types, whereas the second one allowed us to gain new insights into the perceived importance of QRs.

Figure 1 shows the overall selection frequency of the types of QRs as the most important one. Usability (1), suitability (2), maintainability (3), performance (3) and reliability (3) are the types most frequently selected. This result is very similar to the overall rating of the types of QRs as top five types. The main difference is the presence of suitability. Further analysis of this fact shows that more than half the respondents that selected suitability as a top five type also selected it as the most important one. No other type has reached such a high frequency as most important type in relation to its selection as a top five type (if the "other" option is not considered). This suggests that when practitioners care about suitability, it is usually really important for them.

Table I shows a summary of the results. They further indicate the importance of suitability for project leaders and of usability in general. Usability is the only type that is ranked as the most important type of QRs and whose selection is reported for several treatments. With regard to the result about maintainability, we consider that it may need further study.

Maintainability was highly ranked in all the orders of magnitude of requirements when asking the top five types, but its selection as the most important type just in medium-scale RE suggests that the type is more important in that scale. This may have happened because of different reasons. For example, it may be thought that organizations that deal with large-scale RE need (and thus have) more mature software development processes, which impose execution of practices targeted at facilitating maintainability. Once these practices have been introduced, maintainability may be easier and consequently its perceived importance may decrease. Although important, the type would not be the most important one.

When reviewing the reasons behind selection of the most important type of QR, we realized that answers could be divided into three categories: product, project and customer-oriented. An example of product-oriented answer is *"flexibility is necessary for adaptation of a product to new use cases"*, of project-oriented answer is *"highly confidential data are managed in the projects"*, and of customer-oriented answer is *"security is the main point that clients demand"*. This division allowed us to perform two analyses that had not been planned and have not been addressed in any previous publication.

First, we analyzed the frequencies of the categories. Customer-oriented answers are the most frequent ones (at least half the answers had this orientation) for project leaders, market-driven development and small-scale RE, whereas product-oriented answers are for medium-scale RE. No product manager gave a project-oriented answer, and the perspective fulfilled the criteria P2 and P3. Finally, no product-oriented answer was obtained from small-scale RE and the perspective fulfilled P3. This analysis indicates that focus on products, projects or customers when dealing with QRs may vary depending on some factors.

Second, we realized that another analysis was possible. On the basis of existing works [24], we classified the types of QRs selected as the most important one into more important for users (customer-related) and more important for developers (development-related). Maintainability, flexibility, stability and reusability were considered development-related types of QRs, and the rest of types selected as the most important one were considered customer-related types.

Figure 2 shows the theoretical and actual frequencies of customer-related and development-related answers. The theoretical one was calculated on the basis of the previous classification and the selection frequency of the types of QRs as the most important one, whereas the actual one was calculated on the basis of the frequency of the categories of justification answers. The actual frequency of development-related answers was considered to be the sum of the frequencies of product-oriented and project-oriented answers, i.e., we considered that product-oriented and project-oriented answers were development-related.

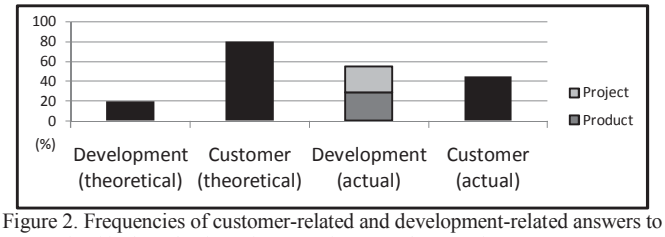

Figure 2. Frequencies of customer-related and development-related answers to justify the selection of a type of QRs as the most important one

Although the actual frequency of customer-related answers is the highest one in the survey, it is lower than in theory. This result suggests that there is a gap between theory and practice on the importance of types of QRs for customers or for development. Difference in the perception of types between academia and industry was discussed in [2], although not in relation to their importance for development and customers.

In summary, the results are in line with those from top five types of QRs. An exception is suitability, whose importance seems to be especially high for the practitioners that focus on it, and maintainability seems to be more important for medium-scale RE. The results also suggest that product, project and customer orientation when considering a type as the most important one may vary, and that there is a difference on this issue between theory and practice. Again, hypotheses can be formulated, such as that market-driven development mainly focuses on customers when prioritizing QRs.

V. CONCLUSIONS

This paper has presented an empirical study on QRs in industry. By means of a questionnaire-based explorative survey, practitioners' perspectives on the importance of types of QRs were obtained.

The results of the survey provide more and new evidence about how the importance of QRs may vary in industry. In general, usability, maintainability and performance are the three most important types for product managers, project leaders and programmers. Nonetheless, the importance of all the types may vary depending on different factors. Among them, evidence of variation has been provided for practitioners' roles, types of project, orders of magnitude of the requirements and application domains. In addition, although practitioners usually think of customer issues when selecting a type of QRs as the most important one, they may also think of development issues even when dealing with customer-related types.

The most immediate future work is to analyze the answers to the rest of questions of the wider survey. New empirical studies would also allow us to gain more insights into the importance of QRs in industry. These studies should aim to test hypotheses formulated from the results of this paper or to further analyze some phenomena by means of different empirical studies. For example, case studies would allow us to analyze the importance of QRs in project development settings.

ACKNOWLEDGMENT

The authors would like to thank all the people that participated and collaborated in the study, and Jose Ignacio Panach and Jose Luis Hervás for their comments on analysis.

***Abstract*—The classification of NFRs brings about the benefits that NFRs with respect to the same type in the system can be considered and implemented aggregately by developers, and as a result be verified by quality assurers assigned for the type. This paper conducts an empirical study on using text mining techniques to classify NFRs automatically. Three kinds of index terms, which are at different levels of linguistical semantics, as N-grams, individual words, and multi-word expressions (MWE), are used in representation of NFRs. Then, SVM (Support Vector Machine) with linear kernel is used as the classifier. We collected a data set from PROMISE web site for experimentation in this empirical study. The experiments show that index term as individual words with Boolean weighting outperforms the other two index terms. When MWEs are used to enhance representation of individual words, there is no significant improvement on classification performance. Automatic classification produces better performance on categories of large sizes than that on categories of small sizes. It can be drawn from the experimental results that for automatic classification of NFRs, individual words are the best index terms in text representation of short NFRs' description and we should collect as many as possible NFRs of software system.**

***Keywords*—Non-Functional Requirements, Automatic Classification, Support Vector Machine.**

I. Introduction

Non-functional requirements (NFRs) describe the expected qualities of a software system such as usability, security and look and feel of user interface. These qualities do impact on the architectural design of the software system [1] and satisfaction of stakeholders relevant with the software system [2] [3] [4]. NFRs are put forward by stakeholders with no expertise in software engineering and the number of NFRs is often very large. Moreover, NFRs are scattered over the functional requirements and the types of the NFRs are unknown because they are written in natural language. These charateriestics of NFRs make its classification a labor-intensive and time-consuming job without the adoption of automatic techniques. Nevertheless, software developers cannot ignore NFRs because they are decisive on the success of the software system.

Compared with functional requirement, NFRs tend to be properties of a system as whole, and hence cannot be verified for individual components or modules [19] [23]. This makes the classification of NFRs necessary in development because , on the one hand,we need to handle NFRs in a different way from functional requirements and, different types of NFRs should be handled by developers with different expertise.

For instance, in a security critical, mission critical, or economy vital software systems, formal method with model checking of the correctness of specification on system security is used to determine whether or not the ongoing behavior holds of the system's structure. However, a serious (and obvious) drawback of model checking is the state explosion problem because the size of the global state graph is (at least) exponential in the size of the program text [21]. Thus, an exigent demand from system developers is to identify the security-related NFRs from the requirement document and express them using formal specifications, and then to conduct verification of the satisfaction of system's properties on those security specifications.

On the other hand, the classification of NFRs benefits an overall decision on the systems' satisfaction on each category of NFRs and the progress of system development developers have made. Functional requirements can be measured as either satisfied or not satisfied, but NFRs can not merely measured by a linear scale as degree of satisfaction [25]. In system testing, for example, we can customize our test strategy based on the classification of NFRs and thus system behaviors of NFRs were reported directly to the project manager.

Most, if not all, projects have resource limitations and time constraints, with different requirements having different concerns of software systems. Even after the requirements are elicited and collected, they are still just an unorganized set of data. As such, it is necessary to categorize the requirements into different types so as to match problems and solutions in separate domain of discourse, especially for large-scale software projects with hundreds or even thousands of requirements.

In human resource allocation and optimization [22], different developers possess different expertise in handling various aspects of software development. Different tasks in development may need different expertise and capability from the developers. Thus, a match of developers and tasks is at the core of the success of software development. The identification of different types of NFRs results in the formation of different types of development tasks. Consequently, those tasks are assigned to developers aggregately according to their expertise and capability level. For instance, the NFRs with "performance" type and the NFRs with "maintainability" type should be dealt with by developers with different expertise.

We forward NFRs of the type "look and feel" to UI (User Interface) design experts of the system so that the satisfaction of these NFRs can be ensured throughout the whole system.

Methods for the elicitation of NFRs include questionnaires, checklists and templates for inquiring stakeholders concerning quality issues [24]. Basically, NFRs are made of textual sentences whose contents concern the expected qualities of a software system. For instance, "*The application shall match the color of the schema set forth by Department of Homeland Security. LF*" is a typical NFR record fetched out from the data set and it comprises two parts: textual description and NFR type as "*LF*". The description of NFR is very simple and easy to understand. It does not need professional knowledge of engineering aspects. Thus, text mining, which combines both natural language processing (NLP) and statistical machine learning, can be used for the task of automatic classification of NFRs.

Although there is substantial literature on NFR classification [2] [4] [5] [17] , we find two problems. First, most methods are purely intuitive and derived without theoretical support or mathematical model. Also, some methods are extremely labor-intensive and time-consuming, and others are qualitative, without quantitative analysis. Second, the index terms used in existing automatic classification of NFRs are keywords extracted directly from requirements without feature selection. This would cause huge dimensionality of NFR vectors and consequently bring about huge computation when quantitative methods are used. Most importance, we are uncertain that other index terms than keywords are more appropriate for automatic classification of NFRs.

The questions devised for this empirical study are: 1) among existing indexing methods, which one is the best performance for automatic classification of NFRs, and 2) is it possible to produce better performance with SVM than those derived in previous work?

The remainder of this paper is organized as follows. Section 2 describes the research approach employed in this paper. Section 3 conducts experiments of using SVM and different index terms to classify NFRs. Section 4 present the related work and Section 5 concludes this paper.

II. Research Approach

The research approach adopted in the empirical study is shown in Figure 1 to automate the classification of NFRs. First, NFRs' textual description are represented using different types of index terms as N-grams, individual words, and MWEs, respectively. Then, we transfer NFR textual description into numerical vectors in different feature space determined by different types of index terms. Second, support vector machine (SVM), which is a popular classifier in machine learning [6] [9], is used to classify NFR vectors. Finally, performance of each classification is evaluated.

A. Index Terms

The requirement data set we collected from the PROMISE web site (http://promisedata.org/repository) and it contains 625 records of both functional and non-functional requirements.

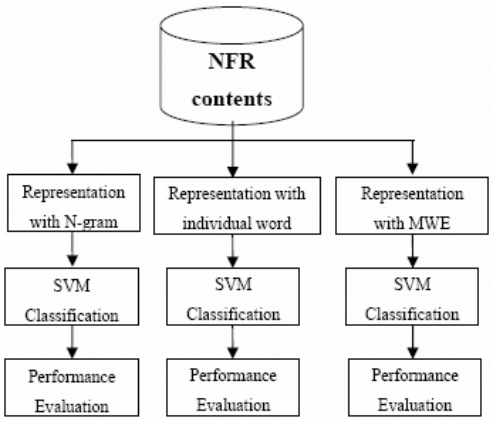

Fig. 1. Procedures of automatic classification of NFRs.

N-gram Representation. N-gram is proposed in text mining to categorize documents with textual errors such as spelling and grammatical errors, and it has been proved as an effective technique to handle these kinds of errors [7]. An N-gram is an N-character contiguous fragment of a long string. Since every string is decomposed into small fragments, any errors that are present in words only affect a limited number of those fragments. If we measure the similarity of two strings based on their N-grams, we will find that their similarity is immune to most textual errors. We used bi-gram (344 2-grams) and tri-gram (1,295 3-grams) for representation of NFRs, respectively.

Word Representation. The method of using individual words of a text content to represent the text can be traced to Salton et al[10]. We follow this idea to use words in NFRs for representation. First, we eliminated stop words from NFRs' description [1]. Second, word stemming [2] was conducted to map word variants to the same stem. We set the minimum length of a stem as 2. That is, only the stems which have more than 2 characters will be accepted as stems of words. Thus, 1,127 individual word stems are produced from the data set.

MWE Representation. We used the method proposed by Justeson and Katz [12] for MWE extraction from NFRs. The basic idea behind this method is that a MWE should include 2 to 6 individual words and it should occur in a collection of documents more than twice. Nevertheless, the part of speeches of individual words of a MWE should meet the regular expression described in formula 1.

$$((A \mid N)^{+} \mid (A \mid N)^{*}(NP)^{?}(A \mid N)^{*})N \qquad (1)$$

Here, *A* denotes an adjective, *N* denotes a noun and *P* denotes a preposition. Using the method adopted from [11], we extracted 93 MWEs from the data set.

[1]We obtain the stop words from http://ftp.uspto.gov/patft/help/stopword.htm

[2]we use Porter stemming algorithm that is available at http://tartarus.org/martin/PorterStemmer/

B. Feature Selection

In this paper, we adopt information gain (IG) [8], which is a classic method for feature selection in machine learning, to select informative index terms for automatic classification of NFRs. IG is defined as the expected reduction in entropy caused by partitioning NFRs according to a given term. The formula of IG is presented in Equation 2 and the formula of entropy is depicted in Equation 3.

$$Gain(S, A) = Entropy(S) - \sum_{v \in Value(A)} \frac{\mid S_v \mid}{\mid S \mid} Entropy(S_v) \tag{2}$$

$$Entropy(S) = \sum_{i=1}^{c} -p_i \log p_i \tag{3}$$

Here, *S* is the collection of the types of all NFRs such as PE (performance) and US (usability). *Value(A)* is a set of all possible values of index term *A*. S_v is a subset for which *A* value *v*, *c* is the number of categories of all NFRs, and p_i is the proportion of the NFRs that belong to category *i*. To observe the performances of textual features on automatic classification dynamically, the different feature sets of textual features are constructed at different removal percentages of low IG value terms (see also removal ratio in Section 3.2).

C. SVM Classifier

The classifier used for automatic classification is support vector machine (SVM) [6] [9], that is introduced in statistical machine learning. We selected this method in this paper because Gokyer et al [9] used it to transfer NFRs to architectural concerns and preferred effectiveness was achieved. In this paper, the linear kernel (u*v) is used for SVM training because it is superior to non-linear kernels for classifying textual contents validated by prior research [8] [13].

III. Experiment

A. Categories of the data set

Table 1 lists the categories of both functional and non-functional requirements in the data set and their numbers. Functional requirements occupy the largest proportion in the data set, amounting to 40.8% (255/625). Moreover, there is a skew distribution among the NFR categories in the data set. For instance, the largest category "usability" has 67 cases while the smallest category "Palm Operational" has only one case. We adopt binary classification in this paper because skew distribution often deteriorates the performance of multi-class classification [28] .

In binary classification, if the number of positive (negative) cases is much larger than the number of negative (positive) cases, the performance of automatic classification may be not convincing because of the biased distribution of data points. For example, if 90% cases in a data set are positive, then the accuracy of automatic classification should be greater than 90% if the classifier predicts all the data points with positive labels. For this reason, the categories "usability", "security", and "Look And Feel" with relatively medium sizes in the data set are used as the positive classes for binary classification one by one and meanwhile, the NFRs in remaining categories are used as negative classes.

TABLE I
Categories of requirements and their numbers in the data set

Abbr.	Full Name	Num
F	Functional	255
US	Usability	67
SE	Security	66
O	Operational	62
PE	Performance	54
LF	Look And Feel	38
A	Availability	21
SC	Scalability	21
MN	Maintainability	17
L	Legal	13
FT	Fitness	10
PO	Palm Operational	1

B. Classification Process

There are actually two kinds of work involved in representing textual contents: indexing and term weighting. Indexing is the job of assigning index terms for textual contents and term weighting is job of assigning weights to terms, to measure the importance of index terms in textual documents. We employ Boolean values as term weights for the index terms for the reason that most NFRs in the data set are very short and contain less than 20 index terms so they do not need complex weighting schemes such as those mentioned for document representation [15].

IG is employed to change the percentages of index terms used for representation. The removal ratio is predefined to remove the index terms with small entropy. For instance, if we set the removal ratio to 0.1 for representation with individual words, then a percentage of 90% of individual words with smaller entropy will be eliminated from the feature set and we only use the remaining 10% of individual words for the representation of NFRs. The purpose of varying different percentages of index terms for representation is that we want to observe the robustness of classification performances when the set of index terms become smaller and smaller. This is especially important for deciding which type of index terms should be used for representing NFRs when computation capacity is not enough to support large dimension of vectors in training classifier. In representation with MWEs, we use all the 1,127 individual words and a proportion, which is is defined by the removal ratio, of MWEs as the index terms.

The experiments in this paper are carried out with 10-fold cross-validation technique. In each experiment, we divide the whole data set (for both positive and negative classes) into 10 subsets. The 9 of 10 subsets are used for training and the remaining one subset is used for testing. We repeat the experiment 10 times and the performance of the classification is measured as average precision and recall [2] of the 10 repetitions.

C. Experimental Results

The outcome of our experiments shows that the precisions of all the automatic classification tasks are significantly higher than those of the classification approach proposed by Cleland-Huang et al [2]. Yet, the recalls of the automatic classifications in this paper are not comparable to the classification proposed by Cleland-Huang et al. We do not list the precisions and recalls produced in our experiments due to space limitation (Readers who have an interest in the precisions and recalls are welcome to ask the authors for more details).

We conjecture that the high recalls of the results of Cleland-Huang et al [2] can be attributed to the small size (within the range between 10 and 20) of index terms they employed in their experiments, which is much smaller than the sizes of index terms (within the range between 100 and 1,000) used in our experiments. When small size of index terms is used, larger number of NFRs is classified as relevant NFRs of the category. Consequently, more irrelevant NFRs will be misclassified as relevant. Considering an extreme case of classifying relevant NFRs with "Usability", if all the NFRs are regarded as relevant with "Usability", then the recall of automatic classification will be 100%. However, this classification result may be of less help for automating the task of classification. Thus, we argue that for automatic classification of NFRs, precision should be given more importance if recall is acceptable.

The F-measure [16] described in Equation 4 combines both precision and recall for performance evaluation. We used F-measure as the indicator for performance evaluation. In general, the larger the F-measure is, the better the classification result is. Here, for the purpose of comparison, we make out the F-measures of Cleland-Huang et al [2] as the baseline performance in the experiments.

$$F - measure = \frac{2 \times precision \times recall}{precision + recall} \quad (4)$$

Figures 2-4 show the experimental results of classifying the assigned three categories "Usability", "Security", and "Look And Feel" at different removal ratios using four types of index terms (2-gram, 3-gram, word and MWE) to represent NFRs.

First, it can be seen that the representation with individual words has the best performance measured by F-measure nearly on all three categories. In some cases, representation with terminologies improves the precision of automatic classification of representation with individual words (when the removal ratio arrives at 0.9). That is, even if most index terms are removed from the feature set, their performances do not decline drastically. However, in most cases, representation with terminologies is not able to improve the performances of automatic NFR classification compared with representation with individual words, even worse than that of 3-gram representation. Both representation with individual words and terminologies produce very robust classification.

This outcome implies that for automatic classification of NFRs, representation with individual words is sufficient to produce a desirable performance. This outcome is very different from the experimental results produced by Zhang et al

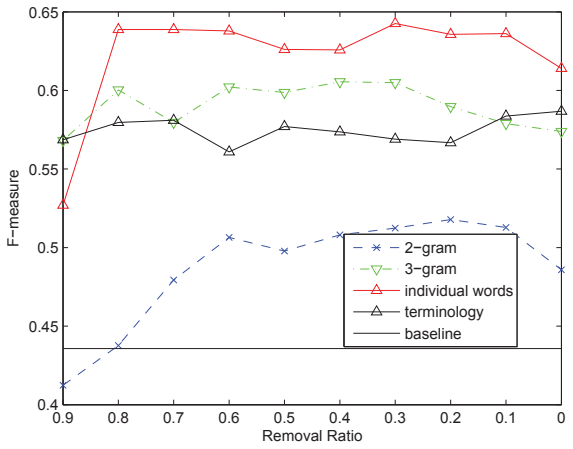

Fig. 2. Classification performances on category "Usability".

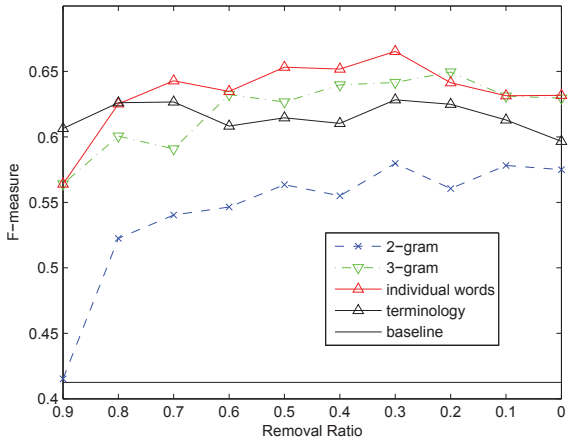

Fig. 3. Classification performances on category "Security".

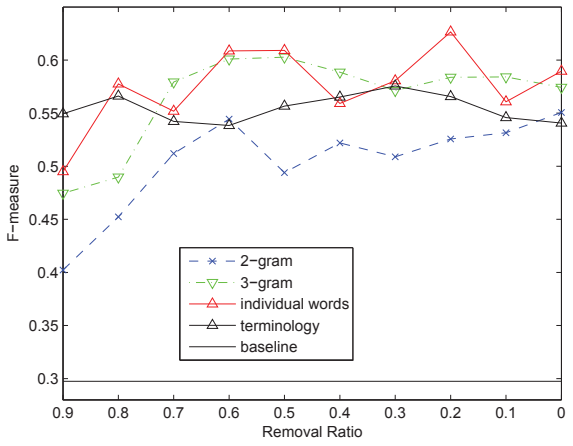

Fig. 4. Classification performances on category "Look And Feel".

[8]. They argued that MWEs are superior to individual words for classifying news documents automatically. We explain that the lengths of NFRs in the data set are much shorter (20 individual words on average) than those of Reuters-21578 news documents (80 individual words on average) so the semantics inherent in textual contents of NFRs is not so much important as those inherent in news documents.

Second, for representation with N-grams, representation with 3-grams outperforms that with 2-grams. This outcome can be attributed to that the number of 3-grams is much larger than that of 2-grams (see Section 2.1). Moreover, the robustness of the 3-gram representation is better than the 2-gram representation because the magnitudes of variations of F-measures of the 3-gram representation are smaller than those produced by the 2-gram representation.

Thirdly, for classification on different categories, the performance on "Security" is as almost the same as that on "Usability" but outperforms that on "Look And Feel". The number of NFRs in category "Security" (66) is approximately equal to that in category "Usability" (67), which is much larger than the number of "Look And Feel" (38). We explain that automatic classification would produce more favorable performance on categories those having large sizes than those having small sizes.

Based on the experimental results, the answer for question 1 devised for this case study in Section 1 should be that to date, keywords are the most effective index terms for automatic classification of NFRs and for question 2, our answer is that the machine learning technique, at least SVM, can improve the classification significantly.

IV. Related Work

NFR has attracted much interest of researchers from software engineering field. Much work has been invested in managing NFRs. Tran and Chung [20] proposed a prototype tool for explicit representation of NFRs. They aim to consider NFRs in a more goal-oriented perspective and argue that NFRs have much influence on the design of the solution as well as reinforce engineering process. In order to formulate implicit relationships of NFRs , ontology and graphic visualization are used in their tool to express softgoals and their interdependencies explicitly.

Cleland-Huang et al [4] introduce a goal-centric approach to managing the impact of change upon the NFRs of a software system. They partition NFRs into different softgoals of a system and construct a softgoal interdependency graph (SIG) to trace both direct and indirect impacts of software changes on NFRs. Probabilistic network model is employed to enable the traceability of impacts. However, the job of constructing SIG is labor-intensive and time-consuming because of the lack of automatic approaches. If we can classify NFRs into different softgoals automatically, it would be much easier to identify the relations between subgoals and softgoals. That is, human workload involved in constructing SIG will be reduced to a great extent.

In another work, Cleland-Huang, et al.[2] proposed an information retrieval method to discover and identify NFRs from system specification. Their basic assumption is that different types of NFRs are characterized by distinct keywords (index terms) that can be learned from documents of that type. However, their method of selecting index terms is ad-hoc and does not consider any linguistic properties of those index terms. Moreover, the classifier used in their method, which is based on the additive weights of index terms on a given NFR type, is quite simple without any theoretical ground.

Rosenhainer [14] proposed aspect mining to identify cross-cutting concerns in requirements specifications. Two techniques are suggested to be used for aspect mining: identification through inspection and identification supported by information retrieval (IR). The former one is manual and the later one is semi-automatic. Rosenhainer argued that IR-based technique is more promising than manual method and their experimental results on interactions between functional and non-functional requirements have validated this argument. This work encourages our study in this paper to use IR techniques for automatic classification of NFRs.

Casamayor et al [24] employed naïve Bayes and EM (Expectation Maximization) algorithm as a semi-supervised learning approach to classify non-functional requirements in textual specifications. They used the same data set as used in this paper and reported that their algorithm produced an average accuracy above 70%. In fact, the performance of SVM in our experiments is better than theirs because we exclude those categories of small number of data points. That is, unbalanced distribution of data points is purposely alleviated in our experiments. Moreover, our conjecture is also validated by their experimental results that those category of large number of data points such as "usability", "security" and "Look And Feel".

V. Concluding remarks

NFR is crucial to the success of a software system as it describes necessary qualities of system to avoid devastating effects and system failure [17]. In this empirical study, vector space model and machine learning technique are employed to classify NFRs automatically. We used different index terms to transfer NFRs into numeric vectors and examined their performances on automatic classification of NFRs. The machine learning classifier we adopted in this paper is SVM with linear kernel, which is widely recommended as a promising classifier for text mining. Information gain for feature selection and SVM for automatic classification is introduced. We conducted experiments using the data set collected from PROMISE data set.

The experimental results show that individual words, when used as the index terms, have the best performance in classifying NFRs automatically. We noticed that, in most cases, the more samples in a category in data set, the better performance the automatic classifier will produce on the category. This outcome illustrated that the number of NFRs in the data set is an important factor for automating the classification of NFRs.

This inference suggests that we need to collect NFRs as many as possible if automatic classification is desired.

This work can be applied in at least two aspects in software engineering currently. First, it can be used to identify NFRs in requirement specification. Usually, customers, testers, and stakeholders of a software system will mix their desirable qualities in a specification. Whereas functional requirements describe what the system needs to do, NFRs describe constraints on the solution space and capture a broad spectrum of properties, such as usability and security [18]. Because the solutions of functional requirements and NFRs are different, or the time to consider these two kinds of requirement in system design is different, we must differentiate these two kinds of requirements. Second, different NFRs are often handled by different designers and developers with different background knowledge in architecture, it is crucial to classify the NFRs into different categories so that the NFRs in the same category can be processed as a comprehensive requirement in system design.

Abstract

Although it is assumed that the implementation of design by contract is better modularized by means of aspect-oriented (AO) programming, there is no empirical evidence on the effectiveness of AO for modularizing non-trivial design by contract code in well-understood modularity attributes. This paper reports a quantitative case study of the adequacy of aspects for modularizing design by contract concern. The study consisted of refactoring a real-life application so that the code responsible for implementing the contract enforcement strategies was moved to aspects. Our analysis was driven by fundamental modularity attributes, such as separation of concerns, coupling, and size. We have found that AO techniques improved separation of concerns between the design by contract code and base application code. However, contradicting the general intuition, the AO version of the system did not present significant gains regarding four classical size metrics we employed.

1 Introduction

Design by Contract (DbC), originally conceived by Meyer [12], is a technique for developing and improving functional software correctness. The key mechanism in DbC is the use of the so-called "contracts". A contract formally specify an agreement between a client and its suppliers. Client classes must satisfy the supplier class conditions before calling one of its methods. When these conditions are satisfied, the supplier class must guarantee certain properties, which constitute the supplier class's obligations. However, when a client breaks a condition (client violation), a runtime error occurs. The use of such pre- and postconditions and invariants to specify software contracts dates back to Hoare's 1969 paper on formal verification [7]. The novelty with DbC is to make these contracts executable. This is useful for isolating errors during debugging, and for validating contracts that are used as documentation or for increasing code reliability and correctness [1, 15].

It is assumed that the contracts of a system is de-facto a crosscutting concern that can be better modularized by the use of aspect-orientation [8, 10, 11]. Recent studies [10, 8, 1, 15, 16] have shown that object-oriented abstractions are not able to modularize the main features of design by contract methodology, such as invariants and pre- and postconditions, and tend to lead to programs with poor modularity (scattered and tangled DbC code).

To the best of our knowledge, Lippert and Lopes [10] conducted the most well-known systematic study that explicitly investigated the use of AO to implement classical design by contract features such as pre- and postconditions of a large OO framework, called JWAM. Among other things, they compared the contracted Java and AspectJ implementations of such OO framework. According to their findings, the AspectJ implementation improved the modularity of design by contract concern. Also, they argue that the use of AO drastically reduced the number of contracts (e.g., precondition) and lines of code (LOC). However, the authors presented their findings in terms of a qualitative as-

sessment. Quantitative evaluation consisted solely of counting LOC. Hence, there is no empirical evidence that AO techniques promote a superior solution in well-understood modularity attributes such as separation of concerns, coupling, and size, when used for modularizing non-trivial homogeneous and heterogeneous design by contract code.

This paper complements Lippert and Lopes work [10] by performing quantitative assessments of OO and AO implementations for invariants and pre- and postconditions of a real-life web-based information system, called Health Watcher (HW) [6]. The OO version was implemented in Java, whereas the AO version was implemented in AspectJ. Our evaluation focused upon on well-known modularity attributes such as separation of concerns, coupling, and size [17, 5]. We have found that the AO solution improved the separation of design by contract concern of the HW system. Moreover, the use of aspects have exhibited significant reuse of DbC features such as preconditions. However, the AO implementation of HW has not presented significant gains regarding four classical size metrics.

This paper is structured as follows: Section 2 describes our experimental settings and justifies the decisions made to ensure the study is valid. The results gathered from applying the modularity metrics are discussed in Section 3. Section 4 analyzes the obtained results and points some constraints on the validity of our study. Finally, Sections 5 concludes this paper by summarizing this paper's findings.

2 Experimental Settings

This section describes the configuration of our study. Section 2.1 briefly exemplifies and explains how we moved design by contract code to aspects. The choice of the target system is discussed in Section 2.2. In addition, the metrics used in the assessment process (Section 2.3), and our assessment procedures (Section 2.4) are described.

2.1 Aspectizing Design By Contract

Our study focused on the placement of contracts. We moved all the JC.requires, JC.ensures, and JC.invariant calls in the selected portions of the selected target system to aspects. These methods are declared in the JC class which encapsulate all the Java contract operations. As such, the methods calls JC.requires, JC.ensures, and invariant denotes pre- and postconditions, and invariants of the target system, respectively.

We used the Extract Fragment to Advice [13] refactoring to move contracts to aspects. Figure 1 illustrates this mechanics. It shows a trivial example of aspectization of preconditions using a **before** advice. Note that since the two methods of the class C have the same precondition α, we were able to refactor it to single advice, hence exploring

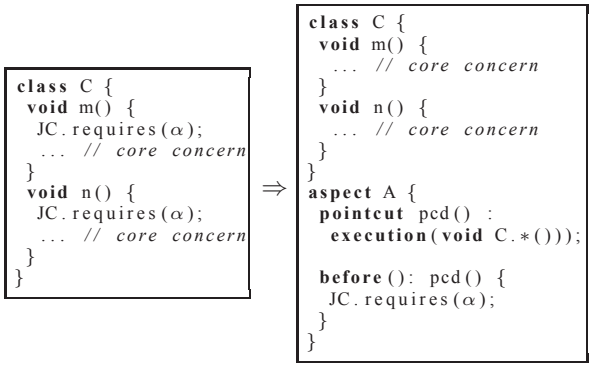

Figure 1. Refactoring DbC code to aspects.

reuse opportunities. Due to space constraints, we do not show how we extracted other DbC features to advice.

2.2 Target System Selection

The first major decision we had in our investigation was the selection of the target system. The chosen system is a real web-based information system, called Health Watcher (HW) [6]. The main purpose of the HW system is to allow citizens to register complaints regarding health issues. This system was selected because it met a number of relevant criteria for our intended evaluation. First, it is a real and non-trivial system with available OO and AO implementations with a number of recurring concerns and technologies common in day-to-day software development, such as GUI, persistence, concurrency, RMI, Servlets and JDBC [6]. Second, the original implementation of HW is composed by eleven use cases that are detailed described by an available requirements document, which is essential to understand its main functionalities [6]. Third, other qualitative and quantitative studies of the HW system have been recently conducted [9, 4, 6, 3], and so provided a solid foundation for this study.

2.3 The Metrics

In our study, a suite of metrics for separation of concerns (SoC), coupling, and size [17, 5] were selected to evaluate the OO and AO implementation versions of the HW system. This suite was adapted from classic OO metrics [2] to be applied to the AO paradigm. In addition, the chosen metrics have already been used in several empirical case studies [5, 9, 4, 6, 3]. For all the employed metrics, a lower value implies better results. Table 1 summarizes each metric used in this case study, and associates it with the relevant modularity attribute.

Separation of Concerns (SoC) metrics measure the degree to which a single concern (design by contract in our

Table 1. The Metrics Suite.

Attributes	Metrics	Definitions
Separation of Concerns (SoC)	Concern Diffusion over Components (CDC)	Number of classes and aspects that contribute to the implementation of a concern [5].
	Concern Diffusion over Operations (CDO)	Number of methods and advice that contribute to a concern's implementation [5].
	Concern Diffusion over LOC (CDLOC)	Counts the number of transition points for each concern through the lines of code. Transition points are points in the code where there is a "concern switch" [5].
Coupling	Coupling Between Components (CBC)	Number of classes and aspects declaring methods or fields that may be called or accessed by other components [2].
Size	Lines of Code (LOC)	Number of lines of code [2].
	Design By Contract Lines of Code (DbCLOC)	Number of lines of code that are relative to DbC.
	Number of Preconditions (NOPre)	Number of preconditions of each class or aspect.
	Number of Postconditions (NOPo)	Number of postconditions of each class or aspect.
	Number of Invariants (NOI)	Number of invariants of each class or aspect.
	Number of Attributes (NOA)	Number of attributes of each class or aspect [2].
	Number of Operations (NOO)	Number of methods and advice of each class or aspect [2].
	Vocabulary Size (VS)	Number of components of the system [2].

study) affects the system. The coupling metric CBC indicates the degree of dependency between components. Excessive coupling is not desirable, since it is detrimental to modular design. Size metrics are important to evaluate the complexity and different perspectives of the final system. In this way, the metric group includes metrics for both general system attributes (e.g., Number of Lines of Code) and quantities that are specific to design by contract such as Number of Preconditions (NOPre). The size metrics related to DbC are useful to quantify reuse of design by contract code in refactored versions of a particular target system. For further details about SoC, CBC, and size metrics, refer to [2, 17, 5].

2.4 Assessment Procedures

The main goal of this empirical case study is to answer how the HW system behaves regarding design by contract modularity when implemented with AO techniques. To this end, our study was divided into three major phases: (i) the implementation of the design by contract concern and alignment of the original HW according to its requirements document; (ii) the refactoring of the design by contract concern (developed in phase i) of HW to aspects, and (iii) the assessment of the two versions (the OO and AO versions developed in phases i and ii, respectively) of HW system.

In the first phase, we implemented the design by contract concern for the OO solution of the HW system, which is already available and implemented in Java. As aforementioned, HW comprises several classical crosscutting concerns, but no existing quantitative work have explored the design by contract one. We analyzed the entire available requirements document of the HW system to understand its functionalities and involved actors. This was fundamental to apply required preconditions, postcondition, and invariants for all the HW use cases. The implementation comprehends both homogeneous and heterogeneous contracts for the HW use cases. We found some inconsistences of the original HW implementation by its validation with contracts. Since this task is out of scope, we just mention that we made an alignment (fixing the found bugs) of the HW implementation to fulfil its requirements.

The second phase involved the refactoring of the design by contract crosscutting concern of HW system to aspects. After extracting all the contracts to aspects, we looked for reuse opportunities and eliminated identical contracts already moved to AspectJ advice. Basically, we implemented contracts in the aspects using before and after advice. Eventually, when we have *old expressions*, which refers to both pre- and post-state of a method execution, we used around advice. Further details on how to instrument old expressions with around advice, refer to [15, 16].

The goal of the third phase was to compare in a quantitative way the OO and AO versions of the HW system performed in the previous phases. In the measurement process, the data was partially gathered by the AJATO measurement tool [1]. It supports some metrics: LOC, NOA, NOO. Additionally, we used the AOP metrics tool [2] to collect CBC, LCOO, and VS. Eventually, we collected the SoC metrics (CDC, CDO, CDLOC) [17, 5] manually.

The data collection of SoC metrics (CDC, CDO and CDLOC) was preceded by what the metrics' authors call as "shadowing" process. In this process, the code implementing DbC was identified and shadowed in every class, interface and aspect. The metrics were, then, manually computed based on the shadowed code. The complete description of the gathered data, measurement tools, and shadowed code is available at [14]

3 Study Results

This section presents the results of the measurement process. The data have been collected based on the set of defined metrics (Table 1). We present the results by means of tables. Rows labelled "Diff." indicate the percentage difference between the original and refactored versions of the HW. A positive value means that the OO version fared better, whereas a negative value indicates that the AO version exhibited better results.

3.1 Quantifying Separation of Concerns

Table 2 shows the obtained results of the separation of concern metrics. The "Diff." row shows significant differences in favor of the AO implementation in terms of the Concern Diffusion over Components (CDC). This divergence is a direct consequence of the adopted strategy for creating new DbC aspects in HW system. For example, we created a new aspect whose sole responsibility was to implement all the non-null input parameters required to fulfil the HW requirements. This classical contract checking denotes an example of homogenous contracts of the HW system. In cases when we had heterogenous contracts, we create one aspect per layer to encapsulate the HW contracts. This scenario contributed to a better result in favor of the AO implementation regarding the CDC metric. The DbC concern is spread over 51 components (classes or interfaces) in the OO version, whereas in the AO solution it was only 12 components (in which 11 are aspects). This led us to a percentage reduction of 76.47% in favor of AO version.

Still regarding the AO solution, the DbC concern fared better for the CDO metric. It is scattered over 297 in the OO solution against to only 196 operations relative to the AO solution. As a result, we had a 34% percentage of reduction in favor to AO solution. Finally, the Concern Diffusion over LOC (CDLOC) was the metric where the AO implementation of HW system performed better against its counterpart in OO implementation. This implies that the design by contract concern is more tangled in the OO solution than in the AO implementation. The OO solution presents 1193 "concern switches" over the system code, whereas the AO solution had no occurrence of concern switches. This means that the DbC concern was completely untangled, localized, and isolated with aspects.

3.2 Quantifying Coupling and Size

Table 3 shows the obtained results for the coupling and size metrics. Regarding coupling, as observed, there is a small difference in favor of the AO implementation of HW system. Aspects reduced the coupling between system classes by removing the DbC-related code from them. However, the aspects still need to reference and, thus, are coupled to classes on which they introduce the DbC behavior. Hence, we had only 6.14% percentage reduction in favor of AO solution (see the CBC column in Table 3).

Contradicting the general intuition that aspects make programs smaller [10, 8] due to reuse, the OO version and its counterpart in AO did not present significant gains in relation to the four classical metrics: VS, NOO, LOC, and NOA. For instance, the Vocabulary Size (VS) grew as expected with 11% more components (classes + aspects) due to the introduction of design by contract aspects. Thus, AO version involved 100 components (with 11 created aspects), whereas the OO implementation included only 89 components to comprise the same functionalities. Moreover, the Number of Operations (NOO) grew significantly in the AO version due to the modularization of DbC with new mechanisms such as advice. As a result, we had 26.59% more method-like definitions in the AO version. In the HW system, the difference of the number of LOC was only 1.92% in favor to AO solution. Hence, even with significant reuse of design by contract code as we discuss next, the aspect code for realizing the DbC concern requires a lot of extra idioms which led to extra effort during implementation.

This finding, contradicts the Lipert and Lopes study [10], on which they had a reduction of more than 50% in LOC due to reuse. This happens because while HW system has homogeneous contracts that can be significantly reused, some heterogenous contracts can be harmful to the final LOC due to the poor reuse of such heterogeneous contracts and the extra aspect code needed to "aspectize" the design by contract concern. Finally, we had no difference between the two versions in relation to the Number of Attributes (NOA).

As aforementioned, in order to quantify the reuse of the design by contract code, we employed specific metrics to DbC concern: DbCLOC, NOPre, NOPo, NOI. The Number of LOC relative to DbC (DbCLOC) was the only specific size metric in which the benefits by the AO solution was less than 10% (7.54%). This happens because the DbC aspects used to modularize the HW contracts (e.g., invariants) have significant extra code (such as pointcuts to intercept the join points involved in the DbC concern realization and advice contextual information) to cope with the crosscutting concern modularization.

The remaining three DbC size metrics performed significantly better in favor to AO solution. For instance, the Number of Invariants (NOI) exhibited a reuse of 90.60%. This is understandable since an invariant implementation in Java needs to be invoked several times to fulfil its semantics. An invariant holds after every constructor execution and just before and after every instance method execution of a class [15]. With AO and AspectJ, we can modularize an invariant with two advice reducing the so scattered implementation of invariant calls to only 2 occurrences [15].

In relation to pre- and postconditions, we had a higher reuse of preconditions in the AO implementation (83.08%). Regarding postconditions, the AO solution fared better with a reuse of 50% against its counterpart in OO implementation. In fact, these numbers can substantially vary depending the degree of homogeneous and heterogeneous pre- and postconditions that can appear in a particular system. In the HW system, we observed that the postconditions are less reusable than preconditions, due to postconditions present more heterogenous contracts.

4 Discussion

This section makes a qualitative analysis of the obtained results (Section 3). Furthermore, we discuss the constraints on the validity of our empirical case study.

4.1 Empirical findings

Our empirical case study confirms some of the findings of the qualitative study conducted by Lippert and Lopes (LL) [10], which claims that the design by contract concern is better modularized with AO programming.

Despite the fact we had significant gains of SoC metrics in favor of the AO implementation of HW system, we found out that reusing contracts can be more difficult than usually advertised [10]. Contracts reuse depends directly on their types (e.g., postconditions) and mainly if such contracts are homogeneous or heterogenous.

For instance, since the nature of an invariant crosscuts several methods in a single class, it is naturally more reusable than pre- and postconditions that are relative to particular methods. However, pre- and postconditions can present significant reuse depends on their contracts. In other words, if several constrained methods present an intersection of common contracts, their reusability can be improved. As an example, similarly to LL [10], we found that several methods in HW present the following homogeneous postcondition: `JC.ensures( result != null)`. This postcondition states that every method using this contract must return an object that is non-null. The same situation also occurred for preconditions on input object parameters. In the HW system we observed that the reuse of postconditions was quite low (50%) when compared with preconditions (83.08%) and invariants (90.60%). This scenario happens due to postconditions in HW being more heterogenous than preconditions or invariants. We found more reusability opportunities for heterogenous preconditions than the heterogeneous postconditions. With this finding, we can conclude that the more heterogenous is a contract, its reuse with AO programming is minimized.

Another important finding of our study is related to the program size after refactoring to aspects. LL [10] discuss that by using AO programming they could reduce more than 50% of the total design by contract LOC due to the reuse. However, contradicting this general intuition that aspects make programs considerable smaller, we found that despite the higher reuse of DbC concern with the AO version of HW system, the gains in terms of the overall system LOC was only 1.92% and only 7.54% considering exclusively the LOC of DbC concern. This was a directly consequence for looking to reusability opportunities for heterogenous contracts. During modularization, we take into account the intercepted join points, contextual information and so forth.

4.2 Study Constraints

System. Although it can be argued that using a single system for such a study is a limiting factor, we claim that the HW system is representative in terms of the non-trivial applied contracts. The HW system is good candidate for empirical studies due to have a lot of documentation and resources available [6]. Naturally it is desirable to involve more systems and more approaches.

Metrics. The applicability, usefulness, and representative of the set of the metrics used in this study can be ques-

tioned. However, due to the nature of the study and the fact that separation of concerns is central to this study, the design by contract crosscutting concern was naturally the one which varied most. Hence, we used a set of metrics related to separation of concerns to better assess the SoC involving DbC. In addition, the SoC metrics described in Section 2.3 have already been proved to be effective quality indicators in several case studies [5, 9, 4, 6, 3].

Languages. In addition, the scope of our experience is limited to Java and AspectJ languages. In relation to design by contract features, our experience only considered the implementation of pre-, postconditions, and invariants.

5 Concluding Remarks

In this paper, we presented an empirical case study to assess various facets of design by contract modularity of object-oriented and aspect-oriented implementations of a real-life system. This study was the first to include a quantitative analysis of design by contract implementations using well-undertood and experimented modularity metrics such as separation of concerns, coupling, and size.

From this analysis we have discovered a number of interesting outcomes. Firstly, the use of aspect-orientation to modularize design by contract improved the separation of concerns when compared to its counterpart in object-orientation. Secondly, the use of aspects tended to present a significant reuse of design by contract features, specially invariants, which we had a reuse more than 90%.

Furthermore, even with the high reuse achieved by AO programming when modularizing DbC, we found out that the aspectization of crosscutting concern such as DbC does not necessarily makes a program drastically smaller than the non-modular one with OO. Aspect code involves much more than just encapsulate a call to a precondition. It is responsible to prepare the crosscutting behavior by intercept all the join points in a system, expose contextual information and so forth. The overall conclusion regarding design by contract modularity is that aspects achieve higher reuse than OO decompositions when handling homogenous contracts, however, not always with large code reduction.

One of the most immediate future work is to derive a predictive model for using aspects to implement design by contract, based on our experience of this study. Hence, developers may recognize the situations where it is advantageous to aspectize design by contract code. Moreover, we intend to conduct a scalability study to analyze how aspects scale up when the number of contracts grows.

***Abstract*—Accurate failure predictions can help in mitigating the impact of computer failures. Resources, applications, and services can be scheduled to limit the impact of failures. However, providing accurate predictions with sufficient lead of time is challenging. Log files track changes of system state. A sequence or a pattern of messages may be used to predict failures. Here we describe an approach to predict failures based on the Cox Proportional Hazards (PH) model that has been applied successfully in various fields of research. We apply our approach to log files collected during approximately 3 months of work in a large Italian company. We compare the performance of the proposed model with Support Vector Machines.**

Keywords-failure prediction, Cox Proportional Hazard model, Log files

I. Introduction

The impact of failures can be substantial since the recovery process can require unexpected amounts of time and resources [1; 10]. Being able to forecast failures is extremely important, even when failures are inevitable – at least recovery or rescue actions can be taken [25].

Methods for the prediction of system failures based on events (in our case, the log messages) have been proposed in various engineering disciplines. These methods can be classified into design-based methods and data-driven rule-based methods. In a design-based method, the expected event sequence is obtained from the system design and is compared with the observed event sequence [19; 21; 24]. The major disadvantage of these methods is that in many cases events occur randomly and thus there is no system logic design information available.

Data-driven rule based methods do not require system logic design information. These methods are made of two phases: 1) identification of temporal patterns, i.e., sequences of events that frequently occur [16] and 2) development of prediction rules based on these patterns [14].

System log files consist of messages created while the system is running. The information recorded varies from general messages concerning user logins to more critical warnings about program failures [10]. Log file information can be analysed to find causes of failures. Although this type of forensic analysis is valuable, it is also possible to use the information contained in system log files for predicting events. There have been several approaches for predicting system failures using system log files.

Prediction methods using log files include standard machine learning techniques such as Support Vector Machines, Bayes networks, Hidden Markov Models, and Partially Observable Markov Decision Process [8; 9; 10; 11; 15; 20; 26; 28; 29]. The use of time-series analysis is common among these methods since a system message in isolation has been shown to be insufficient for predicting failure [29]. Unfortunaly, the large amount of information available in system log files makes finding the right pattern(s) difficult [10].

In this paper we introduce a new approach for predicting critical system events based on the Cox PH model. The actualization of such idea will set the path for the development of devices that read logs of running applications and signal the likely crash of such systems.

The Cox PH model has been applied mainly in biomedicine, often for the study of cancer survival [5; 31]. It has also been applied successfully in various fields of research, such as criminology [4], sociology [2], marketing [3]. There are limited uses of the Cox PH model in cybernetic [14] and also an application to software data [27] where, using as input code metrics, failure time data coming from bug report were analysed.

The paper is structured as follows: in Section 2, we present some background; in Section 3, we introduce our approach. In Section 4, we describe our experiments and results. In Section 5 we discuss our results.

II. Background

A. System Log Files

System log files are important for managing computer systems since they provide a history or audit trail of events. In this context, an event is a change in a system status, such as a user login or an application failure. Several studies have proposed different approaches for predicting system failures using system log files [8; 9; 10; 11; 14; 15; 20; 26; 28; 29].

System log files typically are text files that consist of messages sent to the logging service by applications. Applications can send information to the logging service process that stores the messages in a text file in an arrival

order. The logging service is primarily responsible for managing the log file while the message content is largely created by the application. In the dataset used in this study, each log entry consists of eight fields (Table I). The time field is the time when the message was recorded. One field stores the name of the application that was running; the machine sending the message is identified by two fields, server and computer (since the logging service serves multiple computers on different servers). The logged-in user is reported in the UsedName field, and Severity contains the level of severity of the message. In addition, some of the logs (not all), contain also an error name and description of the event that has occurred.

TABLE I. FIELDS OF A LOG MESSAGE IN THE ANALYSED DATASET.

Field Name	Description
Time	Time the message was recorded
Application	Running application
Server	Machine sending the message
Computer	
UserName	Name of the logged user
Severity	Level of severity of the message
Operation	Performed operation
Description	Some of the logs (not all) contain also the error name and the Description of the event that has occurred
ErrorName	

B. The Cox PH Model

Cox PH model (Cox 1972) gives an expression for the hazard at time *t* for an individual *i* with a given specification of *p* covariates *x*:

$$h(t|x) = h_0(t)e^{\sum_{i=1}^{p} \beta_i x_i} \quad (1)$$

The Cox model formula says that the hazard at time t is the product of two quantities. The first of them, $h_0(t)$, is called the baseline hazard function and is equal for all individuals; it may be considered as a starting version of the hazard function, prior to considering any of the x´s. Cox PH model focuses on estimating regression coefficients *ß´*s leaving the baseline hazard unspecified. *ß* is a vector of regression coefficients; in the p < n setting, *ß´*s are estimated by maximizing the log partial likelihood, which is given by:

$$l(\beta) = \sum_{i=1}^{n} \delta_i \left\{ x_i \beta - \log\left[\sum_{j \in R(t_i)} e_i^x \beta \right] \right\} \quad (2)$$

Where $R(t_i)$ is the risk set at time t_i, i.e. the set of all individuals who are still under study just prior to time t_i.

A parametric survival model is one in which survival time (the outcome) is assumed to follow a known distribution. The Cox PH model is not a fully parametric model; rather it is a semi-parametric model because even if the regression parameters ß´s are known, the distribution of the outcome remains unknown. The Cox PH model is a "robust" model, since the results obtained from it closely approximate the results of the correct parametric model.

The key assumption of the Cox PH model is proportional hazards; this assumption means that the hazard ratio (defined as the hazard for one individual over the hazard for a different individual) is constant over time.

Cox PH model is widely used because of its characteristics: 1) even without specifying $h_0(t)$, it is possible to find the *ß´*s, 2) no particular form of probability distribution is assumed for survival times, and 3) it uses more information – the survival times – than the logistic model, which considers a (0,1) outcome and ignores survival times and censoring. Therefore, it is preferred over the logistic model when survival time is available and there is censoring [13].

C. Performance Assessment

A contingency table (sometimes called confusion matrix) is a convenient way to tabulate statistics for evaluating the quality of a model. In Table II, TP, FP, TN and FN stand for true/false positive/negative counts, respectively; PP and PN stand for predicted positive/negative; and POS and NEG stand for actual positive/negative.

In this paper we will only consider metrics that can be defined in terms of the counts in a contingency table; this excludes, e.g., metrics that consider model complexity [7]. The most relevant metrics of this type are reported in Table III.

TABLE II. CONTINGENCY TABLE (A.K.A., CONFUSION MATRIX).

		Actual Value	
		Pos	***Neg***
Prediction Outcome	***PP***	TP	FP
	PN	FN	TN
PP=Predicted Positive, PN=Predicted Negative, Pos=Actual Positive, Neg=Actual Negative, TP=True Positive, FP=False Positive, TN=True Negative, FN=False Negative			

TABLE III. DERIVATIONS FROM A CONFUSION MATRIX: MOST RELEVANT METRICS FOR CLASSIFICATION PERFORMANCE EVALUATION [17].

Name *(alternative names)*	Definition
True Positive Rate *(TPR, Sensitivity, Recall)*	$\frac{TP}{TP+FN}$
False Positive Rate *(FPR, fall out)*	$\frac{FP}{FP+TN}$
Accuracy	$\frac{TP+TN}{TP+TN+FP+FN}$
True Negative Rate *(TNR, Specificity)*	$\frac{TN}{TN+FP}$
Balance	$1-\frac{\sqrt{(0-FPR)^2+(1-TPR)^2}}{\sqrt{2}}$

We use Receiver Operating Characteristics (ROC) space to analyse the classifier performance. False positive rate is plotted against the true positive rate. The graph (Fig. 1) shows

the trade-off benefits (TP) and costs (FP). The points (0,0) and (1,1) represent the training-free classifiers *AlwaysNegative* and *AlwaysPositive*; the point (0,1) represents the ideal classifier, and (1,0) represents the classifier which gets it all wrong. The ascending diagonal (0,0)–(1,1) represents random training-free behaviour: any point (*p*,*p*) can be obtained by predicting positive with probability *p* and negative with probability (1–*p*). The upper left triangle contains classifiers that perform better than random, while the lower right triangle contains those performing worse than random. The descending diagonal (0,1)–(1,0) represents classifiers that perform equally well on both classes (*TPR*=1–*FP*); left of this line we find classifiers that perform better on the negatives than the positives, to the right performance on the positives dominates [7].

Balance is defined in [17] as the Euclidean distance from the sweet spot FPR= 0, TPR=1 to a pair of (FPR; TPR) . For convenience, we 1) normalize balance by the maximum possible distance across the ROC square ($\sqrt{2}$), and 2) subtract this from 1, i.e. Hence, better and higher balances fall closer to the desired sweet spot of FPR= 0, TPR=1. In particular, classifiers having balance higher than 0.5 fall in the upper left triangle of the ROC space. Thus, we consider 0.5 as a threshold for balance.

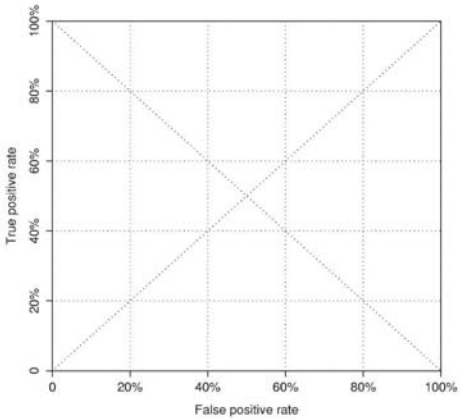

Figure 1. ROC space structure (from [7]).

Ideally, we seek predictors that maximize accuracy, TPR, and TNR. Note that maximizing any one of these does not imply high values for the others. Accuracy is a good measure of a learner's performance when the possible outcomes occur with similar frequencies, and is not suggested when class distributions are uneven [17]. Therefore, this paper will assess its learned predictors using balance, TPR, and FPR and not accuracy.

III. Approach

A. Structure of the approach

We propose a technique to predict the failure of a running software systems using log files. The idea is to develop devices that read logs of running applications and signal the likely crash of such systems. Fig. 2 presents a schematic view of the proposed approach. While the system is running, log data are collected to track the actual execution path. In this work, we look at the running system as a "black box", meaning that we do not have any other information about the system except the log files.

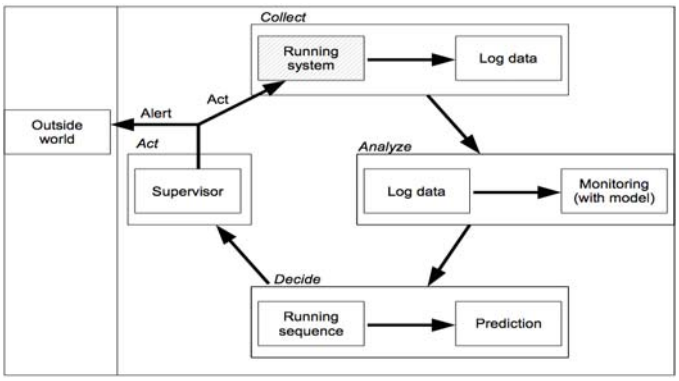

Figure 2. Schema of the proposed approach.

The monitoring process takes log data as input and, basing on the analysis performed, gives to the supervisor a message indicating the "likely failure" for the running application. The supervisor can act directly on the running system to avoid the predicted failure, or send an alert to the outside world. Possible actions could be to abort the running system, to restart it, to dynamically load components, or to inform the running system if it was a suitably structured autonomic system [18].

B. Structure of the Monitoring Process

1) Dimensional reduction of the problem and data preparation

While the system is running, data are *collected* [6; 22; 23] to track the actual execution path. Then, to get from raw logs to temporal event sequences:

1. data are parsed to extract Operation, Time and Severity fields;
2. duplicate rows are deleted together with logs that have missing information in one or several fields Operation, Time stamp, Severity;
3. sequences of activities are extracted: a new sequence starts either if there is a 'Log in' operation or if the day changes.
4. for each sequence, the number of occurrences of each operation is found.

Failures are defined as sequences containing at least one severity "Error".

2) Model Training and Analysis of the results

Following the guidelines of [12; 30; 31], model training includes the following steps:

1. the Schoenfeld test [13] is applied to select the operations satisfying the PH assumption.
2. the Cox PH model is applied and operations that are significantly associated to failures are identified.

3. for each sequence a risk score is evaluated according to the exponential value of a linear combination of the multiplicity of the operation, weighted by the regression coefficients derived from the aforementioned Cox PH model.
4. *m* is extracted, as the third quartile of risk scores of non failure sequences;
5. The risk score RS is then evaluated for the actual sequence of the running application, as in point 4. A message of "likely failure" about the running application is given as output to the supervisor when RS ≥ m.

IV. Experiments

A. Data

We use log files collected during approximately 3 months of work in an important Italian company that prefers to remain anonymous. Table IV presents some descriptive statistics about the six application in the dataset.

TABLE IV. Descriptive statistics.

App	Number of sequences	Pos* (%)
A1	12765	0.84
A2	718	15.88
A3	60	23.33
A4	343	12.83
A5	713	4.77
A6	8593	1.23
Pos = failures (percentage over n)		

After the preprocessing phase, sequences were sampled 1000 times using Monte carlo methods to obtainn training sets (60%) and test sets (40%). The proposed method was then applied as explained in Section III.

To compare the performance of the proposed model with SVMs, we applied SVM with linear, polynomial and radial basis kernel. The cost of misclassifying points was 100 in each case, to force the creation of a more accurate model.

B. Results

Table V shows the results of the proposed approach and compares its performance with the best performing SVM.

Our approach shows TNR higher than 0.70 in five cases. SVMs have almost perfect TNR: data are imbalanced, thus SVMs classify almost all instances as negative. Some specificity (i.e., TNR) is lost in our approach to improve the TPR.

TABLE V. Classification performance.

App	Classification Performance							
	TNR mean(std)		*TPR mean (std)*		*FPR mean (std)*		*Balance mean (std)*	
	Cox	*SVM*	*Cox*	*SVM*	*Cox*	*SVM*	*Cox*	*SVM*
A1	0.49 (0.25)	1.00** (0.00)	0.52 (0.20)	0.00** (0.00)	0.51 (0.25)	0.00** (0.00)	0.46 (0.03)	0.29** (0.00)
A2	0.75 (0.12)	0.98** (0.01)	0.97 (0.08)	0.91** (0.03)	0.25 (0.12)	0.02** (0.01)	0.82 (0.08)	0.93** (0.02)
A3	0.72 (0.14)	0.98* (0.05)	0.05 (0.09)	0.04* (0.09)	0.28 (0.14)	0.02* (0.05)	0.29 (0.07)	0.32* (0.07)
A4	0.70 (0.12)	0.96** (0.02)	0.38 (0.19)	0.33** (0.11)	0.31 (0.12)	0.04** (0.02)	0.50 (0.11)	0.52** (0.08)*
A5	0.93 (0.13)	0.99* (0.01)	0.86 (0.11)	0.73* (0.18)	0.07 (0.13)	0.01* (0.01)	0.88 (0.11)	0.81* (0.13)
A6	0.79 (0.16)	0.99* (0.01)	0.78 (0.18)	0.51* (0.12)	0.21 (0.16)	0.01* (0.01)	0.76 (0.14)	0.65* (0.08)
* Linear kernel; ** Radial kernel								

Fig. 4 show the ROC space of the proposed approach. The mean values of TPR and FPR of the 1000 experiments are plotted together with their standard deviation. Five points fall in the upper left triangle; thus the corresponding classifiers perform better than random. Three points are left of the descending diagonal (0,1)–(1,0); thus, these three classifiers perform better on the negatives than on the positives. It emerges from the comparison of this plot to Fig. 3 that A1 and A3 have now left the (0,0) point and approach the (0,1) point.

Fig. 5 shows that balance obtained with the proposed approach is higher than 0.50 in four out six cases, as for SVMs. Balance increases in three cases when applying our approach (in return of the above mentioned slight loss in TNR).

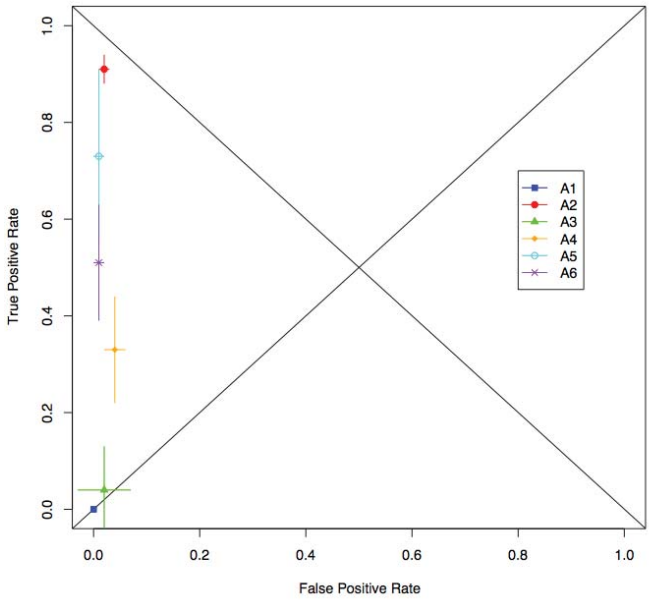

Figure 3. ROC space of the best performing SVMs.

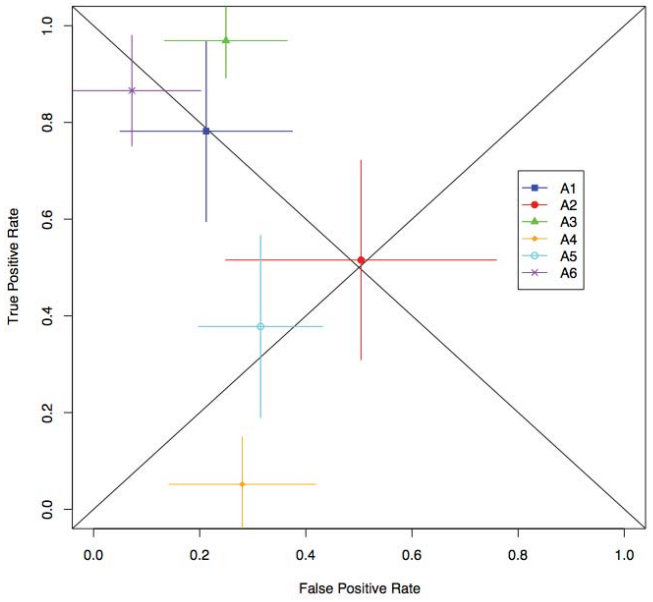

Figure 4. ROC space of the proposed approach based on the Cox PH model.

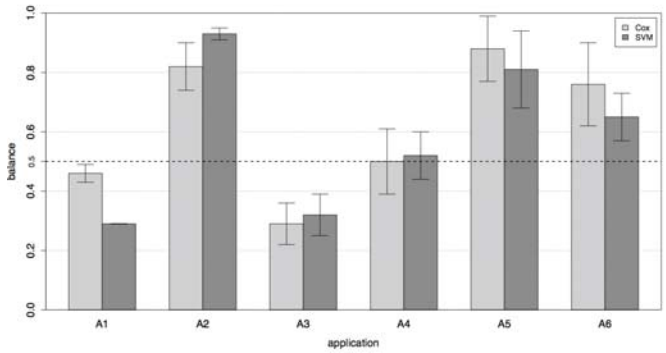

Figure 5. Balance of the proposed approach based on the Cox PH model and of SVMs: a comparison.

V. Conclusions

In this paper we introduce a new approach for predicting failures of a running system using log files; in particular, our approach is based on the Cox PH model. Each sequence of operations is assigned a risk score evaluated according to the exponential value of a linear combination of the multiplicity of the operation, weighted by the regression coefficients derived from the aforementioned Cox PH model. Classification as failure/non-failure is based on this risk score.

It emerges from the comparison with SVMs performance that the proposed approach increases balance between TPR and FPR in three cases. This result is gained in return of a slight loss in TNR which is almost perfect in SVMs. TNR may be so high because data are imbalanced; thus SVMs tends to classify everything as negative. Our approach improves on TPR inevitably sacrificing some specificity. Moreover, the approach based on Cox model gives good performances in the cases where SVMs give their worst results.

Overall, results from our experiments appear interesting and worth further investigations. Our goal now is to study more in-depth our promising model to determine if we can generalize our results. To this end, we plan to replicate the analysis on more industrial datasets. We will also work on broader comparison with other prediction methods to identify the specialities of our approach.

Another aspect that we will evaluate is the possibility of predicting the occurrence of a failure analysing only an initial portion of a sequence, so that there could be an early estimation of failure, providing additional time to take corrective actions. To this end, Cox PH model could be applied to predict survival and the estimate hazard ratio for the various features of the model may contribute to predict the "most dangerous" failures.

Finally, we are now investigating how we could consider other “black-box” properties or applications to predict failures; candidate properties include memory usage, number of open files, processor usage.

The proposed model could be particularly useful dealing with autonomic systems. Autonomic systems could be instructed to receive signals of likely failures and upon reception of such signals could start a suitable recovery procedure [18].

Causal Networks Based Process Improvement

D. Günther[1], R. Neumann[2], K. Georgieva[2] and R. R. Dumke[2]
[1]CERT, Volkswagen AG, Wolfsburg, Germany
[2]Dept. of Computer Science, University of Magdeburg, Magdeburg, Germany

Abstract - **This paper includes a causal-based modelling of software process models in order to analyse the correct relationships between the different (key) process areas of these models. A first short description of causal network approaches shows the identified problems and possible benefits using these formal techniques in the software engineering area. The definition and extension of the causal modelling using causal networks helps to understand the relationships between the different software process artefacts and their causalities. Our causal network based process model (CNPM) concept describes the considered objects outside and inside the software processes or functions and their causalities expressed as roles. The description of first applications of the CNPM approach for the Capability Maturity Model Integration (CMMI) demonstrates the meaningfulness of this approach.**

Keywords - ***Software process improvement, causal network, process analysis and evaluation, software quality***

I. INTRODUCTION

Causal networks as a special kind of semantic networks are very expressive in order to see or analyze the relationships between process activities, areas and indicators in a logical manner. Typical results of such a modelling are

- The consequence of process activities to other ones involving different quality characteristics like correctness, completeness etc. (see [4] and [13])
- The repercussion of the chosen approaches for process evaluation and improvement (see [3] and [9])
- The overview about strong and weak process connections in order to keep quality improvements (see [2], [5] and [6])
- The application of (causal) model-based principles in order to reduce the process complexity and involvements (see [1], [7] and [10]).

In a general manner a causal network "is a directed acyclic graph arising from an evolution of a substitution system, and representing its history" [13]. The process evolution involves causal relationships between events, states, entities, objects, artefacts etc. which could be based on a special kind of empirical reasoning. In following we will characterize a causal network based approach that helps to identify incompleteness and mismatches of text-based process models in an explicit manner.

II. CAUSAL NETWORK-BASED PROCESS MODEL DESCRIPTION AND ANALYSIS

The causal network based process model (CNPM) concept is defined in the following four parts and components of this approach (see [2], [3] and [11]):

A. Causal Network Model Components

The causal network model M^{CNPM} is based on the following software process ingredients and involvements:

$$M^{CNPM} = \langle U^{CNPM}, V^{CNPM}, F^{CNPM} \rangle ,$$

where

- U^{CNPM} is a set of background variables that is determined by ***objects*** $o_{u,i}^{CNPM}$ $(i \in \{1,2,...,m\})$ as software process artefacts outside the considered model
- V^{CNPM} is a set $\{V_1^{CNPM}, V_2^{CNPM}, ..., V_n^{CNPM}\}$ of variables that are determined by ***objects*** $o_{v,i}^{CNPM}$ $(i \in \{1,2,...,n\})$ in the model – that is, variables or objects in $U^{CNPM} \cup V^{CNPM}$; and
- F^{CNPM} is a set of ***functions*** $\{f_1^{CNPM}, f_2^{CNPM}, ..., f_n^{CNPM}\}$ such that each f_i^{CNPM} $(i \in \{1,2,...,n\})$ is a mapping from (the respective domains of) $U^{CNPM} \cup (V^{CNPM} \backslash V_i^{CNPM})$ to V_i^{CNPM} and such that the entire set F_{CNPM} forms a mapping from U^{CNPM} to V^{CNPM}. In other words, each f_i^{CNPM} tells us the value V_i^{CNPM} given the values of all other variables in $U^{CNPM} \cup V^{CNPM}$, and the entire set F^{CNPM} has a unique solution V^{CNPM} *(o)*. Symbolically, the set of equations F^{CNPM} can be represented by writing

$$o_{v,i}^{CNPM} = f_i^{CNPM} (r_i^{CNPM}, o_{v,j}^{CNPM}, o_{u,j}^{CNPM}),$$

$$i,j = 1, \ldots, n, i \neq j$$

where r_i^{CNPM} is any realization of the unique minimal set of variables as ***roles***[1] R_i^{CNPM} in

[1] Against the causality in natural science, software processes are based on activities of subjects. Therefore, we use a description of subjects as *roles*. Note that the roles define the

$V^{CNPM} \backslash V_i^{CNPM}$ sufficient for representing f_i^{CNPM}.

Examples of this CNPM description are

1. $M_1^{CNPM} = \langle U_1^{CNPM}, V_1^{CNPM}, F_1^{CNPM} \rangle$ with U_1^{CNPM} = {'Object 1'}, V_1^{CNPM} = {'Object 2'}, F_1^{CNPM} = $\{o_1^{CNPM}, r_1^{CNPM}\}$, o_1^{CNPM} = {'Function 1'} and r_1^{CNPM} = {'Role 1'}

2. $M_2^{CNPM} = \langle U_2^{CNPM}, V_2^{CNPM}, F_2^{CNPM} \rangle$ with U_2^{CNPM} = {'Object 2'}, V_2^{CNPM} = {'Object 3'}, F_2^{CNPM} = $\{o_2^{CNPM}, r_2^{CNPM}\}$, o_2^{CNPM} = {'Function 2'} and r_2^{CNPM} = {'Role 1'}

Considering the different levels of causality as dependencies and improvements leads to different kinds of analysis and interpretations.

B. Causal Network Model Operations

The M^{CNPM} can be modified in the following manner considering the typical causal relationships between software process artefacts[2]:

- *Union* or *summarizing* of CNPM models consists of the union of the different model parts. A unified CNPM model M_3^{CNPM} could be built as $f\_join(M_1^{CNPM}, M_2^{CNPM})$ with U_3^{CNPM} = {'Object 1'}, V_3^{CNPM} = {'Object 2', 'Object 3'}, $F_3^{CNPM} = \{o_3^{CNPM}, r_3^{CNPM}\}$, o_3^{CNPM} = {'Function 1', 'Function 2'} and r_3^{CNPM} = 'Role1'

- *Partitioning* of a CNPM model consists of building sub models and special parts of models.

- *Restructuring* of a CNPM model is reasonable in different practical situations and consists of addition and extraction of any model parts.

C. Causal Network Model Analysis

The M^{CNPM} can be analyzed considering the typical causal relationships between software process artefacts in the following manner. The CNPM model could be considered as a directed graph where every node has some predecessors and any successors. Hence, it is possible to analyze or count these elements for a first level of CNPM analysis and evaluation. For instance, we obtain the number of all roles in the CNPM, the number of derived objects etc. Based on this idea, we can define the following function $f_{extract\_input}^{CNPM}$ of analysis as

$$f_{extract\_input}^{CNPM} : M_x^{CNPM} \times f_i^{CNPM} \rightarrow U_i^{CNPM}$$

where $M_x^{CNPM} = <U_x^{CNPM}, V_x^{CNPM}, F_x^{CNPM}>$, $f_i^{CNPM} \in F_x^{CNPM}$, $U_i^{CNPM} \subseteq U_x^{CNPM}$ and

$$U_i^{CNPM} = \{ u_i^{CNPM} : u_i^{CNPM} = \textbf{\textit{predecessor}}(f_i^{CNPM}) \}.$$

Applying these functions to our described examples of CNPM models we can derive the following characteristics:

- $predecessor(f_1^{CNPM\_M2})$ = {'Role 1', 'Object 2'}
- $predecessor(f_1^{CNPM\_M3})$ = {'Role 1', 'Object 1'}
- $successor(f_2^{CNPM\_M3})$ = {'Object 3'}

D. Causal Network Model Exploration

The M^{CNPM} can be evaluated in the following manner considering the typical causal relationships between software process artefacts. The CNPM model could be characterized as empirical evaluation that requires the identification of the empirical aspects explicitly. Such empirical characteristic for objects could be process artefact level, artefact quality or process artefact performance. From this point of view, the CNPM model evaluation could be performed as following:

- *causal coverage analysis* of the fulfilled requirements from a special software process point of view,
- *causal trace analysis* of the successful consideration of process flow based requirements,
- *causal achievement analysis* of the derived results and outputs in different parts on the CNPM model.

In order to explain some of these kinds of analysis we will consider the CPNM model M_x^{CNPM} describing the empirical-based process aspects mainly and the CPNM model M_y^{CNPM} describing the causal basics in general. On that we characterize a simple causal coverage analysis as

$$\textbf{\textit{coverage}}_{My}^{CNPM} = \sum(|F_y^{CNPM}| + |U_y^{CNPM}| + |V_y^{CNPM}|) / \sum(|F_x^{CNPM}| + |U_x^{CNPM}| + |V_x^{CNPM}|)$$

where $F_x^{CNPM} \subseteq F_y^{CNPM}$, $U_x^{CNPM} \subseteq U_y^{CNPM}$, $V_x^{CNPM} \subseteq V_y^{CNPM}$.

---

causal heuristics addressed to the considered/presented function in the set of the software process artefacts.

[2] The full formal description you can find in [3] and [11].

Furthermore, in the case of coverage lower 1 we have the situation of any missing objects. That could be characterized in the following manner.

$$F^{CNPM}_{missing\_function} = \{ F^{CNPM}_{x} \setminus F^{CNPM}_{y} : F^{CNPM}_{y} \subseteq F^{CNPM}_{x} \}$$

$$F^{CNPM}_{missing\_input} = \{ U^{CNPM}_{x} \setminus U^{CNPM}_{y} : U^{CNPM}_{y} \subseteq U^{CNPM}_{x} \}$$

$$F^{CNPM}_{missing\_output} = \{ V^{CNPM}_{x} \setminus V^{CNPM}_{y} : V^{CNPM}_{y} \subseteq V^{CNPM}_{x} \}$$

For the causal trace analysis and achievement analysis the existing graph algorithm and methods of evaluation can be used that would not be considered here.

III. CNPM APPROACH APPLICATION FOR CMMI ANALYSIS

One of the possible uses for the CNPM model is the mapping of process standards. This shall be described by example of the key process area „Organizational Training“ (**OT**) of the CMMI (see [8] and [12]). Also it will be considered that specific practices of this model give a hint for the implementation of a CMMI conformant process environment. The specific practice (**SP**) 1.1 will be used as an example for the implementation of a first part of an CNPM network.

A. CNPM-Based Analysis of SP 1.1

The CMMI practice SP 1.1 as “Establish the Strategic Training Needs” contains the following sub practices:

- *Analyze the organization’s strategic business objectives and process improvement plan to identify potential future training needs.*
- *Document the strategic training needs of the organization.*
- *Determine the roles and skills needed to perform the organization’s set of standard processes.*
- *Document the training needed to perform the roles in the organization’s set of standard processes.*
- *Document the training needed to maintain the safe, secure and continued operation of the business.*
- *Revise the organization’s strategic needs and required training as necessary.*

To create a network it is necessary to split the text into tasks, objects and roles. This decomposition leads to the following elements:

Objects: *Strategic business objectives, Process improvement plan, Set of standard processes, Training needs for roles and skills, Training needs for business, Needed roles, Needed skills*

Functions: *Analyse, Document strategic training needs, Determine roles and skills, Document training needs to perform standard processes, Document training needs for safe, secure, continued business, Revise if necessary*

Roles: *The text of the CMMI contains no detailed information about the role executing the task. But it gives the general definition, that the management is responsible for all quality activities. So for the following networks the management will be used as executing instance of this task.*

The resulting network is shown in the following figure 1.

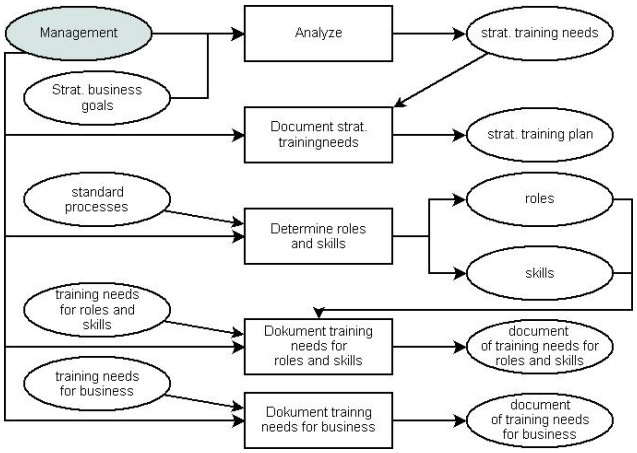

Figure 1: Organizational Training-SP 1.1 – first approach

A deeper analysis of the objects contained in this network shows, that there is no task, creating the objects „training needs for roles and skills“ and „training needs for business“. This shows the incompleteness of the CMMI in some detailed views. The inserted processes are the following:

- *Determine training needs for roles and skills*
- *Determine training needs for business*

Furthermore, it can be seen, that the network contains two functions for documenting two different types of training needs. Giving credit to the fact that the documentation of training needs doesn’t depend on the type of the training need that is to be documented, both functions can be combined to a single one.

- *Document training needs*

The network constructed by these changes is shown in the figure 2. Using the methods described above, the derived networks about the other SP 1 components (as SP 1.2, 1.3, 1.4, 2.1 and 2.2) can be combined to show the complete picture of the tasks fulfilling the requirements of key process area “organizational training”.

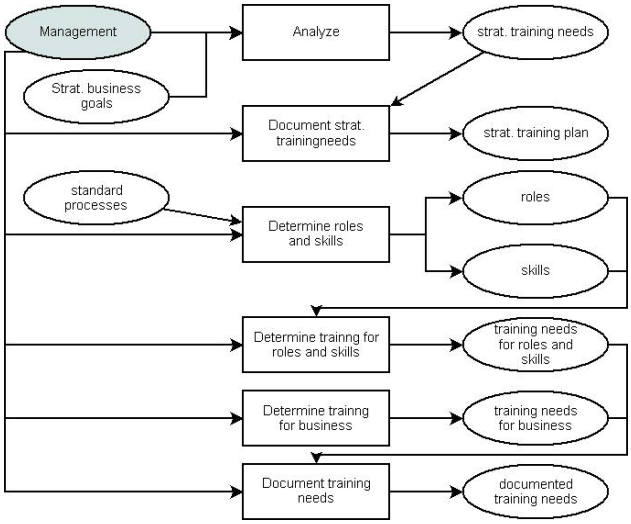

Figure 2: Organizational Training - restructured

B. CNPM-Based Analysis of CMMI Process Descriptions

Further results of CMMI key process (KP) analysis can be characterized as the following chosen situations

- KP "Causal analysis and resolution": created but not used practice 2.1 the "Products",
- KP "Configuration management": created but not used practice 1.2 the "Change request data base"; double (not unique) definition of practice 3.1 as "Configuration documentation"
- KP "Decision analysis and resolution": created but not used practice 1.1 the "Organization standard processes"
- KP "Organizational training": missing management component (see above)
- KP "Project monitoring and control": created but not used practice 1.3 the "Risks documentation" and practice 1.6 the "Changes documentation"
- KP "Project planning": created but not used practice 2.5 the "Knowledge management"
- KP "Process and product quality assurance": created but not used practice 1.2 the "Evaluation criteria" and practice 1.1 "Quality requirements"
- KP "Requirements development": created but not used practice 1.23 the "Requirements history" and practice 1.5 the "Review results"

Note, that the analysis of the KP's "Integrated project management", "Measurement and analysis", "Organizational innovation and deployment", "Organizational process focus" and "Organizational process performance" could be identified with correct (causal-based) semantics.

IV. CONCLUSIONS

The presented CNPM-based approach was applied in practice in order to transform the textual CMMI standard in a causal network based form. This implies the chance of *explicit description* of the CMMI process evaluation from an *implicit* one. Furthermore it allows to consider other causalities and empirical relationships in the software process area depending on concrete industrial situations and methodologies.

In our further research we interpret any improvements in order to keep causal-based correctness in the CMMI. These investigation led to any improvement documented in our next papers.

Measuring Levels of Abstraction in Software Development

Frank Tsui, Abdolrashid Gharaat, Sheryl Duggins, Edward Jung
School of Computing and Software Engineering
Southern Polytechnic State University
Marietta, Georgia, USA

Abstract – In software engineering and development, we are expected to utilize the technique of abstraction. Yet, it is one of the most confounding topics. In this paper we explore the concept of abstraction as applied to software engineering, define and discuss a conceptual metric called levels-of-abstraction, LOA, and show some attributes of LOA.

Keyword: software, abstraction, measurement

I. Introduction

In developing software from requirements we are often faced with a "first step" syndrome of where should one start. Many high level architectural styles and patterns [1] have helped overcome this initial hurdle. However, we are still faced with further analysis to group similar requirements together along functional line or along some data usage line into sub-components. The question that faces many developers during this early stage of analysis is the decision of what should be the appropriate level of abstraction for specification, design and implementation. In this paper we first explore the general notion of abstraction and enhance the concept to include levels-of-abstraction as it applies to software engineering. Next we propose a "conceptual" metric for levels-of-abstraction, LOA, which helps us gauge the amount of abstraction. Finally, we show some interesting attributes of LOA . This is a report on the current status of our research. This research is showing some promise in the area of explaining and formulating guidelines for the amount of abstraction and the depth of abstraction required in performing different software engineering activities.

II. General Concepts Related to Abstractions in Software Engineering

One of the fundamental reasons for engaging in the task of abstraction in software analysis, design and development is to reduce the complexity to a certain level so that the "relevant" aspects of the requirements, design and development may be easily articulated and understood. This starts with the requirements definition through design to actual code implementation. The general relationships of the individual world domain, the abstractions of those domain entities, and the artifacts specifying those abstractions are shown in Figure 1. The bold, vertical arrows represent the intra-transformations occurring within each individual world domain of requirements, design, and implementation. The horizontal arrows represent the inter-transformations occurring across those domains.

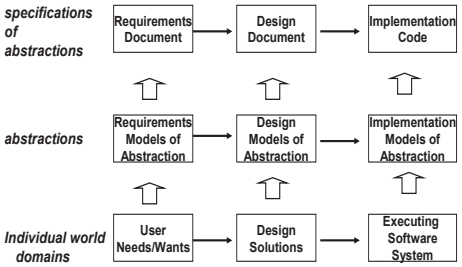

Figure 1: Relationships Among Abstractions, Software Artifacts, and Individual World Domains

The term abstraction used in the form of a verb, as represented with bold vertical arrows in Figure 1 from individual world domain to abstractions, would include the notion of simplification. Simplification represents the concept of categorizing and grouping domain entities into components and relating those components. We simplify: (a) by reduction and (b) by generalization. By reduction, we mean the elimination of the details. Generalization, on the other hand, is the identification and specification of common and important characteristics. Through these two specific subtasks of reduction and generalization we carry out the task of abstraction. Rugaber[6] states that design abstraction is a "unit of design vocabulary that subsumes more detailed information." This notion of abstraction via simplification is also similar to the notion explicated by Kramer [3,4], Perry [5],

Tsui, Gharaat, Duggins and Jung [7] and Wagner and Deissenboeck[8]. Thus via the process of abstraction, we aim to simplify or decrease the complexity of the domain of software design solution.

At the early stage of software development, requirements represent the needs and wants of the users and customers. Different degrees of abstraction may be employed depending on the amount of details that need to be portrayed in the requirements. The intra-transformation is represented by the vertical arrow from User Needs/Wants domain to Requirements Models of Abstraction in Figure 1.

As we move from requirements towards the development of the solution for the user requirements, a new form of abstraction takes place. The new form of abstraction is necessitated due to the fact that the solution world includes the computing machines and other logical constructs that may not exist in the original user requirements. One of the first artifacts from the solution side is the software architecture and high level design of the software system. The inter-transformation of the requirements models of abstraction to the design models of abstraction is shown as the horizontal arrow in Figure 1. Note that the box labeled "Design Models of Abstraction" is the result of two types of transformations:

a) inter-transformation from the requirements domain and
b) intra-transformation within the design solution domain.

The "Implementation Models of Abstraction" box in Figure 1 represents the packaging/loading models of the processes, information and control of the execution of the solution in the form of source code to satisfy the functionalities and attributes described in the requirements and design documents. Thus it is a result of the inter-transformations from requirements models of abstraction through the design models of abstractions and the intra-transformations from the actual software execution domain. The "Implementation Code" box is the specification of this abstraction. The execution of the Implementation Code and the interactions with the users form the "Executing Software System" box in Figure 1. The employment of various abstractions and the transformations of these abstract entities are crucial to software engineering.

III. Measuring Abstraction

Abstraction, both as a verb and as a noun, is a crucial element in software engineering. As a verb, we have defined it as the activity of simplification, composed of reduction of details and the generalization of crucial and common attributes. Now, it is relevant to ask how much abstraction would be appropriate so that we can arrive at the "Implementation Code" and the "Executing Software System" boxes in Figure 1.

Jackson [2] admonishes us that we need to be careful with abstraction and the degree of abstraction because so many seemingly good designs fall apart at implementation time. His warning is well founded in that many design abstractions, the noun, are often missing some vital information for the detail coding activities. In the past, we have utilized the technique of decomposition to move from abstraction to details. However, if our abstraction is generalizing too much to not include the vital information, then Jackson's warning will turn into reality. The levels of abstraction should be different for various software artifacts and be dictated by the purpose of abstraction. Wang [9] has expressed a similar concern and defined a Hierarchical Abstraction Model for software engineering; his hierarchical model of abstraction describes the necessary levels of preciseness in representing abstractions of different objects. In terms of our Figure 1, Wang addressed the issue of rigor of specifications of abstraction in the requirement and design documents, not how much should be included in the abstraction.

The how much, or the amount, of abstraction is a reflection of the result of the simplification activity. Measuring the amount of abstraction is gauging the extent of reduction and generalization that took place. For example, this may be possible in the requirements domain. We may consider the set of the original requirements statements of needs and wants as X in the "User Needs/Wants" box in Figure 1. Then, |X|, the cardinality of X is a count of the raw requirement statements collected through some solicitation process. These are the pre-analysis requirements statements. We then designate Y as the statements in the "Requirements Models of Abstraction" box. The cardinality of Y, |Y|, is a count of the statements that resulted from requirements analysis, which include activities such as organizing, grouping, prioritizing, etc. In other words, the post-analysis of the solicited requirements is a form of abstraction of the raw user needs and wants requirement statements. Then the "difference" between |X| and |Y| is:

$$(\text{Level-of-Abstraction})_{REQ.} = |X| - |Y|.$$

$(\text{Level-of-Abstraction})_{REQ}$ represents the "difference" between pre-analysis and post analysis of requirements, and it may be considered a "conceptual" metric of abstraction for requirements.

Since simplification is a vital characteristic of abstraction, we expect |Y| to be less than |X|. Thus we will need to further refine this definition with the constraint that if |Y| is not less than |X|, then no abstraction activity really took place. We will also take the subscript, REQ, off the terminology for the general case. In general, let X be the statements in the domain world, and let Y be the set of statements in the abstraction, the noun, then

Level-of-Abstraction (LOA) = |X| - |Y|, if |X|>|Y|
else
= 0

Note that when the abstraction activity is carried to its extreme, |Y| should just be 1. For example, all the raw requirement statements of needs and wants are abstracted into one abstract statement. Thus Level-of-Abstraction is bounded by (|X| - 1) and 0.

IV. Requirements Abstraction Example:

In this section we will further explore the Level-of-Abstraction measurement concept, using requirements analysis as an example. Note that it is very likely that X and Y are not expressed with the same language. English sentences and some diagrams may be the main ingredients of the wants and needs expressed by the users and customers. The result of requirements prioritization, categorization and analysis is some form of abstraction, Y, which may be expressed with a Use Case Diagram. The amount of requirements abstraction defined as the "difference" between pre and post analysis of requirements is shown through an example of functionally partitioning the requirements.

Suppose there are X = {x1, x2, ---, xz} raw requirement statements. The set X may contain a variety of statements, referring to functionality, data and other attributes. A common type of abstraction that may be employed is to categorize and group X by functionality. Thus only a subset of X, X', is addressed. X' is the subset of requirement statements that addresses functionality needs. Let X' = {xx1, xx2, ---, xxn}, where |X'| ≤ |X|. The subset X' is analyzed and then partitioned into some set of categories of functionalities. This partitioned set will be called set Y. Y may look as follows.

Y = {(xx1, xx2); (xx3, xx5, xx10); ----}

Every functionality xxi ϵ X' is in one of the partitions of Y and in only one of the partitions. Renaming the partitioned set Y as follows would yield:

Y = {y1, y2, ----, yk} where
y1 = (xx1, xx2)
y2 = (xx3, xx5, xx10)
.
.

The set Y may be represented by a Use Case diagram where y1, y2, ---, yk are the named interaction represented as "bubbles" in the Use Case diagram. Clearly there is more than one way to partition X'; thus there may be different Y's. A use case diagram with one "bubble" would be an extreme case as well as a use case diagram with a bubble for each xxi. The extreme points of |Y| = 1 or |Y| = |X'| would be very rare.

Now consider a specific case where the domain set X has 4 functional requirements x1, x2, x3, x4. Then there are the following partitioning sets, P's for different functional abstractions, Y's.

P0 has Y01 = {(x1); (x2); (x3); (x4)} = X

P1 has Y11 = {(x1); (x2); (x3,x4)},
Y12 = {(x1); (x3); (x2,x4)},
Y13 = {(x1); (x4); (x2,x3)},
Y14 = {(x2); (x3); (x1,x4)},
Y15 = {(x2); (x4); (x1,x3)} and
Y16 = {(x3); (x4); (x1,x2)}

P2 has Y21 = {(x1); (x2,x3,x4)},
Y22 = {(x2); (x1,x3,x4)},
Y23 = {(x3); (x1,x2,x4)}and
Y24 = {(x4); (x1,x2,x3)}

P3 has Y31= {(x1,x2); (x3,x4)},
Y32= {(x1,x3); (x2,x4)}, and
Y33= {(x1,x4); (x2,x3)}

P4 has Y41 = {(x1,x2,x3,x4)}

At P0, there is only one abstraction, Y01, which is the same as the original requirement set X. So Level-of-Abstraction is |X| - |Y| = 0. There is no abstraction at P0. At P1, any of the Y1x has a cardinality of 3. So at P1, |X| - |Y| = 4 – 3 = 1. The Level of Abstraction is 1. At P2, the Y2x's are grouped differently and each has a cardinality of 2. Thus, at P2, |X|-|Y| = 4-2 = 2. P3 partitioning has the functionalities grouped differently, but each Y3x has a cardinality of 2, just

like those in P2. At P3, |X| - |Y| = 4 -2 = 2. Thus all partitions in P2 and in P3 are at the same Level-of-Abstraction, 2. Finally at P4, there is again only one abstraction, Y41, which combined all four functionalities into 1 category. Thus at P4, |X| - |Y| = 4 – 1 = 3. The Level-of- Abstraction is the highest here.

From this example, one can easily see that abstraction of functionalities into groups for a relatively small set of four functional requirements has many choices. In this case there are 15 choices and there are 4 different Level-of-Abstraction, namely 0 through 3. Coming up with the one "best" abstraction is not an easy task even with this small example.

V. Some General Theorems

We have shown that for a |Y| = k, there may be several different abstractions with that same cardinality. That is, given an abstraction level j, there may be more than one solution.

Theorem 1: For Level-of-Abstraction = |X| - |Y| = j, there exists more than one abstraction or partitioned set, Y, at that Level-of-Abstraction, unless j = 0 or j = |X| -1.

Proof: Given |X| - |Y| = j, if j=0 then |X| - |Y| = 0 and there is no abstraction. If |X| - 1 = j, then |Y| has only 1 category with all functionalities included, so |X| - |Y| = |X| - 1, which is the highest level of abstraction. From combinatorics, we know for any set with n>0 elements and r an integer such that $0 \leq r \leq n$, then the number of subsets that contain r elements of S is $\frac{n!}{r!(n-r)!}$. Hence for all the values in between, there will be partitioned sets.

Note that the different Level-of-Abstractions as shown in our simple example of P0 through P4 form a partially ordered set. Next we introduce an Up and a Down operator on Level-of-Abstraction. Given a Level-of-Abstraction, Px, and a Level-of-Abstraction, Py, then UP and Down operators are defined as follows:

UP (Px,Py) = Px if Py ≤ Px and
= Py otherwise.
Down(Px,Py) = Py if Py ≤ Px and
= Px otherwise.

Theorem 2: Set of Level-of-Abstractions, with the operators of Up and Down form a lattice structure.

Proof: The set of Level-of-Abstractions is a partially ordered set, or a Poset. A lattice is a Poset in which any two elements have a lowest upper bound (lub) and a greatest lower bound (glb). The Up operator provides us the glb and the Down operator provides us the lub. Thus the set of Level-of Abstractions forms a lattice.

VI. SUMMARY AND RESULTS

In this paper we explored the general notion of abstraction as applied to software engineering. We further proposed a "conceptual" metric for levels-of-abstraction, LOA, which allows us to gauge the amount of abstraction. Lastly, we showed some characteristics of LOA. Our current research direction is to analyze LOA further to help us pick the "right" level of LOA for a specific domain.

***Abstract* - This work presents an experimental study of an idea related to the automatic generation of performance and stress testing by reusing functional testing. The idea was implemented in a tool named FERRARE GT. This tool is able to generate both test scripts as well as the data required for their execution. In this study we verified that the use of the method can generate benefits related to cost reduction, from the reduction of test effort and, at the same time, benefits related to test quality, from the improvement of the test relevance for the software development.**

Keywords - software testing; data generation; non-functional requirements; experimental study.

I. Introduction

Testing is a critical element in the software quality control and represents the final review of the analysis, design and implementation. However, testing is usually not performed as it should. A fundamental factor that contributes to this situation is the activity cost, which can get as high as 50% of the total project cost [2].

A test category performed by many organizations is functional testing. It aims at verifying the software behavior [6]. There are various other test objectives, as, for instance, performance and stress testing. They are much less often executed that the functional test and have different purposes. The performance test aims at validating the performance requirements, as, for instance, the response time in a specific context, like the access of 100 users in a local network environment. Stress testing is similar to performance testing, however, the execution context is elevated to levels above the average, verifying the system operation in such cases and certifying that no unusual behavior occurs.

In general many organizations that develop Web systems perform functional tests. However, few execute performance and stress tests before launching the system, even though they are just as important for the Web environment. It is fundamental the development of mechanisms which motivates the execution of such tests so needed by Web systems.

From this scenario, it was noticed that the creation of a mechanism, which aids the development of performance and stress testing, from any common artifact to the software development, could result in the cost reduction. Because they are so well known and have a big portion of the necessary information, the functional test was chosen for the input of such automation. From that it was developed a tool, named FERRARE [8], with such an objective. The initial prototype tool enabled the generation of performance and stress testing scripts from functional testing scripts. However, limitations in the tool, which prevented its use in an industrial environment, were discovered.

This paper describes the extensions performed in FERRARE to allow its use in an industrial environment related to software development, as well as an experimental study performed in order to evaluate the benefits related to incorporate the tool in a software development environment.

There are related works that propose the generation of performance tests based on models describing the system under test [4,5,9]. By the other hand, Bertolini et al [1] propose four black box test techniques in order to crash the system, by using a special kind of functional tests. It is important to emphasize that FERRARE does not use models. It generates performance and stress tests scripts by reusing functional tests scripts. Besides, FERRARE can infer the data related to execute a functional test and generate suitable data to execute several tests instances, isolating each one from the others.

This paper is organized as follows: Section II presents FERRARE GT; Section III presents the experimental study; Section IV presents a discussion about the idea and the study results; Section V concludes the paper and presents directions for future works.

II. FERRARE GT

FERRARE is a tool developed for the generation of performance and stress testing scripts from functional testing scripts. It is divided into two modules: Extractor and Generator.

FERRARE was conceived to work with any functional testing tool and any performance and stress testing tool, as long as the extractor and the generator for the desired tools are created, as it is going to be discussed later on. Nowadays, FERRARE works with the functional testing tools Selenium IDE and Canoo Web Test, besides performance and stress testing tools Apache JMeter and WebLoad. This means that it generates performance and stress testing to be executed on JMeter or the WebLoad, from functional testing created with Selenium IDE or Canoo WebTest (input tools) [8]. A sketch of the functioning of FERRARE can be seen in Figure 1.

The Extractor module is responsible for the extraction of the information inside the functional test script. This included the identification of the actions related to the test (test procedure) and of the input data, expected outputs and other

test conditions (test case). The extraction generates an abstract representation of the functional test, independent of technology.

The Generator module is responsible for the generation of performance testing based on the information supplied by the Extractor. This generation involves the specification of different parameters such as the quantity of concurrent users, time limits and number of machines used for test execution.

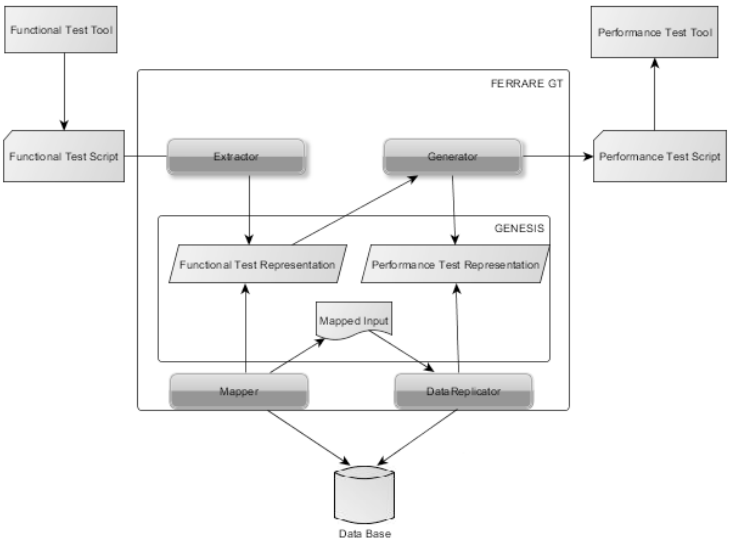

Figure 1. FERRARE GT overview.

FERRARE generates performance and stress testing from the creation of "copies" from functional testing, taking in consideration the restrictions associated to the inputs used in this test. If a functional test that performs a book register in an application is used, FERRARE can generate 100 "copies" of this test, in the format required by performance and stress testing, respecting the characteristics of the fields, as an obligatoriness, sizes and formats. It is important to emphasize that the tool does not perform a simple "copy", since several other actions are also executed, in order to allow its concurrent execution [8].

The initial version of FERRARE did not generate the necessary data for the execution of performance and stress testing. Because of that, its automation level was very limited. This originated another project, with the goal of generating data for performance and stress testing, from an analysis of the data used for the execution of functional testing. Based on that, another module was created for FERRARE, named GENESIS. Its incorporation to the tool originated FERRARE GT [3].

GENESIS aims at generating data for performance and stress testing, by reusing the data from the functional test that serves as a basis for the generation of performance and stress testing. The behavior of the tool is based on the replication of the data derived from the functional test. The central idea implemented is that the replication of data from functional testing can work as a basis for the execution of various concurrent functional testing, resulting in a performance or stress testing.

It is important to emphasize that this approach eliminates the need of having knowledge of all the contraints related to the data model and the application business rules. Because the data are replicated from an instance of the database able to execute a functional test, the replicas should also keep the same feature. This approach is innovative, because it reduces the complexity for the data generation. The innovation is precisely in using a functional test, and the state of the database before its execution, for such replication.

III. Experimental study

A. Goal Definition

An experimental study with the goal of evaluating the use of FERRARE GT in a scenario of software development was performed. The purpose of the study was to evaluate, regarding effort and quality, from the point of view of the researcher, in the context of students of Computer Science, the feasibility of FERRARE GT in order to automate the data generation and performance and stress tests development for a Web system.

The experiment was executed in a controlled environment (in vitro) with the participation of students from Software Engineering Class from the Computer Science Course from UFPI (Federal University of Piauí).

The subjects had to create performance tests for a Web system on book loaning, named in this work BibSystem. The goal of this system is to allow students to perform book loans available in the library. The system users can authenticate themselves in the system, perform a loan, search for a book and return it. The Login (authentication) function was explored in the observation sections.

B. Planning

The experimental study was planned to be executed by students that attended the classes of Software Engineering I and II offered in the first semester of 2010. The Software Engineering I class is offered in the fifth semester of the course and the Software Engineering II class in the sixth, from a total of eight semesters.

The subjects did not have any experience at all in the use of functional testing tools neither in the use of performance and stress testing tools. A verification form was applied to certify this. Therefore, no planning at all was done regarding the type of grouping based on the profile of the subjects [10].

For the execution of the experiment it was planned the use of the tools Selenium (functional testing) and JMeter (performance and stress testing). Both tools were selected because of their big acceptance within the software development industry.

The goal of the study was to evaluate if the reuse of functional testing, for the generation of performance and stress testing, from the support of FERRARE GT is more effective than the development of the same tests in a direct way on JMeter tool. However, generating performance testing without the support of FERRARE GT does not imply only in creating

the test script for the selected tool (JMeter), as well as generating the data required for its execution. This generation is usually done using programs that execute data insertion commands in databases. There are other alternatives, but this was the one used for the study. It is important to emphasize that FERRARE GT does not only support the creation of test scripts, but also generates the data required for its execution.

As mentioned before, the use cases used in the study were Login and Loan. Performance testing for the Login function consisted of executing 100 concurrent authentications, making use of different users and verifying if this happened in up to 5s. Performance testing for Loan consisted of executing 100 different book loans, by different users and verifying if this happened in up to 8s.

Because of that, the main question related with the study was: does the use of FERRARE GT generate a reduction in the required effort for the creation of the performance testing, including the generation of the data necessary for the execution of the tests, when compared with the creation of the same tests using only JMeter? The null hypothesis, related to this question is: there is no difference in terms of effort, measured in minutes, to create tests and to generate data with or without the support of the tool, that is, H0: TestEffort(FERRARE_GT) = TestEffort(JMeter). The alternative hypothesis is that the effort applied in the test, with the support of the method is smaller than the effort applied without the use of the tool, that is, H1:TestEffort(FERRARE_GT) < TestEffort(JMeter).

The experimental sketch used was planned taking in consideration the possible threats to its validity. The Figure 2 summarizes the experimental sketch used. The highlighted parts identify the activities whose time spent by the subjects was registered. The other ones represent the training activities, which respect the times showed in the picture. As it can be visualized in the picture, all the participants had contact with both tools, but in different moments and performing exactly the same tasks. This allowed one group to act as a control of the other. The experiment was divided in two phases. In the first phase all the volunteers generated the data required to execute the 100 book loans simultaneously in the BibSystem. This included the generation of users, books and copies.

In the second phase, the subjects from the Group 1 (G1) should create tests using JMeter and only later create the same tests using FERRARE GT. The subjects from the Group 2 (G2) should begin creating the tests with FERRARE GT and later create tests with JMeter. The attribution to the groups was planned to be random. The selection of the participants was planned based on convenience; that is why the study is considered a quasi-experiment [10].

It was planned that all the tests created by the subjects would be verified by the paper authors, to certify their quality. This means that the difference between them would be only the way used to create them: either using FERRARE GT or JMeter itself. Each submission of the test generated a verification to certify its quality. If the test was not suitable, the registered errors would be highlighted and the subject should proceed with its correction.

The experimental study was planned to reduce threats related to its Internal Validity and External Validity, which are the most important ones related to the studies in the area of Software Engineering [10].

The internal validity defines if the relationship observed between the treatment and the result is causational and not an influence of other factors which are not controlled. The experimental design used reduces the risk of having a bias, since it was planned that every subject would use both treatments, but in different moments. It was also planned the use of the treatments in an alternated order, to evaluate if the execution order could influence the results.

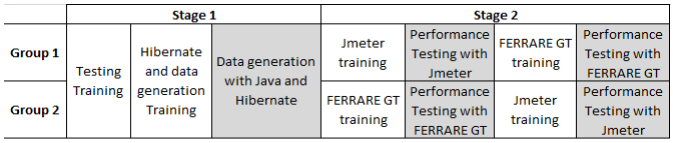

Figure 2. Experimental study scheduling.

The chosen experimental design, where all the subjects used both tools allowing one group to act as the control of the other, validates the conclusion obtained, in the same time that it reduces any threat related to the competitive behavior and to the compensatory behavior [10].

The external validity defines the conditions which limit the ability to generalize the results of an experiment for the industrial practice. The subjects, students from the 5th and 6th semesters of the course, find themselves in the final phase of under graduation, having similar skills of a professional with little experience. The performed trainings, along with the fixation exercise contributed to a good formation of the subjects in the used tools. The BibSystem, although small, had the characteristics commonly existents in Web information systems. Thus, it is believed that the conclusions obtained in the study can be extended to other systems, with the usual size and used by professionals with little experience, without losses in the observed results.

C. *Operation*

Before the beginning of the study activities it was performed a brief presentation related to the activities that would be executed, but the subjects did not have knowledge of the hypotheses that were being tested. It also guaranteed the anonymity of the students explaining even how the data collected would be used.

As mentioned before, the experiment was divided in two phases. In the first phase, all the subjects had training in software testing and in the use of Hibernate[1] and Java to generate data in MySQL database. In the second phase, the subjects had training in the tools that would be used and were asked to create performance tests for the BibSystem.

During the first phase a general vision about software testing was presented to the subjects. The training about tests lasted around 2h and focused on presenting the relevance of the tests, as well as the basic concepts related, the main techniques and existing objectives.

Afterwards, everybody participated in a training about the use of the Java language combined with the Hibernate framework for the generation of data in a MySQL database. The Java language was chosen because it is the one better dominated by the subjects. The Hibernate framework was selected because of the easiness it offers when working with database in the Java language. The MySQL database was used because of its broad use in the academic field and especially in the field where the study took place.

After the training, all the subjects created programs in Java that generated and stored in a MySQL database the required data for the execution of 100 concurrent loans in the BibSystem. It is emphasized that the generated data had to follow the database structure and constraints. The individual time spent by each subject in this activity was registered, since it was executed automatically with the support of FERRARE GT.

During the second phase, the study subjects had to create and execute performance tests for the Loan function. Firstly a training section was performed, lasting about 2 hours, about the tool that would be used. After that the tests were created and executed by the subjects. The Group 1 subjects began using only JMeter in the creation of the tests and used the data generated during the phase one to allow its execution. Afterwards, they used FERRARE GT to create tests for the same function. The Group 2 subjects executed the activities in a reverse path, beginning with FERRARE GT and only later doing the same activity using JMeter.

Twenty-one volunteers participated in the study, from whom 15 concluded all the planned activities. Thus, only the data from these 15 subjects were considered during the analysis and interpretation. This happened because the tests generated by some of them did not reach the quality limit specified. Because of that, their results were not considered concluded.

D. Analysis and Interpretation

Figure 3 presents the data collected from the study. Figure 4 presents the data in the form of a bar chart. Analyzing such data it is perceived that the subjects that used FERRARE GT dedicated an effort considerably smaller for creating performance tests.

The results certify that the idea proposed in FERRARE GT, that reusing functional testing for automation of performance testing is a good alternative. The effort for creating performance testing, as well as the preparation of the environment for its execution, mainly related to the generation of data, can be considerably reduced. This was noted analyzing all the subjects (that is, independent of group) as well as the groups individually. In both cases the gain was expressive and confirmed through student t test.

Group 1 subjects began the study using JMeter directly, while Group 2 began through the use of FERRARE GT. It is possible to notice that the time to generate a test with the use of FERRARE GT by Group 2 was expressively bigger than the time registered by Group 1 for the same task. This indicates that the learning obtained by utilizing JMeter beforehand favoured the use of FERRARE GT. This was expected, once the tools are similar and have similar goals. The knowledge gained with the use of one can influence the use of the other.

Group	Subject	FERRARE GT	Without Using FERRARE GT		
			Data Generation	Jmeter	Total
1	1	7	26	19	45
	2	5	39	19	58
	3	34	31	78	109
	4	6	28	57	85
	5	8	23	54	77
	6	8	45	80	125
	7	7	32	15	47
	8	7	22	58	80
	9	14	33	88	121
	10	9	17	45	62
	11	13	72	85	157
	Average	11	33	54	88
2	12	44	18	54	72
	13	39	26	102	128
	14	23	30	49	79
	15	40	23	74	97
	Average	37	24	70	94

Figure 3. Study data summary.

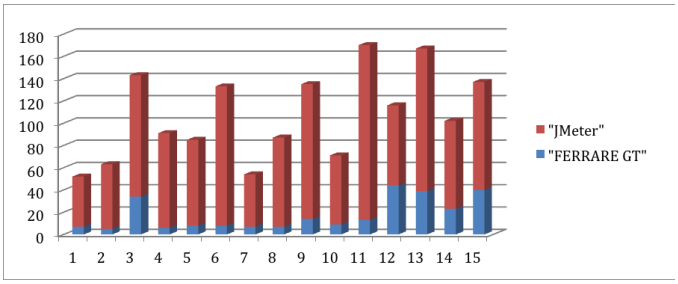

Figure 4. Bar chart showing the study results.

Analyzing the threats to the study, it can be noticed that it does not seem to have been any underlying factor that have interfered in the study. The results reflect the use of treatments and not uncontrolled factors.

Since the subjects had to automate tests for the same part of the system, using both FERRARE GT and JMeter, the problem of instrumentation was not noticed, since there is no difference in the problem used in the study.

Nothing related to the study indicated that there were any threats related to history, that is, it was not identified any external effects that could influence directly in the results differently from what was mentioned above. Relating to maturing, it is believed that the subjects improved with the experience, since they are students and are submitted to new contents, but nothing that could influence directly the result of the developed study.

IV. DISCUSSION

In this article, an experimental study to evaluate the impact of the reuse of functional testing for the generation of performance testing was presented. This was enabled by the tool FERRARE GT, which implements such an idea. It was

possible to verify that this approach is very promising. The effort to generate performance testing with support of the tool FERRARE GT is smaller than the effort to generate the same test without the support of the aforementioned tool.

Performance testing requires data for its execution. The required effort for such preparation can be an inhibiting factor in its use in the industrial environment. The example used in this work illustrates this well: to test the performance of the Loan function of the BibSystem it is necessary to have 100 users and 100 book copies available. Note that this is a fairly simple example and even so it demands a considerable effort. Any tool that helps reducing such effort is contributing to a systematization of performance testing, which is still seldom used by organizations.

The idea explored in this work was based on the reuse of functional testing. Since functional testing indicates the expected inputs and outputs to evaluate a behavior, we can execute such instance various times concurrently to evaluate the performance of this function. However, it is necessary to create copies of the required data, so that each test uses its own data and does not interfere in the execution of the other. The study certified the viability of the proposal, having obtained surprising results to the continuity of the work.

Reusing functional testing to generate performance and stress testing can still bring indirect gains not measured in the study: bigger diffusion of the use of functional testing, because now they have a more important role in the development process, and a bigger quality of the generated tests, since the saved effort can be used in nobler activities.

V. Conclusion and future works

In this work an experiment performed in order to validate the applicability of a tool for the generation of data and performance and stress testing by reusing functional testing, named FERRARE GT, was described. The basic idea is to reuse the existing information from functional tests, in such a way that both the performance and stress testing and the required data for its execution are automatically generated.

Based on the study performed, it was noticed that the use of FERRARE GT in an organization that already performs functional testing can bring a reduction in the effort required to create performance tests and to generate the required data for its execution. This facilitates the systematic use of performance and stress testing by organizations, since the required effort for its use is reduced. Also, the relevance of the functional test increases, what is benefic to the organization, which will be able to give more importance to something that is already considered fundamental by most industries.

As a future work it is intended to increase the experimental study. Also, it is intended to use the tool developed in an industrial environment. FERRARE GT also has many possibilities of improvement, which will be able to allow its use in a simpler and more effective way, raising the associated gains.

VI. acknowledgements

This work was supported by grants from UFPI and CNPq (560128/2010-0). Infoway Technology provided some software products for testing and IT professionals to discuss the directions.

Abstract — **We present, in this paper, a new metric capturing in an integrated way different attributes of object-oriented systems. The metric uses basically control flow paths and probabilities. It captures the interactions between classes and related control. The study presented in this paper aims at exploring empirically the relationship between the proposed metric and testability of classes. We investigate testability from the perspective of unit testing. We designed and conducted an empirical study using data collected from two open source Java software systems for which JUnit test cases exist. To capture testability of classes, we used different metrics to quantify the corresponding JUnit test cases. In order to evaluate the capability of the new metric to predict testability of classes, we used statistical tests using correlation. The achieved results provide evidence that there exist a significant relationship between the proposed metric and testability of classes.**

Keywords: Software Testability, Testing Effort, Metrics, Control Flow, Control Dependencies, Probabilities and Empirical Analysis.

I. INTRODUCTION

Software testing has an important effect on the quality of the final product. Software testing is probably the most complex task in the software development cycle. It's also a time and resources consuming process. The overall effort spent on testing depends, in fact, on many different factors including: human factors, process issues, testing techniques, tools used, and characteristics of the software development artifacts [3, 4, 9, 35, 36]. Testability is an important quality characteristic of software. Software testability is related to testing effort reduction and software quality [14]. It impacts test costs and provides a means of making design decisions [31]. Zhao [36] argues that testability expresses the affect of software structural and semantic on the effectiveness of testing following certain criterion, which decides the quality of released software. Several software development and testing experts pointed out, in fact, the importance of testability and design for testability. Moreover, Baudry et *al.* [3] argue that testability becomes crucial in the case of object-oriented systems (OOS) where control flows are generally not hierarchical, but diffuse and distributed over whole architecture.

Metrics can be used to predict testability and better manage the testing effort. Having quantitative data on the testability of a software can, in fact, help software managers, developpers and testers to [8, 15]: plan and monitor testing activities, determine the critical parts of the code on which they have to focus to ensure software quality, and in some cases use this data to review the code. A large number of object-oriented metrics (OOM) have been proposed in literature [17]. Some of these metrics (such as coupling, complexity and size) have already been used to measure testability of OOS [8]. However, as stated by Gupta et *al.* [15], none of the OOM is alone sufficient to give an overall reflexion of software testability. Software testability is, in fact, affected by many different factors.

We presented in a previous work [2] a new metric, called *Quality Assurance Indicator* (Qi), capturing in an integrated way different attributes of OOS such as complexity and coupling (interactions between classes). The metric uses control flow paths (capturing the distribution of the control flow in a system) and probabilities. The Qi of a class C_i includes different intrinsic characteristics of the class itself, as well as the Qi of collaborating classes. The metric has, however, no ambition to capture the overall quality of OOS. Moreover, the objective is not to evaluate a design by giving absolute values, but more relative values that may be used, for example, for identifying the critical classes that will require a high testing effort to ensure software quality. The metric has been implemented for Java programs. We compared, in [2], the Qi metric using the Principal Components Analysis (PCA) method to some well-known OOM. The evaluated metrics were grouped in five categories: coupling, cohesion, inheritance, complexity and size. The objective was to find in which proportions the Qi metric captures the information provided by the selected OOM. The obtained results provided evidence that the Qi metric captures, overall, more than 75 % of the information provided by most of the evaluated metrics. The purpose of the present paper is to explore empirically the relationship between the Qi metric and testability of classes in OOS in terms of the effort needed for testing. We investigate testability from the perspective of unit testing, where units consist of the classes of an OOS. We designed and conducted an empirical study using data collected from two open source Java software systems for which JUnit test cases exist. To capture testability of classes, we used different metrics to measure some characteristics of the corresponding JUnit test cases. In order to evaluate the capability of the new metric to predict testability of classes, we used statistical tests using correlation.

The remainder of the article is organized as follows: Section 2 gives a survey on related work on software testability. The proposed metric is presented in Section 3. In Section 4 we define the used metrics to quantify JUnit test classes, describe the experimental design and discuss the statistical technique we used. Section 5 presents the used systems. We also present and discuss in this section the obtained results. Finally, Section 6 summarizes the contributions of this work and outlines directions for further research.

II. SOFTWARE TESTABILITY

IEEE [18] defines testability as the degree to which a system or component facilitates the establishment of test criteria and the performance of tests to determine whether those criteria have been met. ISO [19] defines testability (characteristic of maintainability) as attributes of software that bear on the effort needed to validate the software product. Fenton et *al.* [11] define testability as an external attribute. Indeed, testability is not an intrinsic property of a software artifact and cannot be measured simply such as size, complexity or coupling. Testability measurement is, in fact, influenced by various parameters as stated by Baudry et *al.* [3, 4]. Yeh et *al.* [35] argue also that diverse factors such as control flow, data flow, complexity and size contribute to testability. According to Zhao [36], testability is an elusive concept, and it is difficult to get a clear view on all the potential factors that can affect it. Freedman introduces testability measures for software components based on two factors: observability and controllability [12]. Voas defines testability as the probability that a test case will fail if the program has a fault [32]. Voas and Miller [33] propose a testability metric based on the inputs and outputs domains of a software component, and the PIE (Propagation, Infection and Execution) technique to analyze software testability [34]. Binder [7] discusses software testability based on six factors: representation, implementation, built-in text, test suite, test support environment and software process capability. Khoshgoftaar et *al.* address the relationship between static software product measures and testability [23, 24]. McGregor et *al.* [28] investigate testability of OOS and introduce the visibility component measure (VC). Bertolino et *al.* [6] investigate testability and its use in dependability assessment. Le Traon et *al.* [25, 26, 27] propose testability measures for data flow designs. Petrenko et *al.* [30] and Karoui et *al.* [21] address testability in the context of communication software. Sheppard et *al.* [31] focus on formal foundation of testability metrics. Jungmayr [20] investigates testability measurement based on static dependencies within OOS. Gao et *al.* [13] consider testability from the perspective of component-based software construction, and address component testability issues by introducing a model for component testability analysis [14]. Nguyen et *al.* [29] focus on testability analysis based on data flow designs in the context of embedded software. Baudry et *al.* address testability measurement (and improvement) of OO designs [3, 4, 5]. Metrics can, in fact, be used to locate parts of a program which contribute to a lack of testability. Bruntink et *al.* [8, 9] investigate factors of OOS testability and evaluate a set of well-known OOM with respect to their capabilities to predict testability of classes of Java software systems. Bruntink et *al.* investigate testability from the perspective of unit testing. Khan et *al.* [22] focus also on class level testability using OOM. Chowdhary [10] focuses on why it is so difficult to practice testability in the real world.

III. QUALITY ASSURANCE INDICATOR

In this section, we give a summary of the definition of the *Quality Assurance Indicator (Qi)* metric. The Qi metric is based on *control call graphs*, which are a reduced form of traditional *control flow graphs*. A *control call graph* is a *control flow graph* from which the nodes representing instructions, or basic blocs of sequential instructions, not containing a call to a method are removed. The Qi metric is normalized and gives values in the interval [0, 1]. A low value of the Qi of a class reflects that the class (is a high-risk class and) needs more testing effort to ensure its quality, while a high value indicates that (the class is a low-risk class knowing that) the testing effort invested effectively on the class is high (proportional to its complexity). The Qi of a class depends on the Qi of its collaborating classes (invoked classes).

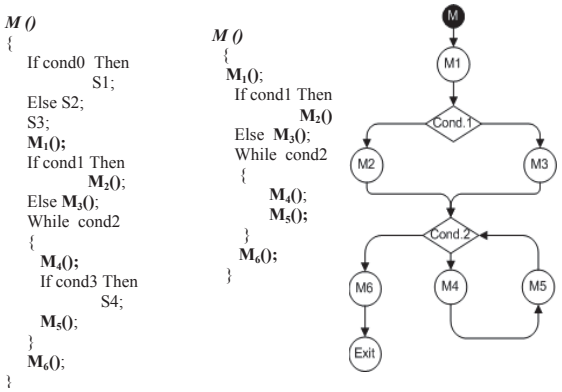

Figure 1 A method and its corresponding control call graph.

A. Control Call Graphs

Let us consider the example of method M given in Figure 1.1. The S_i represent blocs of instructions that do not contain a call to a method. The code of method M reduced to *control call flow* is given in Figure 1.2. The instructions (blocs of instructions) not containing a call to a method are removed from the original code of method M. Figure 1.3 gives the corresponding *control call graph*. Unlike traditional *call graphs*, *control call graphs* are much more precise models. They capture the structure of calls and related control.

B. Quality Assurance Indicator

We define the Qi of a method M_i as a kind of estimation of the probability that the control flow will go through the method without any *failure*. It may be considered as an indicator of the risk associated to a method (and a class at a high level). The Qi of a method M_i depends, in fact, on various intrinsic characteristics of the method itself, such as its unit

testing coverage (testing effort actually invested on the method) and its cyclomatic complexity, as well as on the Qi of all the methods invoked by the method M_i. We assume, in fact, that the quality of a method, particularly in terms of reliability, depends also on the quality of the methods it collaborates with to perform its task. In OOS, objects collaborate to achieve their respective responsibilities. A method of poor quality (lowly tested) can have (directly or indirectly) a negative impact on the methods that use it. There is here a kind of propagation, depending on the distribution of the control flow in a system, that needs to be captured. It is not obvious, particularly in the case of large and complex OOS, to identify intuitively this type of interferences between classes. The Qi of a method M_i is given by:

$$Qi_{M_i} = Qi^*_{M_i} * \sum_{j=1}^{n_i} \left(P\left(C_j^i\right) * \prod_{k \in \sigma} Qi_{M_k} \right) \quad (1)$$

with : Qi_{Mi}: quality assurance indicator of M_i, Qi^*_{Mi}: intrinsic quality assurance indicator of M_i, $P\left(C_j^i\right)$: probability of execution of path C_j^i of M_i, Qi_{Mk}: quality assurance indicator of the methods included in the path C_j^i, n_i: number of linear paths of the control call graph of M_i, and $Card(\sigma)=m_j$: number of the methods included in the path C_j^i. By applying the previous formula (1) to each method we obtain a system of N equations (N is the number of methods in the program). The obtained system is not linear and is composed of several multivariate polynomials. We use an iterative method (method of successive approximations) to solve it. The system is, in fact, reduced to a fixed point problem. Furthermore, we define the Qi of a class as the product of the Qi of its public methods. The calculation of the Qi metric is entirely automated by an Eclipse plug-in that we developed for Java software systems.

C. Assigning Probabilities

The *control call graph* of a method can be seen as a set of paths that the control flow can pass through. Passing through a particular path depends, in fact, on the states of the conditions in the control structures. To capture this probabilistic characteristic of the control flow, we assign a probability to each path C_k of a *control call graph* as follows:

$$P(C_k) = \prod_{i=0}^{n_k} P(A_i) \quad (2)$$

where A_i are the directed arcs composing the path C_k. By supposing, to simplify analysis and calculations, that the conditions in the control structures are independent, the $P(A_i)$ becomes the probability of an arc of being taken when exiting a control structure. The $P(C_k)$ are then reduced to a product of the probabilities of the states of the conditions in the control structures. To facilitate our experiments, we assigned probabilities to the different control structures of a Java program according to the rules given in TABLE I. These values are assigned automatically during the static analysis of the source code of a program when generating the Qi models. As an alternative way, the probabilities values would also be obtained by dynamic analysis, or assigned by programmers (knowing the code). Dynamic analysis will be considered in a future work.

TABLE I ASSIGNMENT RULES OF THE PROBABILITIES.

Nodes	Probability Assignment Rule
(if, else)	0.5 for the exiting arc « condition = true » 0.5 for the exiting arc « condition=false »
while	0.75 for the exiting arc « condition = true » 0.25 for the exiting arc « condition = false »
(do, while)	1 for the arc: (the internal instructions are executed at least once)
(switch,case)	1/n for each arc of the n cases.
(?, :)	0.5 for the exiting arc « condition = true » 0.5 for the exiting arc « condition = false »
for	1 for the arc
(try, catch)	0.75 for the arc of the « try » bloc 0.25 for the arc of the « catch » bloc
Polymorphism	1/n for each of the eventual n calls.

D. Intrinsic Quality Assurance Indicator

The *Intrinsic Quality Assurance Indicator* of a method M_i, noted Qi^*_{Mi}, depends on its cyclomatic complexity as well as on its unit testing coverage (as an indicator of the testing effort). It is given by:

$$Qi^*_{M_i} = \left(1 - \frac{F_i}{F_{\max}}\right) \quad (3)$$

with: $F_i = cc_i * (1 - tc_i)$, where : cc_i : cyclomatic complexity of the method M_i, and tc_i : unit testing coverage of the method M_i, $tc_i \in [0, 1]$.

$$F_{\max} = \max_{1 \le i \le N} \left(F_i\right)$$

Cyclomatic complexity can help software engineers determining the inherent risk of a program. Several studies provided empirical evidence that there is a significant relationship between cyclomatic complexity and fault proneness [1, 37]. Cyclomatic complexity is also recognized as a good indicator of testability [8, 9]. The more the cyclomatic complexity of a program is high, the more likely its testing effort would be high. Testing activities will reduce the risk of a complex program and achieve its quality. Moreover, testing coverage provide objective measures on the effectiveness of a testing process.

IV. EXPERIMENTAL DESIGN

The goal of this study is to explore empirically the relationship between the Qi metric and testability of classes in OOS. We evaluate the Qi metric at the class level, and limit the testing effort to the unit testing of classes. For our experiments, we selected from each of the used systems only the classes for which JUnit test cases exist. In this section, we present the metrics we used to quantify the testing effort required for a class by evaluating the corresponding JUnit test class, and describe the experimental design.

A. Metrics Related to Testability

To indicate the testing effort required for a software class (noted C_s), we used various metrics to quantify the corresponding JUnit test class (noted C_t). JUnit[1] is a simple framework for writing and running automated unit tests for

1 www.junit.org

Java Classes. Test cases in JUnit are written by testers in Java. A typical usage of JUnit is to test each class C_s of the program by means of a dedicated test class C_t. We used in our experiments each pair $<C_s, C_t>$ for classes for which test cases exist. The objective is to use these pairs to evaluate the relationship between the Qi metric and the measured characteristics of the test classes C_t. To capture testability of classes, we decided to measure for each test class C_t, corresponding to a software class C_s, various characteristics. We used the following suite of *test case metrics*:

- *TLOC*: This metric gives the number of lines of code of the test class C_t. This metric is used to indicate the size of the test suite corresponding to a class C_s.
- *TAssert*: This metric gives the number of invocations of JUnit *assert* methods that occur in the code of a test class C_t. The set of JUnit *assert* methods are, in fact, used by the testers to compare the expected behaviour of the class under test to its current behaviour. This metric is used to indicate another perspective of the size of a test suite. It is directly related to the construction of the test cases.
- *THEff*: This measure is one of the Halstead Software Science metrics [16]. This metric gives the effort necessary to implement or understand a test class C_t. It is proportional to the volume and to the difficulty level of the test class. We assume that this will reflect also the difficulty of the class under test and the effort required to construct the corresponding test class.

The approach used in this paper is based on the work of Bruntik et *al.* [8]. Two of the used test case metrics (*TLOC* and *TAssert*) have, in fact, been introduced by Bruntink et *al.* in [8, 9] to indicate the size of a test suite. Bruntink et *al.* based the definition of these metrics on the work of Binder [7]. We assume, in this paper, that these metrics are indicators of the testability of classes. These metrics reflect different source code factors as stated by Bruntink et *al.* in [8, 9]: factors that influence the *number of test cases required* to test the classes of a system, and factors that influence the *effort required to develop each individual test case*. These two categories have been referred as *test case generation factors* and *test case construction factors*. However, by analyzing the source code of the JUnit test classes of the systems we selected for our experiments, we feel that some characteristics of test classes are not captured by these two metrics (like the set of local variables or invoked methods). Since our work is exploratory in nature, we decided to extend the two metrics *TLOC* and *TAssert* by using the *THEff* metric to quantify the global effort necessary to implement a test class. We used this suite of metrics for characterizing the testing effort of classes. We assume that the effort necessary to write a test class C_t corresponding to a software class C_s is proportional to the characteristics measured by the used suite of test case metrics.

B. Data Collection

We calculated the values of the Qi (and Qi^*) metric for all classes for which JUnit test cases exist. We used the Eclipse plug-in we developed. For our experiments, we fixed the unit testing coverage to 75% for each of the methods of the analyzed systems. Furthermore, we evaluated other values of testing coverage. The obtained results were substantially the same (in a relative way). We also used the suite of test case metrics to quantify, for each of the subject systems, the JUnit test classes C_t that have been developed by the programmers using the JUnit framework. The test case metrics have been computed using the Borland Together tool.

C. Goal, Hypotheses and Statistical Analysis

We present, in this section, the methodology of the empirical study we conducted in order to assess the relationship between the Qi (and Qi*) metric and testability of classes. We performed statistical tests using correlation. The null and alternative hypotheses that our experiments have tested were:

- H_0: There is no significant correlation between the Qi metric and testability.
- H_1: There is a significant correlation between the Qi metric and testability.

In this experiment, rejecting the null hypothesis indicates that there is a statistically significant relationship between the Qi metric and test case metrics (the chosen significance level is α=0.05). For the analysis of the collected data, we preferred a non-parametric measure of correlation in order to test the correlation between the Qi (and Qi*) metric and the suite of test case metrics. We used the Spearman's correlation coefficient. This technique, based on ranks of the observations, is widely used for measuring the degree of linear relationship between two variables (two sets of ranked data). It measures how tightly the ranked data clusters around a straight line. Spearman's correlation coefficient will take a value between -1 and +1. A positive correlation is one in which the ranks of both variables increase together. A negative correlation is one in which the ranks of one variable increase as the ranks of the other variable decrease. A correlation of +1 or -1 will arise if the relationship between the ranks is exactly linear. A correlation close to zero means that there is no linear relationship between the ranks. We used the XLSTAT software to perform the statistical analysis.

V. EMPIRICAL STUDY

A. Selected Systems

The selected systems are : ANT (www.apache.org): a Java-based build tool, with functionalities similar to the unix "make" utility, and JFREECHART (http://www.jfree.org/jfreechart): a free chart library for Java platform.

TABLE II summarizes some characteristics of the analyzed systems : number of software classes, number of attributes, number of methods, number of lines of code, average value of lines of code, average value of cyclomatic complexity, percentage of tested classes (software classes for which JUnit test cases have been developed), number of JUnit test classes, and for software classes for which JUnit test classes have been developed : total number of lines of code, average value of lines of code and average value of cyclomatic complexity.

TABLE II SOME CHARACTERISTICS OF THE USED SYSTEMS.

	SOFTWARE CLASSES							TESTED SOFTWARE CLASSES			
SYSTEMS	#Classes	#Attributes	#Methods	LOC	MLOC	MWMPC	%TestedClasses	#TClasses	LOC	MLOC	MWMPC
ANT	713	2491	5365	64062	89.85	17.1	16.1%	115	17655	153.52	30.37
JFC	496	1550	5763	68312	137.73	28.09	46.37%	230	53131	231	46.08

The first observations that we can already make are: only a subset of software classes have been tested using JUnit, the pourcentage of tested classes varies from one system to another, and the software classes for which JUnit test cases have been developped are in general large and complex classes.

B. Results

For each pair <C_s, C_t> we analyzed the collected data set by calculating the Spearman's correlation coefficient r_s for each pair of metrics. TABLE III summarizes the results of the correlation analysis. It shows, for each of the subject systems and between each distinct pair of metrics the obtained values for the Spearman's correlation coefficient. We also calculated the Spearman's correlation coefficient r_s for each pair of test case metrics (TABLE IV). The obtained Spearman's correlation coefficients that are significant (at α=0.05) are set in boldface in the two tables. This means that for the corresponding pairs of metrics there exist a correlation at the 95 % confidence level.

TABLE III CORRELATION VALUES BETWEEN THE Q_i AND Q_i* METRICS AND TEST CASE METRICS.

ANT	TLOC	TAssert	THEff
Qi	**-0.560**	**-0.326**	**-0.448**
Qi*	**-0.586**	**-0.393**	**-0.523**

JFC	TLOC	TAssert	THEff
Qi	**-0.425**	**-0.365**	**-0.353**
Qi*	**-0.447**	**-0.458**	**-0.439**

TABLE IV CORRELATION VALUES BETWEEN TEST CASE METRICS.

ANT	TLOC	TAssert	THEff
TLOC	**1**	**0.679**	**0.900**
TAssert		**1**	**0.781**
THEff			**1**

JFC	TLOC	TAssert	THEff
TLOC	**1**	**0.848**	**0.922**
TAssert		**1**	**0.896**
THEff			**1**

The first global observation that we can make is that the obtained results confirm that there is a significant relationship between the Qi and Qi* metrics and the used test case metrics. The obtained Spearman's correlation coefficients between the Qi and Qi* metrics and the test case metrics are all significant (at α=0.05) for the two selected systems (for all the pairs of metrics). We can reject the hypothesis H_0 and accept the hypothesis H_1. Moreover, the measures have negative correlation. As mentioned previously, a negative correlation indicates that the ranks of one variable (Qi and Qi* values in our case) decrease as the ranks of the other variable (test case metric) increase. These results are plausible knowing that the more classes (and methods) are complex, the more they are difficult to test and their Qi (and Qi*) values decrease. The second global observation that we can make is that the Qi* metric is, overall, better correlated to the test case metrics than the Qi metric. This may be explained by the fact that the metric Qi* takes into account only the inherent characteristics of methods (and classes) compared to the metric Qi which take into account the dependencies between methods (and classes). The other global observation that we can make is that the test case metrics are also correlated between themselves (TABLE IV).

C. Limitations

The study performed in this paper should be replicated using many other systems in order to draw more general conclusions about the relationship between the metrics Qi and Qi* and testability. In fact, there are a number of limitations that may affect the results of the study or limit their interpretation and generalization. The obtained results are based on the data set we collected from the analyzed systems. To collect data we only used a subset of classes (and corresponding JUnit test cases) from each of the subject systems. From TABLE II we can see that for system ANT we used only 115 software classes and corresponding JUnit test cases, and for system JFREECHART we used 230 software classes and corresponding JUnit test cases. In total, we analyzed 345 software classes and corresponding JUnit test classes. Even if we believe that the analyzed set of data is enough large to allow obtaining significant results, the study should be, however, replicated on a large number of OOS to increase the generality of the results. Moreover, we can also observe from TABLE II that the classes for which JUnit test cases have been developed are relatively large and complex classes. This is true for the two subject systems. This may affect the results of our study in the sense that depending on the methodology followed by the developers while developing test classes and the criteria they used while selecting the software classes for which they developed test classes (randomly or depending on their size or complexity for example, or on other criteria) the results may be different. It would be interesting to replicate this study using systems for which JUnit test cases have been developed for a maximum number of classes. By analyzing the source code of the JUnit test classes, we observed that, in many cases, they do not cover all the methods of the corresponding software classes. This may also affect the results of the study. It is also possible that facts such as the development style used by the developers for writing test cases might affect the results or produce different results for specific applications.

VI. CONCLUSIONS AND FUTURE WORK

We presented, in this paper, a metric capturing in an integrated way different attributes of OOS. The metric, called *Quality Assurance Indicator*, uses control flow paths and probabilities, and captures the collaboration between classes. The paper investigated empirically the relationship between the proposed metric and testability of classes. Testability has

been investigated from the perspective of unit testing. As a first attempt, we designed and performed an empirical study on two open source Java software systems, for which JUnit test cases exist. We used three metrics for characterizing the JUnit test classes. We performed statistical tests using correlation. The achieved results support the idea that there is a statistically and practically significant relationship between the Qi and Qi* metrics and the used test case metrics.

The performed study should, however, be replicated using many other systems in order to draw more general conclusions. The findings in this paper should be viewed as exploratory and indicative rather than conclusive. Moreover, knowing that software testability is affected by many different factors, it would be interesting to extend the used suite of test case metrics to better reflect the testing effort. We hope, however, this study will contribute to a better understanding and characterizing of what contributes to testability of classes in OOS. As future work, we plan: to extend the used test case metrics to better reflect the testing effort, to extend the study by using some well-known OOM, and to replicate the study on other projects to be able to give generalized results.

ACKNOWLEDGEMENTS

EMPIRICAL STUDY UPON SOFTWARE TESTING LEARNING WITH SUPPORT FROM EDUCATIONAL GAME

Marcello Thiry, Alessandra Zoucas and Antônio C. da Silva
Master's degree course in Applied Computing
Universidade do Vale do Itajaí - UNIVALI
Florianópolis, Brazil
{thiry, azoucas, antonio.carlos}@univali.br

Abstract— **Although software testing is seen as one of the main quality measurements of software, test practices and techniques are still seldom applied by software development companies. One possible reason to this scenario is the lack of skilled and available professionals to implements such techniques and practices. The teaching of software testing is typically approached as a topic of Software Engineering lectures. In this context, one of the main challenges is to allow the student to apply the concepts seen in classroom. The developed educational game aims to allow the students to practice through experimenting concepts, techniques and practices of software testing in a simulated environment. To evaluate the game contribution, we present the results of two experiments performed with undergraduate students. In the first experiment the learning effectiveness was compared to students who did not play the game. In the second experiment, the learning effectiveness was compared to a traditional pencil-and-paper exercise.**

Keywords: Software testing; educational game; learning; Experimental Software Engineering.

I. INTRODUCTION

The quality control and assurance in software projects consist in activities and techniques that, when systematically applied, permit to assess the chances of success of a software project concerning the fulfillment of the expectations of internal and external clients [1]. Models as CMMI [2] include concepts and practices to increase capacity and maturity of an enterprise's processes [3]. Lined up with the models and standards of process, Software Engineering (SE) gathers activities and techniques that excel by anticipating, in a systematic, organized and controlled way, the identification of nonconformities in software. These activities and techniques are called Verification and Validation (V&V).

Although software testing is present in the developing process, researches show that its techniques and practices are not totally employed by the software development organizations [4] [5]. In the research performed in [4] it was evidenced that, even though the organizations admit they apply software tests, almost half (48,5%) of software testing practices are regarded as not applied and not important. Among the practices regarded as not applied and not important are all those related to measurement and analysis, including test coverage [6]. Considering these results, we can conclude there are a great amount of practices regarded as not important and not applied, regardless how big the companies are [4]. The reasons for that include the lack of knowledge about the practices, lack of skilled and available human resources to its implement, lack of support of high level managers, lack of approaches, among others.

The results obtained in [4] confirm the results of another study performed in 2004 that assessed software testing in software development enterprises [6]. It was observed a great distance between what is produced in the academic environment and what is put into practice by software enterprises. The results allow verifying how immature the assessed enterprises are, concerning software testing.

One of the challenges of teaching SE is the necessity to assure that the student acquires enough experience in applying the concepts through laboratory practices [7]. As an alternative to the practical approach in Software Engineering, an experiment performed with Computer Science undergraduate students explored the possibility of having the students working on a real software project [8]. Before the experiment application, it was verified that the SE students from the third semester had little capacity to remember concepts already approached and the possible cause was the little practice the students had. The experiment main goal was the application of concepts and techniques of Software Engineering [8]. The result identified greater motivation and interest from the participants in the SE subject.

Other approach to the practice in SE teaching refers to the application of educational games [9][10][11][12]. However, it is possible to verify a small number of experiments performed to verify the games learning effectiveness [9][10][11][12]. In this context, this paper intends to promote learning software testing techniques and practices through an educational.

The next section presents researches related to this work. Section III presents the developed game "U-TEST". The details of the game learning effectiveness assessment are presented in section IV. Section V presents a discussion on the results and the conclusions of this paper.

II. Related Work

The analysis of similar solutions, besides the definition of the assessment criteria was based in a search using different information sources: Google Scholar, CiteSeer, IEEExplorer and ACM Digital Library. At first, specific games to support Software Engineering teaching were sought, using a protocol containing terms such as: *software testing game learning, software testing game based learning, software testing teaching approach*, among others. As a result, it was observed the absence of games in software testing. Therefore, games to support Software Engineering teaching in general were chosen. In this new search, seven games were found: (1) **SimSE** [9], (2) **SE•RPG** [10], (3) **TIM - The Incredible Machine** [13], (4) **Planager** [14], (5) **SESAM** [11], (6) **X-MED** [12] e (7) **SimulES** [15].

The games were analyzed under seven criteria: (1) It has the definition of educational goals; (2) Game genre: action, adventure, puzzle, simulation, strategy, etc.; (3) It gives a feedback to the students about their performance; (4) The game is available for free use; (5) There is game learning effectiveness assessment; (6) Game platform: non digital, web, desktop, etc. ; and (7) Field of knowledge on SE.

Characterization of the works assessed uses the following description: (T) Totally present; (P) Partially present and (N) Not present. Table I presents criteria and assessment results.

TABLE I. Assessed Games Result

	SimSE	SE•RPG	TIM	Planager	SESAM	X-MED	SimulES
1	T	P	P	P	T	T	P
2	Simulation	Simul. RPG	Simulation	Simulation	Simul Advent	Simulation	Simulation
3	T	T	P	T	T	T	T
4	T	T	T	T	T	T	T
5	T	T	T	N	T	T	P
6	desk top	web	desk top	desk top	desk top	desk top	not digital
7	Project Mgmt	Project Mgmt	Project Mgmt	Project Mgmt	Project Mgmt	Softw. measu rem.	Softw. pro cess

There is a concern in most studies according to the importance of experiments to the game learning effectiveness assessment, although they was not applied to all assessed games. Based on the results, little can be concluded about the game learning effectiveness and it continues to be a topic to be explored in future studies [10]. It was also observed that most of the games focus on project management or general Software Engineering. Thus, specific games in software testing may increase the didactic content and offer a complement to traditional capacitating.

III. The Educational Game "U-TEST"

This section presents the educational game "U-TEST" developed to assist software testing teaching. The game has an instructional design based on ADDIE model [16] and it was designed to support Software Engineering students. It is expected the students have basic concepts of programming, Software Engineering and software testing. The educational goals were based on the Bloom's revised taxonomy [17] and comprehend the Remember, Understand and Apply levels. The game goals are: (1) Recognize and Understand the main concepts of software testing in a general way and (2) Understand and apply the techniques of data entry selection, equivalence class partitioning and boundary-value analysis.

"U-TEST" is a simulation game to support software testing with focus on unit tests and black box techniques, approaching theoretical and practical questions. The game is based on a case where the player is seen as a candidate to a position in a software company. After an interview the player must solve challenges to prepare unit test cases. The game presents brief comments about the company and the project the player will take part. Next, the player must build the test cases to the presented functions. As a result of their performance, the player is informed about his position on the players' ranking. The challenges proposed by the game focus mainly on the data entry selection, using a combination of equivalence classes partition and limit value analysis. It allows the player to identify the necessity of application of test techniques and practices. Figure 2 presents the screen of the first challenge of the game.

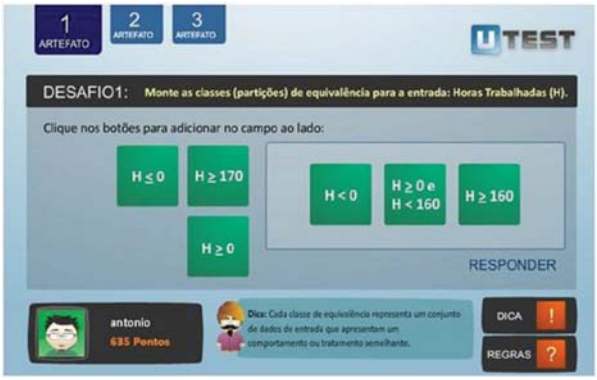

Figure 2- Screen of the "U-TEST" game.

During the game, the player will undergo ten stages, and in six of them there are the following challenges: 1) Presentation of the artifact; 2) Setup the equivalence classes; 3) Define limit values for the identified classes; 4) Select the correspondent value to the identified value; 5) Setup a cause-effect graph or decision tree; and 6) Project final feedback. The feedback is provided by a graphic indicator placed on the interface and at the end of each challenge. The player is informed about their performance and its indicator is updated. At the end of the game, the player is informed about their general performance and position on the players' ranking.

IV. Learning Assessment

A. The Empirical Study

During this study, two research questions were defined: 1) Is the learning effect on the remembering, understanding and applying level in the group of students that played the

game higher than in the group that didn't play?; 2) Is the educational game considered appropriate in terms of content relevancy, correctness, sufficiency and degree of difficulty, sequence, teaching method and duration in the context for which it is intended? Is the game considered engaging?

Based on the first research question, it was established the following hypotheses:

- **H_0**: There is no significant difference in relative learning effectiveness between group A (experimental group) and group B (control group).
- **H_1**: There is significant difference in relative learning effectiveness between group A and group B.

These hypotheses were assessed from a statistical test whereas the second research question was assessed from the qualitative assessment based on the questionnaire answered by students.

Two experiments were performed, the first one involving Computer Science undergraduate students and the second one involving Information Technology undergraduate students. Each experiment was based on the proposal defined by Kochanski [18]: 1) the assessment was designed considering all the contents fulfilled in the game; 2) the students signed a term showing interest in taking part on the experiment; 3) the students filled a questionnaire about their experience and previous knowledge to establish each student and group backgrounds; 4) all students attended theoretical lectures about software testing before playing the game; 5) all students performed a *pretest* measuring their knowledge after the lectures; 6) the students were randomly partitioned into two groups in a balanced manner, one experimental group (A) and other control group (B); 7) in the first experiment, the group A played the game and the group B played another game with no relation to Software Testing (this game was considered a placebo). In the second experiment, the group B took part in a traditional pencil-and-paper exercise with problems to solve on the same content explored in the game; 8) all students performed a *posttest* measuring again their knowledge after the previous step; 9) using the data collected from pre and posttest, hypothesis tests were conducted to verify any improvement on student's performance after playing the game; 10) all students in the group A answered questions related to their perception of the game (this questionnaire served as a base to a qualitative assessment of the game).

The pre and posttest questions (steps 5 and 8) were developed based on the Bloom's revised taxonomy [17] and comprehend the Remember, Understand and Apply levels.

B. Hypothesis Testing and Data Analysis

In this series of experiments, our principal concern for accuracy and to overcome problems with statistical power is due to the very small sample size. For such small data sets, it is basically impossible to tell, if the data come from a variable that is normally distributed [19], as with small sample sizes ($n < 20$), tests of normality may be misleading. Unfortunately, with small samples, parametric tests lack statistical power and it may be almost impossible to generate a p-value of < 0.05, whatever the differences between the groups of sample data. But, on the other side, nonparametric tests are not robust. However, inspecting the data distribution we could not assume a normal distribution of the variables. Therefore, we used non-parametric test (one-tailed Mann-Whitney U) as it is considered the most powerful nonparametric alternative to the t-test for independent samples. Due to the small samples size ($n<20$), we also did not use a z-value to approximate the significance level for the test, but compared the minimum U to tabellized U values [19].

The first experiment was performed with ten Computer Science undergraduate students. They are independently and randomly sorted into two groups, the first of size $n_A = 5$ (experimental group) and the second of size $n_B = 5$ (control group). The students of the group A played the game "U-TEST", while those of the group B played another game with no relation to Software Testing (this game was considered a placebo). Both groups performed a pretest (before the treatment) and a posttest (after the treatment). Each test has 20 questions distributed according to the Remember, Understand and Apply levels (Bloom's revised taxonomy).

The first step was to assembly the measures (each measure represents the difference between the student pretest and posttest scores) from groups A and B into a single set of size $N = n_A + n_B = 10$. These measures were then rank-ordered from lowest (#1) to highest (#N). When measure entries are tied for ranks, each measure receives the average of those ranks. After they have been sorted out, the rankings are then returned to the group, A or B, which they belong and substituted for the original measures that gave rise to them.

The next step was to calculate w_A (the sum of the n_A ranks in group A) e w_B (the sum of the n_B ranks in group B). In this experiment, $w_A = 40$ e $w_B = 15$. Using the Mann-Whitney U formula, we calculated $U_A = w_A - n_A (n_A+1)/2 = 40 - 5*(5+1)/2 = 25$ e $U_B = w_B - n_B (n_B+1)/2 = 15 - 5*(5+1)/2 = 0$. Considering the smaller value of U, we obtained $U_{obt}=0$. Then, we consulted the critical value $U_{crit} = 2$ for the Mann-Whitney Test (U) considering $n_A = 5$ and $n_B = 5$ with the level of significance 0.05. According to the Mann-Whitney Test, once $U_{obt} <= U_{crit}$ ($0 <= 2$) is true, **we could reject H_0**.

The second experiment was performed with ten Information Technology undergraduate students. They are also independently and randomly sorted into two groups, the first of size $n_A = 6$ (experimental group) and the second of size $n_B = 7$ (control group). The students of the group A played the game "U-TEST", while those of the group B took part in a traditional pencil-and-paper exercise with problems to solve on the same content explored in the game. Both pretest a posttest were the same of the first experiment.

In this case, we have $N = n_A + n_B = 13$. After following the same procedure described for the first experiment, we calculate $w_A = 44$ e $w_B = 47$. We also obtained $U_A = 23$ e $U_B = 19$. Considering the same level of significance 0.05, we have $U_{crit}=7$. Once $U_{obt} <= U_{crit}$ ($19 <= 7$) is false, **we could not reject H_0**.

To assess the second research question, we applied a perception questionnaire with students of the experimental groups. In both experiments, students answered they liked the game and felt motivated, besides they thought the game contributes to learning. Based on these results, we verify that the game, besides promoting a significant improvement at the students' scores in the first experiment, was positively evaluated by them. In the second experiment, although it was not possible to confirm higher learning effectiveness in relation to a traditional pencil-and-paper exercise, the game was also considered more motivating that the exercise. It may be an indication that, even when educational games are not superior to the traditional exercises, the students' motivation may be a decisive factor to long term learning. A question to be assessed in the future is: if the students who played the game had a greater capacity to keep the knowledge than the ones who only did the exercise.

V. CONCLUSION

The experiments were conducted in a systematic and documented way, establishing a formalized assessment that can be repeated countless times. This repetition allows the comparison with previous assessments, offering better conditions to analyze historical results and identify positive/ negative learning tendencies. Although the number of experiments is still reduced, as well as the number of participants, the positive results (effects with statistical validity) are a stimulus to the continuation of this research. The results also helped to identify strong and weak points of the game and it will guide its development in the future. Based on the feedback obtained, the game is already been improved, mainly to increase its difficulty levels and variability of directions. Moreover, we intend to increase the number of software testing topics considered by the game.

An initial concern was the comparison of the game with a traditional pencil-and-paper exercise, once the game is still very direct and based on problems solution. However, according to the feedback received from the qualitative questionnaires, we verify that the game is a motivational differential, increasing interest and raising greater curiosity on knowledge. As a continuation of this study, researchers have been developing and experiment educational games in other areas of Software Engineering. Currently, games on Project Management, Requirements Engineering and Software Improvement Process are being studied.

The results obtained so far, even under the statistic rigor, cannot be generalized. Among the main threatens to the assessment, it must be considered that the experiments were performed inside two institutions only, where teachers are part of the research group. This way, it is necessary to widen the set of experiments and number of students so that it will be possible to assess learning tendencies with more accuracy. Other threaten was the inequality on the students knowledge and experience in Software Testing students. However, it was treated with a previous evaluation of the profile questionnaire answered by the students before the experiments. In this case, no student who could have been a threat to the obtained results was found.

Abstract

Background: *Many comparative studies have been performed on effort estimation models. Linear regression (LR) and Estimation by Analogy (EbA) were often compared. The past research revealed that those comparative studies reported inconsistent results among performance measures. However, those studies seemed not to reflect actual or desirable study procedure.* ***Aim:*** *We aimed to examine performance inconsistency in comparative study on LR and EbA under more desirable procedure.* ***Method:*** *We carefully determined datasets and experiment procedure. LR and EbA were then compared under appropriate condition.* ***Results:*** *Performance measures showed statistically consistent results in almost all datasets.* ***Conclusion:*** *Comparative study could show consistent results with suitable experiment procedure.*

1. Introduction

Software effort estimation is popular and important research area. Model-based effort estimation has been very studied in this area. Many software estimation models have been proposed showing its superior predictive performance to that of old or popular models.

Linear regression (LR) and Estimation by Analogy (EbA) are the most popular methods among them [6] and repeatedly compared. Comparative studies on them often reported inconsistent results regarding predictive performance. Myrtveit et al. [10] revealed using simulation that performance measures favored different models in a comparative study on LR and EbA. Mair et al. [7] revealed with systematic review that predictive performance was inconsistent between and within the past comparative studies on LR and EbA even if the same dataset and performance measures were used.

Revealed interesting knowledge, these studies seemed not to reflect actual or desirable comparative study. Myrtveit et al. compared 7 performance measures with 1000 simulated datasets. However, those datasets were generated using a single dataset. Furthermore, they selected "best results" for EbA after performing evaluations on different parameter settings. Thus, their result was not generalized for usual comparative study. The past comparative studies reviewed in [7] actually performed with a few dataset or a few performance measures. It has been criticized to insist validity of new proposed models by an experiment with a few datasets. Performance evaluation with only MMRE and PRED(25), for instance, was not enough because MRE-based measures were biased and tend to penalize overestimation more seriously. Furthermore, in contrast to [10], they did not control potential sources of inconsistency such as dataset, experiment procedure, and options like variable selection methods. In addition, clear dataset selection criteria were rarely found. We believe that controlled and recommended conditions were important for comparative study to discuss sources of inconsistent results.

This paper thus conducted comparative study on LR and EbA with not a few datasets and performance measures. We carefully selected datasets suitable for experiment procedure and performance measures. As a result, we found that performance measures could be consistent in almost all datasets. This result can contribute for discussing and investigating sources of inconsistent results.

2. Experiment Settings

2.1. Performance Measures

This study used the same performance measures as [10]: Mean MAE (MMAE), MMRE, Median MRE (MdMRE), PRED(25), MMER, RSD, and LSD. MAE, MRE, and MER-based measures are very popular ones. RSD and LSD

are defined as follows:

$$\mathrm{RSD} = \sqrt{\frac{\sum(\frac{\mathrm{Act}_i - \mathrm{Est}_i}{\mathrm{Size}_i})^2}{n-1}},$$

$$\mathrm{LSD} = \sqrt{\frac{\sum(e_i - (-\frac{s^2}{2}))^2}{n-1}}.$$

Here, s^2 is an estimator of the variance of the residual e_i, where e_i is given by $e_i = \ln \mathrm{Act}_i - \ln \mathrm{Est}_i$.

2.2. Experiment Procedure

Cross-validation (CV) has been popular experiment procedure in comparative study. Two types of CV have been often used: leave-one-out CV and K-fold CV. Leave-one-out CV allows us use smaller datasets than K-fold CV. It was also recommended because of its deterministic property.

However, we adopted K-fold CV for two reasons related to evaluation reliability. First, leave-one-out CV may lead unreliable estimates because an estimate from it has high variance [3]. Second, leave-one-out CV produces identical values for average-based and median-based measures such as MMRE and MdMRE. This is because a fold of leave-one-out CV has only one project and performance measures for a test subset are calculated from single estimate. In case of K-fold CV, we can avoid this situation if a test subset has more than 2 test cases.

Eventually we adopted 10 $\times$ 10-fold CV followed by paired t-test with 10 degree-of-freedom in order to avoid inflated Type I error [2]. Comparative studies often adopted nonparametric test for the reason that distributions of a performance measure were skewed. In fact, skewness was not a problem because for most of the distributions one encounters in practice, the significant level of the t-test is almost exact for sample sizes greater than 12 [4].

2.3. Outlier Elimination

We removed influential data points (outliers) by Cook's distance [9] in advance so that all projects had Cook's distance lower than $3\times4/N$, where N is the number of projects in a dataset. In contrast to [9], this study left projects with distance higher than $4/N$ but smaller than $3 \times 4/N$. This is because decision of inclusion or exclusion for these projects depends on model-based judgment and it was difficult when two different models were compared.

3. Effort Estimation Models

3.1. Linear Regression

In many situations, a fitted regression model is likely to be reliable when the number of predictors p is less than $N/10$ or $N/20$. Following this rule, sample size N must be $N > \frac{100p}{9}$ in case of 10$\times$10-fold CV. This is because $p < 1/10 \cdot 9/10 \cdot N$ must hold.

Linear regression can utilize multiple predictors in order to improve predictive performance. However, simple models including only size-related metric as a predictor are also popular because it is easy to construct and to be able to avoid variations in an experiment. Myrtveit et al. revealed inconsistent results in [10] even if simple models were used. The size of dataset must be equal or more than 12 for simple models because of $p = 1$. In order to include more datasets, we determined to adopt simple models. This study adopted the following popular formulation:

$$\log(\mathrm{Effort}) = \beta_0 + \beta_1 \log(\mathrm{Size}).$$

3.2. Estimation by Analogy

In EbA estimation process, similarity between a target project and historical projects is calculated from recorded metrics and then some projects similar to that target project are selected. EbA estimates effort of that target project from the similar projects.

EbA has several options for fitting to a specific dataset. This study adopted the following options:

- Size-related metric for only predictor
- Euclidean-distance as similarity function
- Geometric mean as projection method

This EbA tried to estimate p50 Effort [5]. Geometric mean is identical to median under log-normal distribution. It also mitigates effect of extremely large effort under a distribution skewed right.

This study determined the number of similar projects k before an experiment by 10-fold CV which minimizes an average of MMREs. This was because EbA showed better result than LR only with k minimizing MMRE [10] and thus we expected to find inconsistency.

4. Datasets

4.1. Source

We performed comparative study with some datasets listed in [8] and served on PROMISE repository [1] at January 2011. We used only public datasets because they are freely available and replication can be open.

Table 1. Selected datasets descriptions

Name	Sample Size	Removed
COCOMO81	63	–
CSC	145	4
Desharnais	81	1
Heiat-Heiat	35	–
MERMAID2	30	–
Miyazaki94	48	1
Moser-etal	37	–
cocomonasa_v1	60	–
Maxwell	62	–
NASA93	93	1

PROMISE repository site serves datasets as readable text file which can include comments. We selected datasets from this repository which contain a comment regarding information of projects or a citation they were used.

Dataset listed in [8] were from three journals: Transactions on Software Engineering, Information & Software Technology, and Journal of Systems & Software. We selected datasets freely available from original papers they referenced. We also limited datasets to which were collected in software development organizations.

Having removed duplicates between the two sources, we identified 28 datasets as an initial set.

4.2. Dataset Selection

We selected datasets with the following conditions:

- effort or size-related metrics must be contained.
- at least 30 projects must be contained.

Effort estimation models usually estimate target effort at least from size-related metrics such as KSLOC and Function Points (FP). We thus imposed the first condition.

Second condition was related to the limitation in subsection 2.2. This limitation imposed that the size of test subsets must be more than 2. Supposing that test subsets of a dataset have 3 or more projects, $1/10 \cdot N \geq 3$, where N is size of that dataset, must hold. Consequently a dataset must have 30 or more projects. Although performance measure based on 3 results was still less precise and less fine-grained, it was a reasonable criterion for dataset selection.

As a result, we specified 10 datasets. Table 1 shows their descriptions. "Removed" indicates results of outlier elimination. The number of removed was small for all datasets and thus it did not influence dataset selection results.

5. Results

Table 2 shows averages of performance evaluation results. At the next most right column, we counted performance measures showing higher performance. Performance measures showing the same values were ignored. We found consistent results on Moser-etal, cocomonasa_v1, and Heiat-Heiat. However, we found inconsistent results on the other datasets.

Table 3 shows p-values for performance measure comparisons. The most right column shows the number of performance measures with statistical significance at $\alpha = 0.05$. We having used k based on MMREs for EbA, statistical tests on MRE-based measures turned to be significant less times than those on the others.

The most right column of Table 2 shows the number of statistically higher performance measures. Considered statistical significance, we could found inconsistency results only on MERMAID2. EbA was consistently preferable on Maxwell and Heiat-Heiat. LR was consistently preferable on the other datasets.

MRE-based and MER-based measures were inconsistent on MERMAID2. Following definitions of MRE and MER, LR might tend to overestimate and EbA might tend to underestimate on MERMAID2. In contrast, we did not find statistical inconsistency among performance measures based on MRE. Thus, inconsistency could be explainable.

We think that our experiment procedure contributed to consistency. This study adopted more reliable evaluation procedure than that of [10] and performed under identical conditions in contrast to [7]. Carefully selected datasets suitable for experiment procedure was also effective. We thus concluded that a large part of inconsistency in the past study might be due to experiment procedure.

6. Conclusions

This study revealed that performance measures could be consistent with appropriate experiment procedure. Out experiment procedure reflect actual or desirable comparative study style and thus it was useful and practical to adopt our experiment procedure style for future comparative studies.

These results can be useful as a starting point for investigating and discussing sources of inconsistency. Investigating multiple feature models, some datasets having no useful feature will have to be dropped, though.

This study does not deny using datasets we dropped. However, using the selected datasets would be more suitable and reliable in comparative study, at least with our experiment procedure.

***Abstract*—Reusing existing components can help developers improve the development productivity as well as reduce the cost. Reuse repositories in this scenario act as a fundamental facility for acquiring needed components. While retrieving components in reuse repositories, developers often face the problem of choosing components from candidates that provide similar functionalities. To address the problem, this paper proposes a semi-supervised method to recommend developers components in reuse repositories. Different from existing rating based recommendation approaches that often suffer from the lack of user ratings, our approach calculates the recommendation probabilities of components based on their citations on the Internet. The citations are acquired through the websites (called *host* in this paper) that are associated with the components. Using a random walk algorithm, the associations between components and hosts are explored with recommendable components identified. We implemented our approach in a prototyping system based on which we conducted an experimental study to evaluate our approach. The experimental results demonstrate that our approach can accurately recommend components and thus has the potential to assist developers in reuse.**

Keywords-software reuse;component recommendation;reuse repository

I. INTRODUCTION

It is widely believed that reusing existing components can help developers create applications with less effect and improved quality [1]. To find proper components, developers need to retrieve reuse repositories according to their reuse plan [2]. Generally, the component retrieval process can be divided into two steps: Firstly, developers search reuse repositories to find component candidates that provide needed functionalities. Secondly, developers select components from candidates and integrate them together to build the target system.

Selecting components from candidates is very crucial for system integration. Before the adaption and integration of the components, developers often have to prototype a testing environment to validate the selected components to make sure that the selected components could satisfy the detailed requirements [3]. A casual selection of components may put developers into the risk of wasting a lot of time and effort. The situation becomes even worse if the components are not cost-free.

Currently, most widely used mechanism to provide hints for developers to make informed component selection decision in real world reuse repositories, such as SourceForge [5] and ComponentSource [6], is the user rating/review system. In such systems, developers can share their experience of certain component by simply giving a rating or a paragraph of remarks. Then all the ratings are aggregated for providing decision information to assist developers with components selection. User rating/review systems can provide information to assist developers in making selection decision; however, this kind of mechanisms is always blamed for their limited ratings due to the user motivation problem [7]. In most cases, developers have to spend extra effort collecting related information or try the retrieved candidates one by one to decide which component to use. The retrieval process becomes inefficient.

To resolve the problem, we propose a novel component recommendation method based on the citations of components appearing on the Internet. The citations of components on the Internet can be components for download (such as the components in Download.com [21]), components at runtime (like Java Applet [9]) or component-centric description or discussion (such as the appearance in Ohloh [22]). No matter what cases, components appearing on the Internet would relate to certain hosts. In general, the more times a component appears on the Internet, the more probable it should be recommended to developers [8]. Furthermore, if a host is known to involve amounts of recommended components, components cited by this host are more likely to be recommendable ones. Therefore, a component's citation on the Internet can be utilized for recommendation instead of user ratings.

In this paper, we propose a semi-supervised approach for component recommendation in reuse repositories based on their citations on the Internet and implement the approach in a prototyping system. In the approach, we obtain the hosts that involve the components from the Internet and build the associations between the components and the hosts. Through exploring the associations with a random walk algorithm, we work out the recommendation probability for each component. We evaluate our approach through an experimental study based on our implemented system and real world data. The results show that our approach can accurately identify recommendable components.

†Corresponding Author

The rest of this paper is organized as follows: Section 2 describes our approach for recommending components and an implemented prototyping system. Section 3 presents our experimental study on the proposed approach with the results analyzed. Section 4 presents some discussions about the approach and the future work. Section 5 describes the related works. Then in the last section, we conclude this paper.

II. OUR APPROACH

In this section, we will introduce our approach for recommending components as well as an implementation of the approach based on which we conducted the experimental study. The approach consists of following steps.

- Obtaining hosts associated with components. This step aims to find hosts related to the components from the Internet and build associations between them.
- Setting up the association weight. The relevance degree of components with their hosts is considered in our approach. For each association, a weight denoting the relevance degree is assigned for further computation.
- Computing component recommendation probability. This step computes the recommendation probability for each component through exploring the associations using a random walk algorithm and finally identifies the recommendable components.

Details of these steps are described below.

A. Obtaining Hosts associated with Components

To obtain the hosts related to the components from the Internet, we use the web search engine Google[1] to accomplish the hosts crawling task. We use Google to search the components with component name as the query and extract URLs from the returned result list. Since the most relevant results are usually distributed at the top position, we only keep the top 30 URLs for each component (returned list less than 30 URLs will all be kept). Then the hosts related to the component are identified (we use the domain part of a URL to represent a host. URLs with the same domain part will be merged).

However, the returned results by Google do not always refer to the exact component if we directly use the component name as the query. In order to obtain the hosts and build the associations more accurately, some strategies are adopted to refine the associations between the components and the hosts. Firstly, Google in general will split the input keywords into word segments, search each segment separately and at last merge the results of each word segment to produce the final results. Such manner, however, is intended to fetch web pages that contains word segments of the query but in fact are irrelevant to the components in our scenario. To solve the problem, we validate the returned results by using full match of the component name in both the title and the snippet. This can be fulfilled by adding quotation mark to the component name when searching components. Secondly, the Google web search engine aims to obtain as diverse results as possible, but in our scenario, the returned results by Google should be restricted in the domain of "Software" or "Software Development". For this problem, we append the keyword "Software" to the query to refine the returned results.

Formally, the associations between components and their hosts can be described as a bipartite graph, $G=<COMP, HOST, EDGE>$. The component set *COMP* and the host set *HOST* constitute the partitions of the graph. Every association is described as an edge $(comp, host) \in EDGE$ where $comp \in COMP$ and $host \in HOST$. Fig. 2(a) gives an example of a bipartite graph.

B. Setting up the Association Weight

In our approach, we consider the degree of components associated with their hosts and a weight is assigned to each association. The association weight between a component and a host denotes the relevance degree of the component to the host. In general, the more times a component appears on one host, the more degree it is relevant to the host.

The association weight of a component related to a host is firstly set as the number of URLs related to the component that are merged into the host. Then, the weights of all associations are normalized using (1) where $N_{comp\text{-}host}$ is the number of URLs related to the component *comp* and merged into *host*. Since the association is non-directional, the weight of a component related to a host equals to the one in reverse order.

$$w_{comp-host} = w_{host-comp} = \frac{N_{comp-host}}{\sum_{c,h:(c,h)\in EDGE} N_{c-h}} \quad (1)$$

C. Computing Component Recommendation Probability

The idea behind our component recommendation approach is that the more hosts by which a component is cited, the more probable a component is to be recommended. More importantly, if a host is known to involve amounts of recommended components, components appearing on the host are more likely to be recommendable ones. To implement the idea, we assign each component a recommendation probability (called "component recommendation probability" in this paper), which means the degree of the component to be recommended. We also set a weight (called "host recommendation probability" in this paper) to every host. The host recommendation probability indicates the degree of a host involving recommended components.

Let *P(host)* denotes the host recommendation probability of *host* and *P(comp)* denotes the component recommendation probability of *comp*. Clearly, a host that involves more components with high component recommendation probability will gain higher host recommendation probability. We use (2) to calculate the host recommendation probability of *host* where *C(host)* denotes the components cited by *host*.

$$P(host) = \sum_{comp:comp\in C(host)} w_{host-comp} P(comp) \quad (2)$$

[1]http://www.google.com/

On the other hand, a component that is involved by more hosts with high host recommendation probability can also gain higher component recommendation probability. Hence, we use (3) to update the component recommendation probability of a component where *H(comp)* denotes the hosts that involve *comp*.

$$P(comp) = \sum_{host:host \in H(comp)} w_{comp-host} P(host) \qquad (3)$$

The starting point of the computation is a set of components that are prejudged to be recommended ones and assigned high recommendation probability. We call this group of components "seeds". To implement the computation, we propose a propagation algorithm by adopting a random walk algorithm with absorbing states [14]. The algorithm is presented in Fig. 1.

Input: the seed set S, COMP-HOST bipartite graph G, the vanishing threshold β, the transition probability α to ω
Output: *P(comp)*, for every component except for the seeds

1: **for each** *comp* **in** S **do** *P(comp)*=1
2: **repeat**
3: **for each** *host* **in** HOST **do**
4: $P(host) = (1-\alpha)\sum_{comp:comp \in C(host)} w_{host-comp} P(comp)$
5: **if**($P(host) < \beta$) **then** *P(host)*=0
6: **end for**
7: **for each** *comp* **in** COMP \ S **do**
8: $P(comp) = (1-\alpha)\sum_{host:host \in H(comp)} w_{comp-host} P(host)$
9: **if**($P(comp) < \beta$) **then** *P(comp)*=0
10: **end for**
11: **until** convergence

Figure 1. The propagation algorithm

The input of the algorithm contains the seed set S, COMP-HOST bipartite graph G and two parameters α and β. The transition probability α denotes that both the components and the hosts have the probability to transfer to the absorbing state ω [14]. This means that if a component or a host does not keep acquiring the recommendation probability, its probability will gradually decrease to 0 and thus be absorbed by ω. The vanishing threshold β is used as the threshold to distinguish the recommendable components. The output of the algorithm is the component recommendation probability *P(comp)* for each component except the seeds.

Initially, the component recommendation probabilities of the seeds are set to 1 (Line 1). Then the algorithm (Line 3 to Line 10) iteratively calculates the probability for both the hosts and the components. In each iteration the host recommendation probability for each host is calculated using (2) and weakened by $(1-\alpha)$ (Line 4). If the calculated probability is less than β, the probability is set to 0. The calculation of the component recommendation probability is similar to the one of host recommendation probability. Note that besides the components, we also use β as a threshold to discard the probabilities of hosts in Line 5. This is mainly for efficiency purpose [14]. The iteration will continue until the recommendation probabilities of both the components and the hosts are convergent. Components with the recommendation probability greater than 0 then will be regarded as recommended ones.

To explain the propagation algorithm in a more concrete way, an illustrated example is given in Fig. 2. In the example, there are 5 components (indicated as squares) and 4 hosts (indicated as circles) that have associations with the components as shown in (a). Components *C2* and *C3* are seeds. Suppose that all the associations have the same weight. Initially, the component recommendation probabilities of *C2* and *C3* are set to 1. In the first iteration, hosts that have associations with *C2* and *C3* will gain host recommendation probability. Thus, the host recommendation probabilities of *H1*, *H3* and *H4* (indicated as solid circles) are updated as shown in (b). Note that the host recommendation probability of *H3* will be larger than those of *H1* and *H4* since *H3* have associations with both *C2* and *C3*. The hosts will also backwards affect the recommendation probabilities of the components except the seeds. Therefore, the component recommendation probabilities of *C4* and *C5* (indicated as solid squares) will be updated as shown in (c). Similarly, the host recommendation probabilities of all the 4 hosts (shown in (d)) and backwards the component recommendation probabilities of *C1*, *C4* and *C5* will be updated (shown in (e)) in the following iteration. The iteration continues until the recommendation probabilities of both the components and the hosts converge.

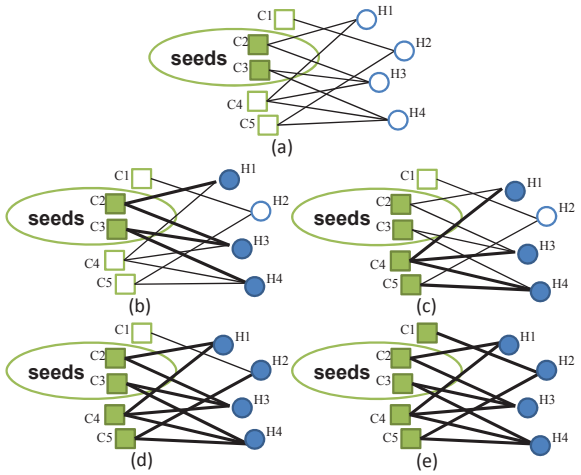

Figure 2. An illustrated example of the propagation algorithm

D. Implementation with a Prototyping Reuse Repository

We implement our approach with a prototyping reuse repository that simply provides free-text based component retrieval [10]. Note that although we use free-text approach to acquire relevant components in the prototyping system, our method for recommending components is not limited by the component retrieval mechanisms. The architecture of the reuse repository with our recommendation approach is presented in Fig. 3. Components are stored in the ***reuse repository***. The ***retriever*** accepts queries of developers and retrieves relevant

component candidates from the reuse repository for further recommendation.

The implementation of our approach is denoted in the dash line rectangle in Fig. 3. The ***crawler*** obtains the hosts that have association with the components in the reuse repository from the Internet and stores the associations in the ***association database***. Based on the work done by the crawler, the ***analyzer*** computes the recommendation probability for each component utilizing the associations and produces the recommendable components based on the retrieved candidates to developers.

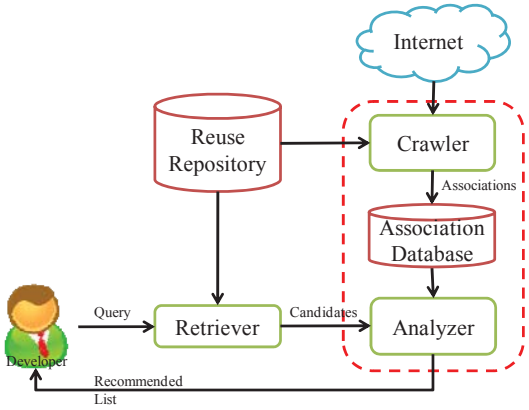

Figure 3. The architecture of the reuse repository with our remmendaiton approach

III. EXPERIMETNAL STUDY

A. Experimental Organization

To evaluate our approach, we applied it to the data collected from a real world reuse repository, i.e. SourceForge, which not only provides software systems, but also many reusable libraries that fuel the further development of new applications. Particularly, we selected the category "Software Development" as our evaluation base. Category "Software Development" totally contains 35,602 software projects at the time we carried out the evaluation. We acquired the project information including project name, description, user positive rating and negative rating etc. by implementing a web page crawler. The 35,602 software projects constituted the reuse repository in our approach. In our experiment, each software project was viewed as a component.

Based on the built reuse repository, we used Google to search for the hosts that involve the components in the reuse repository and extracted associations between the components and the hosts. In this study, we removed the SourceForge from the host set to eliminate the impact of SourceForge since SourceForge acts as the evaluation base of our experimental study. Associations including SourceForge were also excluded. Thus, we totally fetched 251,873 hosts as well as 937,016 associations between the component set and host set.

We sorted the 35,602 projects according to the user ratings provided in our crawled pages from SourceForge. After a review of the sorted list, 100 projects were selected as seeds (less than 0.3% of the component set). The 100 projects were either famous software projects, or with high user positive rating that are supposed to recommend to developers.

In the execution of the propagation algorithm, we also need to set the parameters, i.e. α and β. In our experiment, α was set to an empirically small value 0.01 [14] while the selection of β somewhat depends on the application scenarios. To solve the selection of β, we used the seed set to tune it. We divided the seed set into 2 parts. Four fifth of the seed set were still used as seeds in the propagation algorithm while the remaining one fifth were regarded as the test set to tune β. The tuning algorithm is shown in Fig. 4. After conducting the tuning algorithm, we finally set β to 5E-5.

Step 1: Randomly select 80 seeds from the seed set.
Step 2: Conduct the propagation algorithm with the parameter α set to 0.01 and β set to 0.
Step 3: Store the minimum value of the calculated probabilities of the remaining 20 seeds.
Step 4: Repeat Step1, Step 2 and Step 3 in 5 runs and set β as the average of the stored minimum values.

Figure 4. The tuning algorithm for β

B. Experimental Results

We evaluated the effectiveness of our approach by using developer queries. In order to decide which queries to use, we interviewed 7 graduate students in Peking University who have more than 2 years of software development experience. Finally, 11 queries were identified. We then submitted the 11 queries to our prototyping system to retrieve relevant components and more importantly the recommended ones by our approach. To validate the recommended components, we adopted the user ratings provided by SourceForge. Components were regarded as recommended ones if their number of positive ratings in SourceForge is larger than the one of negative ratings.

TABLE I. RECOMMENDED COMPONENTS BY SOURCEFORGE COMPARED TO THE ONES BY OUR APPROACH

Query	Recommended	Retrieved
XML Parser	3(5)	14
Data Encryption	1(1)	7
Logging	9(11)	12
Math	5(5)	12
Statistics	5(5)	7
Data Compression	1(1)	10
Email	1(1)	6
File Upload	2(4)	14
Configuration File	3(3)	11
Network Utility	1(1)	11
IO Utility	2(2)	14

To evaluate our approach, we identified the recommended components by SourceForge from the retrieved ones for each query and then found out whether our approach could produce similar recommended list. The results are presented in TABLE I. The queries are listed in the "Query" column. Column "Retrieved" indicates the number of retrieved components according to the query while the "Recommended" column

represents the number of recommended components by our approach contained in the recommended list of SourceForge. The number of components recommended by SourceForge is also indicated (in the bracket). Take query "XML Parser" as an example, the number of retrieved components related to the query is 14 and in the 5 recommended components of SourceForge, our approach suggests 3 of the 5.

Through the comparison with recommended components by SourceForge that are based on user ratings, we preliminarily drew to the conclusion that our approach possesses the ability to identify the recommended components suggested by SourceForge. More queries should be performed to further validate our approach; however, the selected queries to some extent cover amply portion of fundamental software development needs based on our interview with software developers. In order to show the effectiveness of our approach in a better fashion, seeds (if retrieved) were excluded in the retrieval results.

We also evaluated the precision of the recommended components by our approach. Precision here means the ratio of actual recommended components compared to the ones suggested by our approach. We compared the number of recommended components by our approach to the ones suggested by SourceForge. The 11 queries were still used. TABLE II shows the comparison results. In the column "Recommended", the number of recommended components of our approach is indicated in the bracket. In the recommended list of our approach, the number of components that are also suggested by SourceForge is indicated outside the bracket. In half cases, our approach performs well and produces recommended components similar to the ones by SourceForge, such as "Logging", "Statistics". While in the other half, our approach recommended more components than SourceForge does, especially in the case "Network Utility".

TABLE II. OUR RECOMMENDED COMPONENTS COMPARED TO THE ONES BY SOURCEFORGE

Query	Recommended	Retrieved
XML Parser	3(7)	14
Data Encryption	1(3)	7
Logging	9(9)	12
Math	5(8)	12
Statistics	5(6)	7
Data Compression	1(3)	10
Email	1(5)	6
File Upload	2(7)	14
Configuration File	3(7)	11
Network Utility	1(8)	11
IO Utility	2(6)	14

To explore the reason of this phenomenon, we investigated the recommended components by our approach while not suggested by SourceForge. We found that almost all these components received 0 positive rating and 0 negative rating in SourceForge. According to the criteria of recommended components, such components will be judged as not recommended by SourceForge. "GSA Simple XML Parser[2]" is one of the examples. However, through our investigation of "GSA Simple XML Parser" by hand, we finally judged that this component should also be recommended.

[2] http://sourceforge.net/projects/gsa-simple-xml/

IV. DISCUSSION AND FUTURE WORK

A. Issues about the Association Refinement

In our approach, we refine the association between components and hosts using the strategies described in section 2, but there are still some problems in building the associations. The most extrusive case is that the name of a component is too general. For example, an xml parser named "xml parser". To search such keywords in Google, the returned results are often irrelevant to the component. Such cases will reduce the effectiveness of our approach and provide problematic recommended list to the developers. Nevertheless, we find that such examples only occupy a very small fraction of the components in real world reuse repositories since people who develop components are mostly intended to pick up a more meaningful name for their components while further consideration should be taken to deal with such cases.

B. How to Obtain the Seed Set

In our approach, one of the inputs to calculate the recommendation probabilities of the components is the seed set. The effectiveness of our approach will be greatly reduced if the seed set is hard to obtain. However, the seed set seems not so difficult to identify in real world reuse repositories. Firstly, just like our experimental study, components that have already received high user positive ratings can be considered. Secondly, famous software components are another option. Thirdly, components that developed by famous companies or organizations can also be taken into consideration.

Another issue about the seed set is how to construct a better seed set. The selection of the seeds may influence the performance of our approach since it is the starting point. Selecting seeds as divergent as possible may be one of the possible strategies that can be used to enhance the performance of our approach. For instance, seeds can be selected considering different application domains. Further study will be carried out in our future work.

V. RELATED WORKS

Helping developers obtain appropriate components is crucial for successful software reuse. In the literature, many research works have been studied to facilitate the component retrieval, such as 1) free text approaches [10]; 2) facet based approaches [11]; 3) signature based approaches [12] and 4) behavior based approaches [13]. Most of these research works concentrate on obtaining relevant components while pay little attention to providing information for developers choosing components from candidates that provide similar functionalities. As the size of reuse repositories becomes large, helping developers make informed decision among functionally similar components can accelerate the process of selection and this is what our approach is trying to accomplish.

To recommend software components among candidates, Inoue et al. proposed the component rank model based on which they developed SPARS-J, a java class retrieval system

[4]. The component rank model analyzes the usage relation of components so as to identify recommendable components that are used more frequently. The work is based on the premise that the component source code is acquirable but in many cases (e.g. COTS) this is unrealistic. Ichii et al. proposed a software component recommendation approach based on collaborative filtering (CF) utilizing user browsing history [15]. However, CF inborn suffers from the "Cold Start" problem. In real world reuse repositories, such as SourceForge and ComponentSource, user rating/review systems are usually used to recommend software components while these systems are often blamed for their shortage of ratings/reviews [7]. In our approach, we make use of the associations between components and hosts obtained from the Internet to avoid the above problems as well as provide hints to help developers make selection decision.

There are also several pieces of work concerning recommendation systems in the research area of software engineering. CodeBroker [16] provides recommendation of APIs for developers that may implement the needed functionalities the moment developers write down comments or the signature of methods. Strathcona [17] developed by Holmes et al. recommends example code to developers by monitoring the code under development. The recommendation is made according to six structure-based heuristics. Li et al. proposed an approach to recommend typical usage example of APIs by adopting code clustering [18]. Kim et al. presented an approach that searches code bases on the Internet and extract code examples to insert into API documents to recommend developers suitable examples while using certain APIs [19]. ParseWeb [20] is another useful tool to suggest call sequences for developers when developers are using certain APIs. Different from these approaches that recommend implemented APIs or example code, our approach aims to help developers make informed choice facing components that provide similar functionalities.

VI. CONCLUSION

In this paper, we proposed a semi-supervised approach to produce recommended components to the developers to assist their selection of components in reuse repositories. The approach utilizes the associations between the components and the involved hosts. Through a selected group of components that are supposed to be recommended and a propagation algorithm, the recommendation probability for each component is calculated. We also implemented a prototyping system and conducted an experimental study on our approach using real world data. The results show that our approach can accurately recommend components to the developers comparing to the data from SourceForge.

ACKNOWLEDGMENT

Xiaoying Bai
②Tsinghua University, China

David C. Kung
University of Texas at Arlington, USA

Abstract: As the advance of software component technology, engineers encountered different issues and challenges in testing and automation of configurable components and component-based programs. One of them is how to validate configurable components and programs to achieve adequate test criteria and support test automation. This paper uses a test model, known as *a semantic tree*, to assist engineers to model and analyze diverse composite components and configurable software in terms of configurable environments, organization structures and functions. Based on this model, well-defined test criteria are presented to address the adequate testing issues. In addition, the paper discusses two test complexity evaluation methods for configurable components and software. Furthermore, some case study results are reported to demonstrate the testing complexity of diverse configurations.

KEYWORDS: test modeling and analysis, configurable software testing, test complexity, test criteria, and configuration testing.

1. Introduction

In the last two decades, software component reuse has been a popular concept and approach in software construction. To assure software product quality, engineers need to assure the quality of reused components and programs before deployment. Hence, testing component-based systems has been a very hot research subject in the past decade.

As the advance of component technology, the complexity of components increased from functional component box to frameworks/middleware and configurable/customizable components. Software users (or clients) are allowed to configure, select, and customize components and software based on their functional requirements, desirable environments, and selected organization structures. In the past two decades, many published papers focus on software design, construction and management issues concerning configurable components and programs in production lines [2][4][5][6][7][8]. Although there are numerous published papers discussing how to construct configurable software and components in different aspects, only a few of them focus on testing and automation of configurable components and software [21-26].

In 2003, the authors have pointed that there is an emergent need in testing configurable and customizable components [1][27]. In the past decade, there are numerous published papers addressing issues on testing components and component-based systems. However, only a few of them addressed testing issues and challenges for configurable components, frameworks, and configurable component-based software [21-26]. From 2008 to 2009, we collaborated with a software QA group in SUN Microsystems to set up several test projects in the software testing class at San Jose State University to validate the selected open-source components and middleware developed by ***SUN Microsystems***. Typical examples are ***SocialSite, SailFin, and Glassfish***, After went through the projects, students not only found numerous bugs, but also discovered some other problems in testing component-based software with configurable features and structures. These issues and challenges are summarized below.

- How to identify and present diverse configurations in terms of component/software composition structures, functions, and environments?
- How to define adequate test criteria and evaluate the test coverage for configurable components and software?
- How to analyze and measure the test complexity of configurable components and software?

Today engineers lack well-defined test process, adequate test models and criteria, as well as test automation solutions for configurable components and systems. According to QA and test engineers in the real world, there are the following needs.

- Effective test models to assist test modeling and analysis of components and systems with configurable structures and features.
- Well-defined test criteria and coverage analysis for components with diverse configurations in environments, functions, and structures.
- Cost-effective solutions to evaluate configuration-oriented test complexity and cost.
- Test automation solution to support auto-testing of configurable components and software.

This paper focuses on the first three needs. The paper uses a model-based approach to address testing issues. A new model, known as a semantic tree, is used to assist engineers to perform test modeling and analysis for configurable component-based systems. This model can be used to present diverse component configurations statically or dynamically, including their configurable environments, organizational structures, and functions. Based on the given model, a set of configuration-based test criteria is defined, and a test complexity evaluation method is provided.

The paper has three primary contributions in software component testing. Firstly, it uses a model-based approach to modeling, presenting and analysis of diverse configurations in components. Unlike the existing work, the proposed model allows engineers to present and analyze both static and dynamic configurable structures and features of component-based systems. Secondly, it presents well-defined test criteria based on the proposed model to address configuration-oriented test adequacy. Thirdly, it provides a systematic method to evaluate test complexity of diverse configurations in components and systems.

The paper is structured as follows. The next section discusses the background and related work. Section 3 discusses the essential issues in testing configurable components. Section 4 presents a test model, known as a semantic tree, and related properties and

spanning trees to model the configurable structures for software components. Section 5 discusses a set of test criteria for configuration features in components and software. Finally, Section 6 reports some case study results, and the conclusion remarks and future work are given in Section 7.

2. Related Work

There are numerous published books and papers addressing different topics and issues on component testing in the past decade.

- *Component testing techniques* - For example, the authors in [13] presents flow-graph based test model and a technique to support API-based component black-box testing by focusing on a component's accessible functional sequences. In addition, the paper in [17] discusses testing of state-based dynamic behaviors for a component.
- *Design for component testability* – Roy Freedman [10] discusses how to measure component function testability. Gao et al. in [11] proposed a component testability model to evaluate software components from five different factors. In addition, there are a number of papers discussing how to design for component testability using different approaches.
  - Built-in-test components [9][20], where component tests are coded inside components.
  - Framework-based testable components [14][15], where test-driven handlers are built inside components based on well-specified component APIs.
  - Systematic wrapping for testable components [19], where test-oriented component wrappers are created to support tests based on well-defined API artifacts.
- *Component test adequacy and coverage* – As pointed out in [1][27], most existing test criteria and test methods can be used in component testing to achieve function-oriented test criteria and state-based test adequacy. However, there are some open questions. One of them has been addressed by [12], which is API-based access sequences and related test criteria. The other open issues are relating to component reuse contexts, component interactions, and configurations.

Based on our recent literature survey, there are only a few of papers addressing testing issues and challenges in configurable components. The existing work can be classified into three groups:

- *Testing configurable system constraints using combinatorial interaction testing* (CIT) [24, 25, 26] – CIT is a method to sample configurations of a software system systematically for testing. Many algorithms have been developed to create CIT samples. A general constraint representation and the related solving technique are presented in [26]. It focuses on this problem by examining two highly configurable software systems to quantify the nature of constraints in real systems. CIT can provide an effective way to sample configurations for testing. Cohen et al. in [25] focused on CIT-based test coverage and fault coverage for crossing system configurable parameters and their constraints. Based on CIT, Qu et al. in [21] introduced an approach to regression testing of configurable software using prioritization, which aims at earlier detection of defects.
- *Regression testing of system with configurable features* – For instance, Robinson et al. proposed a firewall method for regression testing of user-configurable software [22]. This paper focused on user-centered tests for system configuration. They constructed a firewall to identify the impacted area in system based on setting changes and configurable element changes respectively, then created or selected test cases to cover the impacts. Some case studies are reported.
- Component compatibility testing – Yoon et al. in [23] presented some configuration space models, known as CDG (component dependency graph) and ACDM (annotated component dependency model), to present the relationships among components, their versions, inter-component dependency, and constraints. Moreover, they also provided three test strategies based on the proposed models and experimental results.

Unlike the existing research, this paper provides a configuration model to present three-dimension configuration space for components and systems, which includes configurable environments, compositional architectures, and selective functions. The model is known as a semantic tree model, which can be used to present both static and dynamic configurations for component-based software and its parts. Instead of focusing on configurable system combinational constraints based on parameters, we focus on diverse configurations in environments, architectural structures, and selective functional features. We use a model-based approach to address the testing issues in three-dimension configuration space for component-based systems, including test modeling, test adequacy, and test complexity analysis. Some case studies are reported.

3. Testing Configurable Software

What is a *configurable component*? It refers to a compostable component, which not only provides a specified contracted interface, domain-specific service functions, and deployment solution with necessary artifacts, but also is equipped with the configuration capability that allows its users to make configuration selections in its environments, functions, and structures statically or dynamically. Similarly, *configurable software* is a program supported with a capability that allows users to make various configuration decisions statically or dynamically to generate different deployment instances based on their desires. Component-based software usually supports configurations in two different ways: a) static configuration, in which decisions and selections are made statically, and b) dynamic configuration, in which decisions and selections are made during runtime. Based on our recent experience, many modern frameworks and component-based software allow users to make following types of configuration decisions.

- Environment configuration capability – which allows users to configure and select different deployment environments.
- Organization configuration capability – which allows users to select different organization and composition structures based on available components and building parts.
- Function configuration capability – which allows user to select different functional features based on their needs.

Figure 1 presents the configuration test space as a 3-dimension space for configurable *software* and *components*, in which the X-axis presents all possible environment configurations, the Y-axis presents all of configurable structures/organizations, and the Z-axis presents all of configurable functions.

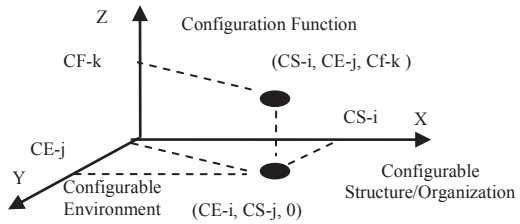

Figure 1 Configuration Test Space for Configurable Software

3.1. A Test Process

Figure 2 shows a test process for a configurable software and its components, which consists of the following steps.

1. ***Configuration environment check***, in which different environments are set-up to check product installation and deployment. The focus of this step is to make sure that the under-test component (framework or software) can be operated properly under each specified configuration environment.
2. ***Configurable structure/organization validation***, in which diverse configurable architectures (or organizations) are the focuses. Its primary purpose is to assure that configurable architectures can be structured successfully to support functions.
3. ***Configuration function check,*** in which configuration functions must be validated to achieve the selected test criteria. The major focus here is to assure the quality of the provided configuration service functions.
4. ***Configurable instance validation***, in which each configured component/software is deployed and validated under a specific environment to assure its quality in a reuse context.

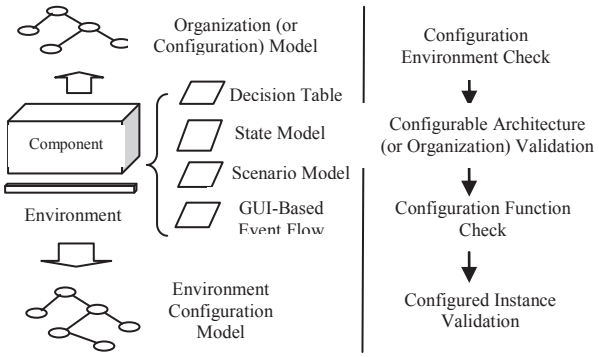

Figure 2 A Test Process for Configurable Software

3.2. Testing Myths

Since 2009, we used two software testing classes (collaborated with Sun Microsystems) to test several open-source configurable frameworks and platform servers (i.e. glassfish-v3) in San Jose State University. Both of them support rich configuration functions and environments. Here, we summarize our findings regarding to problems and myths in testing configurable software (or component) ***P*** below. Assume P' is a configured instance of P.

Myth #1*:*
If P_1 has been tested in a deployment environment P_E, then, there is no need to validate another configured instance P_2 of P on the same deployment environment P_E.
Realty:
We found that P_2 may have problems to perform its quality function services on P_E, even though P_1 functions well on the same deployment environment P_E.

Myth #2:
When Component A is a configurable part of a software P, if it has been tested as a part of one instance of P, then there is no need to test it again in another instance of P when it is included as its part.
Realty:
We found that as a configurable part, Component A may work well in one deployed instance of P, but it may not work properly inside another deployed instance of P, because both instances may include component A with different composition structures (or relations). This leads to two different reused contexts for Component A. Therefore, it should be tested in both reused contexts.

Myth #3*:*
When a function (F) is a configurable part of a configurable component P, if it has be tested in one of its configured instance P', then there is no need to validate the function F again in another configured instance P".
Realty:
We found that a configurable function F in a configurable component P may work well in one configured instance, but may not work properly in another instance of component P although both instances provide function F as one of their service functions. This leads to two different reused contexts for Component A. Therefore, it should be tested in both instances since they are different reused contexts.

4. Test Modeling for Configurable Software

Although there are numerous useful models in software testing, very few are suitable to model and present diverse configurations and their mappings in the 3-dimension configuration space for configurable component-based software. As shown in Figure 1, we need a well-defined test model to assist engineers to analyze and present each configurable structure (or compositional architecture) (say CS-i) under a specified configurable environment (say CE-j) as well as the corresponding configuration function (say CF-k), so that model-based test criteria, test generation methods, test complexity analysis techniques can be developed.

This section first discusses an updated test model to serve this purpose. It is known as a semantic tree model, which has been proposed as a test model to address problems and needs in software installation testing [16]. Here, the semantics tree model is used as a basis to model to address the needs in configuration testing of the configurable component-based software in the 3-dimension space.

4.1. Test Model – A Semantic Tree Model

Intuitively, a semantic tree is a special tree model for configurable component-based software. Each tree can be used to model and present the configuration elements and their relations in one of three dimensions in the configuration space. The tree nodes present configurable parts (or elements), for example, configurable

components. The links present different semantic relations between nodes. A semantic tree model can be formally defined as 3-tuple = (N, E, R), where

- N is a set of tree nodes. There are three types of nodes: a) a single root node, b) intermediate nodes (or parent nodes), and c) leaf nodes.
- E is a set of links between nodes. Each link connects a parent node and one of its child nodes in a tree. Each link show a part of a semantic relation between a parent node and its child nodes.
- R is a set of relations, and each item in R has a semantic label that presents a semantic relation between a parent node and its child nodes. There are four types of semantic relations with labels: EOR, AND, SELECT-1, and SELECT-M. Their detailed semantics are given in Table 1. Figure 3 shows their notations, where P-Node is a parent node, and C-nodes are its child nodes.

To support the model-based analysis, we introduce a concept of semantic spanning trees based on the semantic tree model.

Semantic Spanning Tree:

A semantic spanning tree G_{SPT} is a sub-tree of a given semantic tree G_{ST}. Unlike common spanning trees, a semantic spanning tree G_{SPT} for G_{ST} only can be derived based on the following properties:

- For each parent node (Np) with an AND relation in G_{SPT}, it must include all of its child nodes and its links.
- For Np with an EOR relation in G_{SPT}, it must include only one of its child nodes and the corresponding link.
- For Np with a SELECT-1 relation in G_{SPT}, it must include only one of its child nodes and the corresponding link.
- For Np with a SELECT-M relation in G_{SPT}, it must include only M child nodes and the related links.

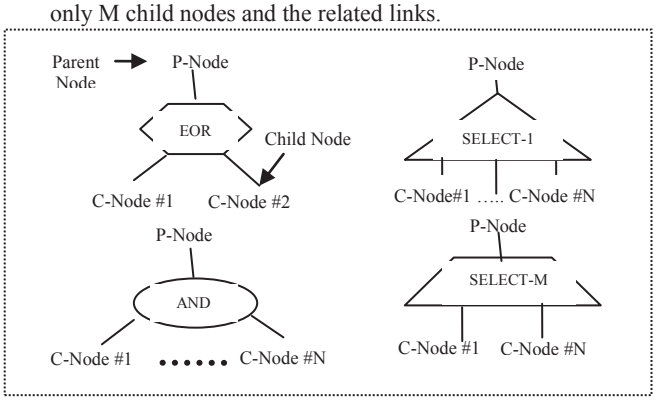

Figure 3 The Notation of Semantic Relations in a Semantic Tree

Table 1 Different Semantic Relations in a Semantic Tree Model

Relations	Relation semantic descriptions (where P is a parent node, and Ci is its child node)
EOR(P, <C1, C2>)	EOR relation indicates that P-Node has two child nodes C1 and C2. They only can be configured exclusively.
AND(P, <C1,…,Cn>)	AND relation indicates that P-Node must be configured with all of its child nodes C1,…,, Cn.
SELECT-1(P, <C1,…,Cn>)	SELECT-1 relation indicates that P-Node must be configured with one of its selective child nodes C1,…, and Cn.
SELECT-M(P, <C1,…,Cn>)	SELECT-M relation indicates that P-Node must be configured with M selective nodes from its child nodes (C1,…, and Cn).

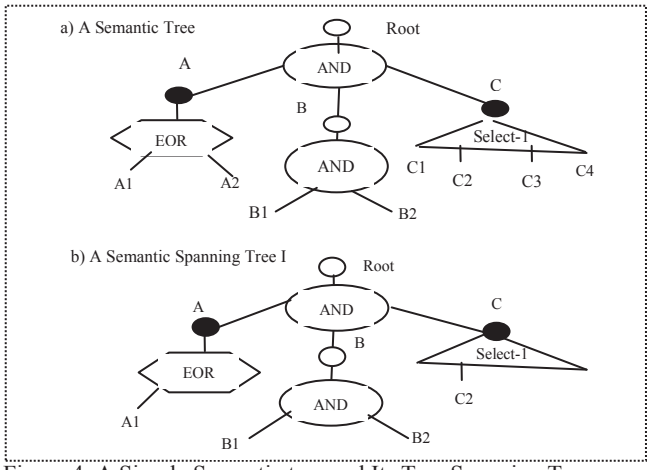

Figure 4. A Simple Semantic tree and Its Two Spanning Trees

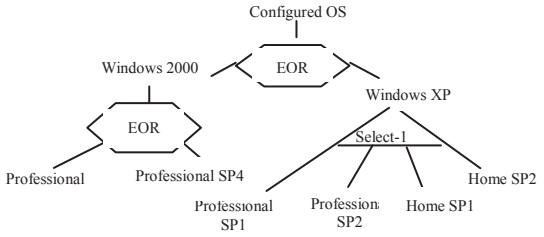

Figure 5 A Sample Model for Component Environment Configuration

As shown in Figure 4(a), a simple semantic tree example is presented with one root node and three parent nodes (A, B, and C). Each has one relation. One corresponding semantic spanning trees are given in Figure 4(b). An algorithm is given in Figure 6 to find out a semantic spanning tree for a given smantic tree model.

```
Semantic-Spanning-Tree(GST-Node, NSPT)
{
if GST -Node is a leaf node, then GST –Node →NSPT; // add this leaf node into NSPT
        return
else add GST -Node into NSPT
        switch (GST -Node"s relation) {
        case "EOR": pick a GST-Node"s child node (say Ci);
                Ci →NSPT // add into NSPT
                Add GST-Node"s link to Ci →ESPT
                Semantic-Spanning-Tree(Ci, NSPT);
                break;
        case "Select-1": pick a GST-Node"s child node (say Ci)
                Ci →NSPT // add into NSPT
                Add GST-Node"s link to Ci →ESPT
                Semantic-Spanning-Tree(Ci, NSPT);
                break;
        case "AND": GST-Node"s child nodes →NSPT
                Add all its links to its child nodes →ESPT
                Loop for each child node (say Ci) and do:
                Semantic-Spanning-Tree(Ci, NSPT);
                break;
        default "NOT": pick a GST-Node"s child node (say Ci)
                Ci →NSPT // add into NSPT
                Add GST-Node"s link to Ci →E SPT
                Semantic-Spanning-Tree(Ci, NSPT);
                break;
        }
}
```

Figure 6. An Algorithm for Finding A Semantic Spanning Tree

4.2. Modeling for Configuration Testing in Configurable Component-Based Software

Since 2009, we used two software testing classes and two master project teams to apply the semantic tree model and spanning tree concept onto one in-house-built component-based system and several open-source configurable frameworks and platform servers in San Jose State University. Here, we provide some examples to demonstrate its effectiveness in modeling various environment configurations, diverse configurable organizations, and configuration functions.

4.2.1 Modeling Diverse Configurable Environments

All commercial software and components must be executed in a certain operation environment Figure 5 shows a simple semantic tree example which presents different configurable operating system environments for software. In the real world, we can use this model to consider all required configurable hardware and software elements (or entities) in a product's operation environment. They include different configuration selections in network protocols, device drivers, diverse operating systems and their versions, multimedia and third-party dependent technologies. As shown in [16], it is very important and necessary to have a model like semantic tree to present diverse configurable environments in software installation testing. Similarly, in a component-based software production line, test engineers also need a semantic tree model to perform test modeling and test complexity of these diverse configuration environments. Since each configurable environment usually requires a set of environment-oriented test scripts to set up so that system function and performance testing can be conducted properly.

4.2.2. Modeling Configurable Structures/Organizations

In a configurable component-based system, the program can be configured by using selective components and parts to form different organizational structures. In this case, software testing must address and cover these diverse structures to make they are adequately covered whenever they are required. In 2009, we have used the semantic tree model to present the different configurable organization structures for a configurable component-based elevator simulation system, which is developed by SJSU students using Java-based component technology. This system provides a set of configurable components, including Floor Panel, Door, User Panel, and Elevator Car components. A user interface is provided to its customer to support a user to select and build diverse elevator system instance based on their need. For example, a user can configure a Door component with two models: a) Single-Door and b) Double Door. Similarly, the user can configure other parts of an elevator system. For example, Figure 7 shows the semantic tree model for the Lift component (known as a ICar) of the elevator system.

4.2.3. Modeling Diverse Configuration Functions

Today most configurable programs (or frameworks) provide rich configuration service functions that allow users to make many configuration decisions to configure different product instances. All of them provide an Administration Console with a graphic user interface to support user's selections in setting diverse configurations. To test the GUI-based configuration service functions, we can apply many existing black-box test methods, such as decision table, category-partition, and boundary value analysis. However, based on our testing experience, students entered the difficulty in dealing with the configuration-oriented test coverage for the provided configuration service functions; because these methods are not designed to easily address the diverse configuration selections and decisions. They found that using the semantic tree model is more effective to address and model the test problems in software configuration functions in configurable software. Due to the space limitation, we report the detailed finding in our future publications.

4.3. Configuration Model Identification and Generation

It is important to have some systematic way to specify diverse configurations to support test modeling, complexity and coverage analysis. Although there are well-established software analysis and design models, such as UML, they are not suitable to present the diverse configurations in configurable software in terms of environments, organizational structures, and configuration functions. The proposed semantic tree model provides an effective modeling tool to support engineers to perform software configuration analysis and specification for configurable component-based system in the 3-dimensional configuration space. The *first* approach is a static specification-based approach, in which engineers use the semantic tree model to specify and model the configurations in three steps:

1. Identifying and modeling configuration environments.
2. Identifying and modeling configurable component-based organizational structures (or architectures) based on the customer needs.
3. Identifying and modeling configuration functions, including their sectional options.

Clearly, when the given software supports complicated configurations, this approach becomes tedious. Therefore, the second approach is more dynamic and systematic one, in which some built-in dynamic configuration discovery and tracking capability will be provided in configurable software. With this capability, dynamic configuration decisions in environments, organization structures, and configuration functions can be tracked and analyzed for the purpose of test modeling, test complexity analysis, and test coverage measurement.

5. Configuration Test Criteria and Complexity

To adequately test configurable component-based software (***P***), engineers must answer the following questions:

- Have we adequately checked ***P*** under each configurable environment?
- Have we adequately tested ***P*** with each of configurable organizational structures?
- Have we adequately tested ***P*** for each of its provided configuration service functions?

To answer these questions, engineers need well-defined test criteria and an effective test coverage analysis solution. This section defines the test criteria based on the semantic tree model given in Section 3. In addition, two configuration test complexity evaluation approaches are presented.

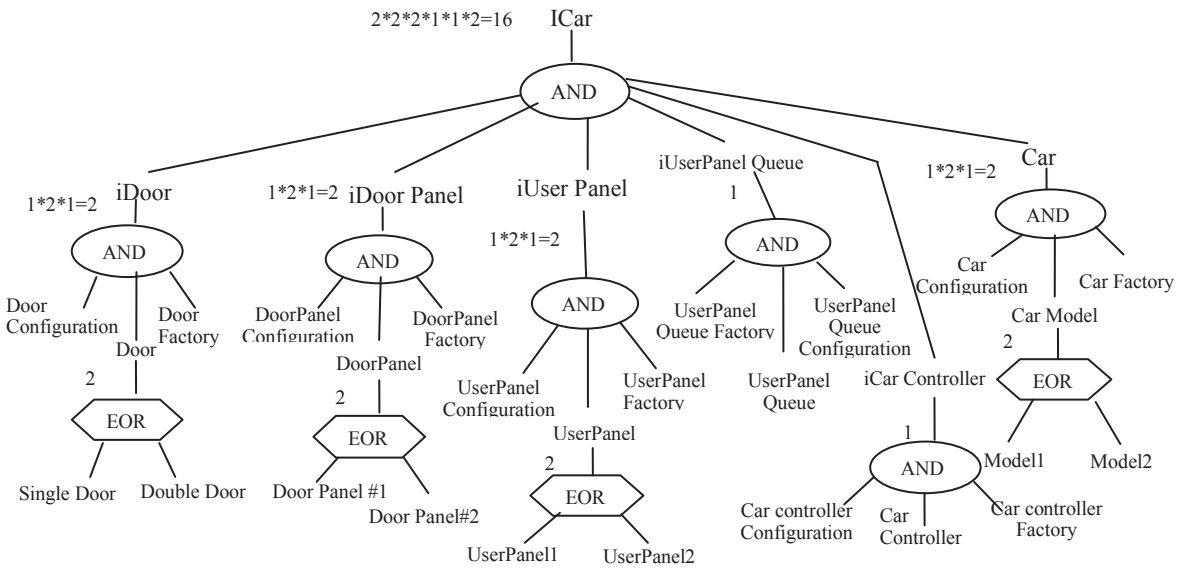

Figure 7. A Semantic Tree Model and Test Complexity for Configurable Organization Structures of the Elevator Car (ICar)

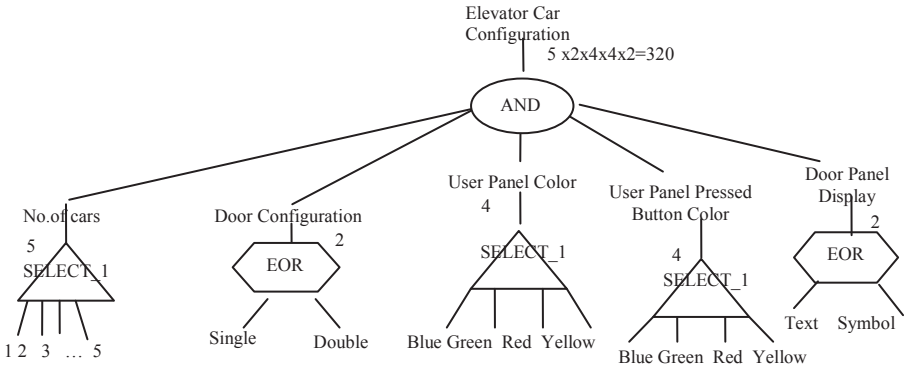

Figure 8. A Semantic Tree Model and Its Test Complexity of One Configuration Functions for the Elevator Car (ICar)

5.1. Test Criteria and Complexity for Configuration Environments

When configurable software (say ***P***) can be operated under different configurable environments, it must be validated under diverse configured environments to achieve certain environment test criteria for vendors and customers. For example, if a customer requires P to be functioned properly in a set of specified operation environments, then *P* must be validated under these environments.

Let's use the semantic tree model (G_E) to present the diverse configurable environments of software *P*. G_{SPE} be the set of semantic spanning trees of G_E. Since each configured operation environment for ***P*** can be modeled as a semantic spanning tree, we can define the test criteria for configuration environments of ***P*** below.

Test criterion for Single-Operation-Environment:

- *For any configured operation environment, this test criterion can be achieved only when software **P** has been tested under this configured environment.*

Test criterion for All-Operation-Environment:

- *This criterion can be achieved only when software P has been validated under each of the configurable environments.*

Clearly, setting up these various configurable environments require engineers efforts to prepare and execute the set-up scripts. Using the semantic tree model G_E for ***P***, engineers can easily prepare the environment set-up scripts based on its semantic spanning trees in G_{SPE}. Hence, the test environment complexity, represented as $T\text{-}complexity_P(G_E)$ of ***P*** can be computed below.

$$T\text{-}complexity_P(G_E) = \text{No. of semantic spanning trees in } G_{SPE} \quad (1)$$

This complexity formula enables to engineers to figure out the required number of pre-test scripts for environment configuration and set-up. This will be useful for test planning in test cost and complexity analysis.

5.2. Test Criteria and Complexity for Configurable Organization Structures

For a configurable component-based software P, each configurable organizational structure directly corresponds to one of its semantic spanning trees of G_S, For a software vendor of P, it is very important to validate its instances to cover its diverse organizational structures.

Since each semantic spanning tree in G_S represents one of its configured organization structures, it is necessary for us to understand and define the adequate test criteria for validating its various organizational (compositional) structures. Here, we

provide test criteria for configurable organization structures of P based on a semantic tree model. Let's use $G_S = (N_S, E_S, R_S)$ as a test model to present its configurable organizations. $\boldsymbol{G_{SPT}} = \{\boldsymbol{G_{SPT\text{-}i}} \mid i = 1,..n\}$, where $\boldsymbol{G_{SPT\text{-}i}}$ is a semantic spanning tree *of* $\boldsymbol{G_S}$. Let *Ts* be the test set for *P*.

Adequate test criterion for Single-Organization-Structure:

- *For a single organization structure modeled as a semantic spanning* $\boldsymbol{G_{SPT\text{-}k}}$ *of* $\boldsymbol{G_S}$*, this test criterion is achieved if and only if* T_S *of P has been exercised onto at least one deployed instance Pi with* $\boldsymbol{G_{SPT\text{-}i}}$ *as its organization structure.*

Adequate test criterion for All-Organization-Structures:

- *This test criterion is achieved if and only if* T_S *of P has been exercised onto the deployed instances of P configured with each spanning tree in* $\boldsymbol{G_S}$.

To support the evaluation of test complexity of diverse configurable organization structures, we provide a hierarchical computation method below. For any parent node N_{Pi} in N_S of G_S, its organizational configuration complexity can be computed based on its semantic relation with child nodes. Let *T-complexity*(N_{Pi}) be the configuration complexity for its organization structures. It can be computed below.

- If the node N_{Pi} has the EOR semantic relation with its child nodes, then its configuration complexity can be computed below.
  $T\text{-}complexity_C(N_{Pi})$
  $= T\text{-}complexity_C(N_{C1}) + T\text{-}complexity_C(N_{C2})$ (2)
  Where N_{C1} and N_{C2} are the two child nodes of N_{Pi}
- If the node N_{Pi} has the AND semantic relation with its child nodes, then its configuration complexity can be computed below.
  $T\text{-}complexity_C(N_{Pi}) = \prod (T\text{-}complexity_C(N_{Cj}))$ (3)
  Where j = 1, …, n, and N_{Cj} is a child node of N_{Pi}.
- If the node N_{Pi} has the SELECT-1 semantic relation with its child nodes, then its configuration complexity can be computed below.
  $T\text{-}complexity_C(N_{Pi}) = \sum (T\text{-}complexity_C(N_{Cj}))$ (4)
  Where j = 1, …, n, n is the number of its child nodes, and
  N_{Cj} is a child node of N_{Pi}.
- If the node N_{Pi} has the SELECT-M semantic relation with its child nodes, then its configuration complexity can be computed below.
  $T\text{-}complexity_C(N_{Pi})$
  $= \sum (T\text{-}complexity_C(N_{Cj}) * n!/(m!(n-m)!))$ (5)
  Where j = 1, …, M, N_{Cj} is one of M selected child nodes of N_{Pi}.from its N child nodes.

Following these formula, engineers can easily implement an automatic solution to compute the test complexity for diverse configurable organization structures in any given configurable component-based software. Figure 7 presents the detailed test complexity of different configurable organization structures for Elevator Controller (ICar), which is a composite component in the elevator simulation system. For example, a Door component with an EOR relation to its two child nodes (Single Door and Double Door) has to be checked for two different settings. Hence, its test complexity is 2. The iDoor component has a AND relation with its three child nodes, including Door component. Its test complexity for different compositions is 2 based on the formula in (3). The test complexity for the Elevator Controller (ICar) is 16.

Similarly, the test complexity computation approach can be used for a semantic tree model to present diverse configuration functions in the elevator simulation system. Figure 8 shows the detailed results of test complexity for testing function configurations for the Elevator Controller (ICar) based on the same approach. As shown in Figure 8, its test complexity is 320.

6. Case Study Results on Configuration Testing

In 2010, we used our students in software quality testing class (CMPE287) to conduct a case study, where 10 student groups are required to conduct a term-project to validate the given component-based elevator systems. One of the tasks is to use the semantic tree model to support configuration-based testing, so they are able to understand the testing complexity and challenges in testing configurable component-based software.

In this case study, we focus on the following items:

- Discover the semantic tree model for the selected configurable software to see the effectiveness of the model in presenting different configurations, including environments, organization structures, and configuration functions.
- Identify, understand, and analyze the test complexity of configuration-based testing in configurable component-based systems.

Table 2. The Semantic Tree for Organization Structures and Its Complexity

Semantic Tree for Organization Structures	# of Spanning Trees	# of Nodes /# of Leaves	# of Links	Max Height	# of EOR	# of AND
Elevator Semantic Tree	64	54/36	53	4	6	12
ICar Semantic Tree	16	33/22	32	3	4	7

Table 3. The Semantic Tree for Configuration Functions and Its Complexity

Semantic Tree for Configuration Functions	# of Spanning Trees	# of Nodes /# of Leaves	# of Links /Max Height	# of EOR	# of AND	# of SELECT-1
Elevator Configuration	640*256	47/37	46/3	4	3	6
ICar Configuration	320	23/17	22/2	2	1	3

As shown in Figure 7, the semantic tree model for ICar has 33 nodes. Among of them, there are 22 leaf nodes, and 10 parent nodes. In addition, there are two different types of semantic relations, including EOR and AND. And its test complexity of various configurable organization structures is 16 since the semantic tree has 16 different spanning trees. Table 2 shows the detailed complexity of the semantic tree model of the Elevator Simulation System. Its total test complexity is 64, which presents the total number of different configured structures for the elevator system. Hence, while validating this software, a vendor's engineers must test its deployed instances to cover its configurable organization structures. In practice, they can achieve the defined adequate test criteria (discussed in Section 5) in an incremental approach. For example, whenever a customer is deployed one instance, its configured system organization structure (or component composition structure) will be recorded. This idea has been implemented in one of our master project. For this system, we

found that we need to develop 64 scripts to set up and cover different organization structures so that the deployed system instance can be tested with certain adequate function test set using the existing test methods. Table 3 shows the related semantic tree model for configuration functions in the system based on the provided system user interface and configuration service functions. Clearly, its complexity is much higher due to more choices are given in the semantic tree. This suggests the configuration testing could be very complicated. More test automation research work for configurable software testing is needed.

7. Conclusions and Future Work

Although there are numerous papers addressing how to construct configurable software and components, only a few papers discussed how to test configuration features and structures of component-based software. This paper uses a model-based approach to discussing the relating issues, challenges, and test process. It applied a semantic tree model as a test model to present and analyze the diverse configuration environments and configurable structures in component-based systems. In addition, a set of adequate test criteria configurations has been defined. Furthermore, some case study results are reported demonstrate its effectiveness and application in test modeling and test complexity analysis. Currently, we are developing a test automation solution to support automatic testing of configurable component-based software. The future extension of this research is to study how to use a model-based approach to addressing regression testing issues and challenges in configurable features and services in SOA applications.

***Abstract*—Mashup is a new kind integration application and users can compose related services as components to build new application—the mashups. Now the services on the web have different degrees of data uncertainty, including data error, stale data, and improper data processing and so on. We provide a data uncertainty model for mashup component which is assessed in the space of the homogeneous components that have the same functionality, and then we give the uncertainty computation mechanism of mashups based on the data uncertainty of mashup components and the computation sequence for different composition relationships.**

Keywords-component; mashup; data uncertainty

I. INTRODUCTION

In Web development, a Mashup is a Web application that combines data from more than one source into a single integrated tool. The term Mashup implies easy, fast integration, frequently done by access to open API's and data sources to produce results data owners had no idea could be produced[1]. And mashups are applications developed by integrating content and functionality sourced from the Web. Mashups typically integrate heterogeneous elements available on the Web, such as RSS/Atom feeds, Web services, content scraped from third-party websites, or widgets (such as Google Maps)[2]. Different kinds of mashups reuse user interface (UI) components to build the composite application's UI, leverage and require external computational services, or simply integrate multiple plain data sources. So web environment has been required to provide data services with high quality.

With more and more sources of web service, the number and types of web service increase significantly. Now the services that we can get from the Internet include maps, e-mail, pictures, weather, traffic, search, etc. From the QWS Dataset [3,4,5] and ProgrammableWeb [6], the statistics of web service shows that there are a lot of choices in each type, and the overall amount of web service increases all the time. So we regard these services that share the same functionality as homogeneous services. There are thousands of web services, and also a large number of mashup services for the users, which build a solid base for related applications. From the point of view of the source of web service, it has changed from the original single site to numerous web application's open APIs and service supporting architectures like SaaS, SOA, and Cloud computing. So the users can access to the original stand-alone local application in the form of service by the service framework like Axis, and also can access to the core data and applications through SaaS platforms and the OpenAPI of flickr, Google and yahoo on the web.

So user can use the mashup tools to build the new application, just so-called situational applications—that is, applications where the developer is also the final user and that serve a highly focused purpose. Situational applications typically aim to answer a precise query over a limited but heterogeneous data space. Their quality, therefore, depends strongly on the information that different integrated components can provide. As the promotion of mashup applications, there is one issue that has taken more attentions and is unavoidable: data uncertainty.

The uncertainty of the data source is very common on the web. We can see the web as the largest database of human society. This database is variable and uncertain because of numerous sources, complex structure, frequent change and dynamic transmission. The data uncertainty exists as inconsistent data, fault data, data variance, service instability and the impossible traceability of the change of data. We focus on the variance of web data which can be caused by error data source, unsuitable data process and stale data. So there are always many alternate results for the same data. For example, yahoo search service and Google search service have different results for the same keyword by a compare web site [7]. So the web can also be viewed as the largest uncertain database, and uncertain homogeneous service is an important part. For example, there are many services from travel sites which provide hotel information of scenic spots. But because of different information source and data update mechanism of these web sites, there may be some differences of price and room number among the services, and the uncertain data will mislead the travelers. Now most of service selection methods only focus on QoS strategy without considering the uncertainty aspect, so it can't meet the requirement of providing users with reliable service in web environment. The mashup tools use these uncertain services as mashup components to build mashup applications, and it needs corresponding solutions for the data uncertainty of mashup. So data uncertainty is crucial for both components and composition in mashup. Assessing a mashup's data uncertainty requires understanding both

component data uncertainty and the effect that the composition has on the final mashup's overall data uncertainty.

In this paper, we introduce a data uncertainty model for mashup components, analyze different types of composition in mashup, and then define the calculation of data uncertainty for mashups based on the relationships of mashup components in the mashups. In the following parts of this paper, section 2 describes related work of mashup and data uncertainty. Section 3 describes the data uncertainty of mashup components, including the model to describe uncertain mashup components and the mechanism to access the data uncertainty of components. Section 4 introduces the composition of mashup components. Section 5 describes the data uncertainty of mashups, including the model describing the mashups and the mechanism to access the data uncertainty of mashups. Section 6 makes the conclusions and discusses the future work.

II. RELATED WORK

In traditional database applications, the existence and accuracy of the data is deterministic. In recent years, as technology advances, people deepen the understanding of data acquisition and processing technology. Now uncertain data problem has widely attracted public's attention, and many researchers have focused on uncertainty in data processing. Literature [12] describes the background of uncertainty in the application of the data, and summarizes the challenges of uncertainty data management. Literature [13] gives an overview of algorithms and application of uncertain data management techniques. From the point of view of uncertain systems, Purdue University's Orion project [10] tries to design a general-purpose uncertain database system; the Trio project at Stanford University [11] studies the lineage according to the analysis of uncertainty. In the model aspect, the most commonly used model is possible world model [8, 9], which evolves a lot of database instances (called possible world instances) from uncertain database. There are also some researchers who focus on data integration, and literature [14] designs data-integration system which handles uncertainty at three levels: semantic mapping, uncertain data and uncertain queries. So based on these progresses of data processing on uncertain data, we can carry out the work to handle data uncertainty of web service regarded as the data source.

Currently there are a number of Mashup tools. Damia[15] is a Mashup tool provided by IBM, which allows the users to assemble data feeds from Internet and enterprise data sources. Yahoo Pipes [16] is a web-based tool provided by Yahoo. The users can build mashup applications by aggregating and manipulating data from web feeds, web pages, and other services. A pipe is composed of one or more modules, each one performing a single task like retrieving feeds from a web source, filter, sort or merge feeds. Popfly[17] is a web-based Mashup application by Microsoft. It allows the users to create a Mashup combining data and media sources. The Mashup is built by connecting blocks. Apatar[18] is a Mashup data integration tool that helps users to integrate desktop data with the web. Users install a visual job designer application to create integration schemas called DataMaps. MashMaker[19] is a web-based tool by Intel for editing, querying and manipulating web data. So we can see that many mashup tools focus on the integration of web data sources, and the mashups is the result of data integration of web data from the data aspect.

There are only a few researches on the data uncertainty of mashup application. The UQBE [20] is a mashup tool for non-programmers that supports query-by-example (QBE) over a schema made up by the user without knowing the schema of the original sources. Based on automated schema matching with uncertainty, the UQBE system returns the best confident results. MashRank [21] is a mashup tool that treats ranking as a first-class citizen in mashup construction, and allows for rankjoining Web sources with uncertain information. Both these two tools which consider the uncertainty problem just study the data uncertainty of the ranking data and schema matching, but don't study the composition of uncertain data and the data uncertainty of mashups. So the research on data uncertainty in mashup is in the initial stage, and more and more people will take attention to this topic.

III. DATA UNCERTAINTY OF MASHUP COMPONENTS

On the web, there are many alternates for each kind service as the result shown in ProgrammableWeb, and we refer to them as homogeneous services. And these services can be used as the components of mashup, and data uncertainty of these homogeneous services is just the main data uncertainty of mashup components. We think that the data uncertainty of mashup component is relative to their alternate components, and the data uncertainty is considered in the space of all the mashup components which share the same functionality. We see these mashup components as the tuples in uncertain database, each of which has its information and its confidence possibility that reflects component's uncertainty. We think that the data uncertainty of component is caused by component's quality to provide data service and user's distrust among all the alternate choices. So we can get the information of the confidence degree of the component based on user's decision when the users participate in the selection of homogeneous components, which can give the uncertainty assessment of the component. Based on the assessments, we can build uncertain model for these homogeneous mashup components.

A. Uncertain component model

We consider the data uncertainty of mashup component from two aspects: the ability to provide data service and user's confidence of component's data. Before the data processing of the data uncertainty of mashup components, we first need to propose the syntax description of mashup component. Now services for mashup are mainly described by the basic information, such as service name, operation and corresponding input / output, etc. At the same time, we should also consider the quality of the component and the attributes which can describe QoS (quality of component). Then we can provide the components which meet user's requirements based on QoS and user decision. Therefore we need a unified component description model with additional QoS information, and the service model is extended to following model:

Definition 1: According to the consideration of QoS, a component can be identified as a six-tuple set:

MC={ComponentName, Op, Input, Output, Profile, Qset}

Where ComponentName is the name of the component, Op is the operation to get corresponding data, Input / Output is the input and output of the operation, Profile describes component auxiliary information. And Qset is a set of attributes which represents the qualities of component to provide data service.

$$\text{Qset}=\left\{\begin{matrix}\text{Response Time，Availability，Throughput，}\\ \text{Reliability Success ability Latency}\end{matrix}\right\}$$

QoS attributes help determine which of the available components is the best and meets users' requirements. The meanings of the attributes are as follows：

a) Response Time：Time taken to send a request and receive a response
b) Availability：Number of successful invocations/total invocations
c) Throughput：Total Number of invocations for a given period of time
d) Reliability：Ratio of the number of error messages to total messages
e) Success ability：Number of response / number of request messages
f) Latency：Time taken for the server to process request

Considering the problem of uncertain data management, we apply probabilistic database model to create uncertain service model. We wish to model probabilistic information using a probability space whose possible outcomes are all the conventional instances. The finiteness of D implies that there are only finitely instances $I \in D$. By finite probability space we define a probability space (D, P[]) in which D is finite. We shall use the equivalent formulation of pairs (U, p), where U is the finite subset of D and the probability assignment $p: U \rightarrow [0,1]$ satisfies $\sum_{w\in D} p(w) = 1$ and $\sum_{w\in U} p(w) = P[U]$. Therefore, we use probabilistic model to map data uncertainty by adding the probability attribute to the description of components. This uncertain component model is as follows:

Definition 2: An uncertain component model can be identified as a four-tuple set:

$$\text{MC}=\{\text{ComponentName, N, Qset, P}\}$$

Among them, ComponentName stands for the service; N is a number which stands for the times that this service has been chosen, and it is also the subjective information of user decision in the model; the Qset is the same as definition 2; the additional P represents the assessment of the credibility of each component. So D_S represents the domain of all the homogeneous components, and D_u represents the subset of D_S, then satisfied:

$$\sum_{\text{MC}\in D_u} p(\text{MC}) = P[D_u] \text{ and } \sum_{MC\in D_S} P(MC) = 1$$

B. Uncertainty component Model Building

From the definition of uncertain component model, we can see that how to compute probability attribute is the core work, and it relates to the problem of what is certainty and what is uncertainty. In our view, the origin of certain in the web is credibility assessment by users. Mashup component is a kind of software application in web environment, and is a dynamic changing data carrier for numerous users' ideas and thoughts. So for the component, the user is the root cause of its existence, and the user's knowledge and sense of service determines the credibility of the service. And from the further analysis, user awareness of the component's credibility comes from user's intuitive understanding of component's quality properties which represent the objective uncertainty of component and user's requirements which represent the subjective uncertainty of component. Therefore, the service's credibility can be evaluated based on the combination of these two kinds information of component. In order to support uncertain data assessment of homogeneous components, we need to establish the appropriate process to meet the requirements of component registration and management, component accessing and uncertainty modeling. Our approach sets the probability attributes in uncertain service model as follow: we first calculate the weight of each quality attribute according to statistics on the user's selection through the neural network approach; and then calculated quality of component; finally, according to the quality of components we get the credibility of uncertain component model which is the value of corresponding probability property.

Set up a group of homogeneous components $MC = \{mc_1, mc_2, mc_3 \dots mc_n\}$, and users give the choice based on personal feeling. Then we can use the number of choices of homogeneous components from the user group to calculate the services QoS attribute weights by neural network.

First, we need to collect and organize the user's choice of homogeneous components. Within a certain period of time the user's choice is a collection of components, which can be expressed as $\text{UserChosen} = \{N_{i_1}, N_{i_2}, N_{i_3} \dots N_{i_m}\}$, where N_{i_k} means that the i_k component has been chosen N_{i_k} times. Use matrix to organize QoS attributes of selected components as follow. It is the matrix in which each row represents a single component metric, where each column represents a single QoS attribute and the QoS attributes include Response Time，Availability，Throughout，Successability，Reliability and Latency.

$$\text{QosM}=\begin{bmatrix} RT_1 & A_1 & T_1 & S_1 & R_1 & L_1 \\ RT_2 & A_2 & T_2 & S_2 & R_2 & L_2 \\ \dots & & & \dots & & \dots \\ \dots & & & \dots & & \dots \\ RT_k & A_k & T_k & S_k & R_k & L_k \end{bmatrix}$$

Then set QosM^T, which is a 6*n matrix, as the input of neural network algorithm unit which means that set every QoS attribute as a node in the neural network and the corresponding value of each component is an assignment of the node; set the times of each component being selected in the form of $[N_1, N_2, \dots, N_n], \sum_{i=1}^{n} N_i = m$, which is 1*n matrix, to be the target; at last, construct the training sample. Through the training of neural network, we can get the weight for each QoS attribute. Then each QoS weight divides the max of them, and we can get the set of relative weights：

$$W = \{W_1, W_2, W_3, W_4, W_5, W_6\}$$

which are corresponding to the six attributes of QoS. Regarding the evaluation mechanism of service credibility, we view homogeneous components as an independent set and

compute relative quality of each component in the corresponding homogeneous component set as follow:

$$\overline{RT_i} = 1 - \frac{RT_i}{\sum_{k=1}^{m} RT_k};\ \ \overline{A_i} = \frac{A_i}{\sum_{k=1}^{m} A_k}$$

$$\overline{T_i} = \frac{T_i}{\sum_{k=1}^{m} T_k};\ \ \overline{R_i} = \frac{R_i}{\sum_{k=1}^{m} R_k}$$

$$\overline{S_i} = \frac{S_i}{\sum_{k=1}^{m} S_k};\ \ \overline{\mathrm{L}_i} = 1 - \frac{\mathrm{L}_i}{\sum_{k=1}^{m} L_k}$$

Because response time and latency are smaller, the quality of component's data is better, so they are represented by their complements. Thus quality of component is formed by these relative qualities and the relative weights, just as follow:

$$\overline{QoS_i} = \{\overline{RT_i}, \overline{A_i}, \overline{R_i}, \overline{T_i}, \overline{S_i}, \overline{\mathrm{L}_i}\}, 1 \le \mathrm{i} \le \mathrm{m}$$

$$Q_i = \overline{QoS_i} \cdot W^T = \overline{RT_i} * \mathrm{W}_1 + \overline{A_i} * \mathrm{W}_2 + \overline{R_i} * \mathrm{W}_3 + \overline{T_i} * \mathrm{W}_4 + \overline{S_i} * \mathrm{W}_5 + \overline{\mathrm{L}_i} * \mathrm{W}_6$$

When we get the relative quality $\mathrm{Q_i}$, the degree of credibility which is also the attribute $\mathrm{P_i}$ of component can be calculated by $\mathrm{Q_i}$, in proportion to the overall relative qualities of homogeneous components, just like:

$$\mathrm{P}_i = \frac{Q_i}{\sum_{k=1}^{m} Q_k},\ \ 1 \le \mathrm{i} \le \mathrm{m}$$

IV. COMPOSITION IN MASHUP

Assessing each mashup component's data uncertainty isn't enough: the final mashup application's data uncertainty also depends on how these components are interconnected. We can assess the final applications' overall data uncertainty by aggregating the composing services' data uncertainty. Mashup's data uncertainty isn't simply an aggregation of individual component's data uncertainty. Instead, it depends on how particular components combine into a composite logic, layout, and hence user experience. By analyzing the most popular mashups published on programmableweb.com, the paper [2] identified the following typical roles:

1) Master. Even if a mashup integrates multiple components in a single page, in most cases, one component is more important than the others.

2) Slave. A slave component's behavior depends on another component: its state is mainly modified by events originating in another (master) component.

3) Filter. Filter components let users specify conditions over the content the other components show. They provide (possibly hierarchical) access mechanisms that let users incrementally select which content they want to see.

Based on these three roles, there are three basic patterns that characterize most mashup applications (see Figure 3) and highlight some mutual dependencies among the identified roles that impact mashup's data uncertainty.

1) The slave-slave pattern, in which the mashup integrates several slave components the user can interact with in an isolated fashion, without any propagation of data or events from one component to another. At startup or during runtime, users define filter conditions that steer all the slave components. The effect is that of a rather static application with very simple interaction facilities that lets users "query" the slave components' data set. Regarding the resulting mashup's data uncertainty, we assume that the filter doesn't increase the components' data uncertainty.

2) The master-slave approach, the most widely used pattern among today's mashup applications. It features all three component roles. A filter component lets users restrict the data all the other components simultaneously show. Users employ the master component to perform the main interactions with the application, such as selecting related data items. The slave component is automatically synchronized according to the selections performed on the master component, thereby visualizing the selected elements' details. With the master-slave pattern, the final application's data uncertainty could depend on the application's composition logic. Provided that master and slave are compatible in terms of data to be visualized, their integration might increase the slave's data uncertainty.

3) The master-master pattern. This is the most complete pattern, in which — in addition to suitable filter components — all integrated components are masters. All components provide interaction facilities that let users perform selections or that provide inputs that propagate to all the other components that synchronize accordingly. The master components therefore also act as slaves. From a data uncertainty perspective, the master-master pattern is similar to the master-slave pattern. If the components have different underlying data sets, situations could occur in which one component satisfies the user request, while another component can't, lowering the mashup's overall perceived data uncertainty.

We will give our data uncertainty computation mechanism based on these three roles of mashup components and the three mashup patterns. In this paper, we assume that the mashup composition performs integration at the process and presentation levels correctly. To characterize data uncertainty in the context of mashups, we focus on the data level.

V. DATA UNCERTAINTY OF MASHUPS

A. Date Uncertainty in the data sets of mashups

Data integration in mashups corresponds to a global-as-view (GAV) problem, in which the global schema is expressed in terms of views over the integrated data sources. During mashup development, the designer can inspect the attributes the components expose, as specified in the component APIs, and infer join attributes on which to base data integration.

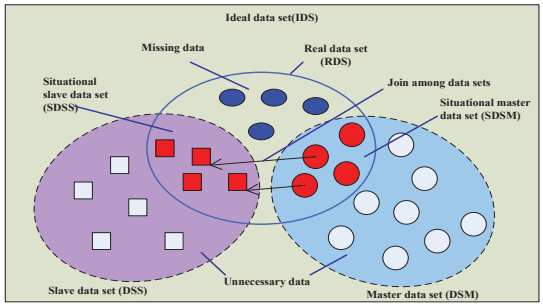

Figure 1. Data sets involved in data integration of mashup.

We can characterize data integration for mashups by categorizing the data relationship between different data sources as follows:

- Mashup applications are developed to let users retrieve and access a set of data that we call the ideal data set (IDS); it is the final data view of mashup components.
- Each component k has its own data set DSk. To fulfill the mashup requirements, a smaller portion SDSk ⊆ DSk could be sufficient. SDSk is the corresponding components' situational data set.
- The integration of all situational data sets SDSk gives the real data set RDS ⊆ IDS that the mashup provides. RDS's data uncertainty thus depends on the uncertainty of the data individual components provide.
- We can determine the mashup's data uncertainty by comparing its RDS with the corresponding IDS.

Now we analyze the corresponding data uncertainty for RDS based on the forward work on data uncertainty of mashup components and their composition relationships.

- The data uncertainty of situational slave data set is the same as the data uncertainty of slave component. And we set it as P(S).
- The data uncertainty of situational master data set is the same as the data uncertainty of master component. And we set it as P(M).
- For the missing data is not the core data part of RDS and always have no strong relations with the slave component or the master component, now we don't consider its data uncertainty.

Then the data uncertainty of RDS is calculated based on the type of Join relationship among data sets and the structure of mashup components. We assume components are sourced from the Web, we also assume they're independent of each other. Because our data uncertainty is computed for the data source among the data space which is composed of the data sources which belong to the same domain, like weather, news, sales and so on, the data uncertainty of slave component and that of master component are independent. So the data uncertainty of join relationship between slave component and master component is as follow:

$$P(MS) = P(M) * P(S)$$

$$\mathrm{P}(US|CM) = 1 - \mathrm{P}(S)$$

We describe data uncertainty of data source with the probability of the data source to be certain. So P(M) is not only the probability of master component to be certain, but also the data uncertainty of mater component; P(S) is the data uncertainty of slave component; P(MS) is the data uncertainty of the join data set between mater component and slave component. P(US| CM) is the probability that the slave component is uncertain when the master component is certain. And we will describe different ways to compute RDS's data uncertainty for different composition situations in mashups.

B. *Data uncertainty of RDS*

In the Slave-slave pattern, every mashup component is independent with each other, and the data uncertainty of mashup components is the maximum data uncertainty of all the slave components. Because we describe data uncertainty of data source with the probability of the data source to be certain, the data uncertainty of mashup components is described by P({S1,S2,…,Sn}).

$$\mathrm{P}(\{S1,S2,...,Sn\}) = \mathrm{MIN}\{\mathrm{P}(S1), \mathrm{P}(S2), ..., \mathrm{P}(Sn)\}$$

For the Master-slave pattern and Master-Master pattern, the data uncertainty is mainly to compute the data uncertainty between master component and slave component, because of the data uncertainty between master component and master component can be transformed to data uncertainty between master component and slave component. In the situation of Master-slave pattern, there are two sources of data uncertainty which are the one that the mater component is uncertain and the other one that the slave component is uncertain when the master component is certain. So the data uncertainty between master component and master component is as follow:

$$\mathrm{P}(\mathrm{M\_S}) = 1 - (\mathrm{P}(UM) + \mathrm{P}(US|CM))$$
$$= \mathrm{P}(\mathrm{M}) - \mathrm{P}(US|CM) = \mathrm{P}(\mathrm{M}) + \mathrm{P}(\mathrm{S}) - 1$$

Where P(M_S) means data uncertainty between a master component and a slave master component, P(UM) means the probability that master component is uncertain and P(US| CM) means the probability that the slave component is uncertain when the master component is certain.

We can consider Master-Master pattern to be the combination of two Master-slave patterns: a selection in one master causes the other master to act as a slave and vice versa.

$$\mathrm{P}(\mathrm{M\_M}) = 1 - (\alpha(\mathrm{P}(UM1) + \mathrm{P}(UM2|CM1)) + (1-\alpha)(\mathrm{P}(UM2) + \mathrm{P}(UM1|CM2)))$$
$$= \mathrm{P}(\mathrm{M1}) + \mathrm{P}(\mathrm{M2}) - 1$$

Where P(M_M) means data uncertainty between two master components; P(UM) means the probability that master component is uncertain; P(UMi|CMj) means the probability that one master component is uncertain when another master component is certain.

In real mashups, we can analyze the mashups into the three patterns, but we also need to set the data uncertainty computation sequence for the mashups. For the computation sequence, we have set three rules:

- Master-Master pattern is computed prior to others.
- Master-Slave pattern is computed prior to Slave-Slave pattern.
- The pairs of mashup components which have smaller data uncertainty are computed prior.

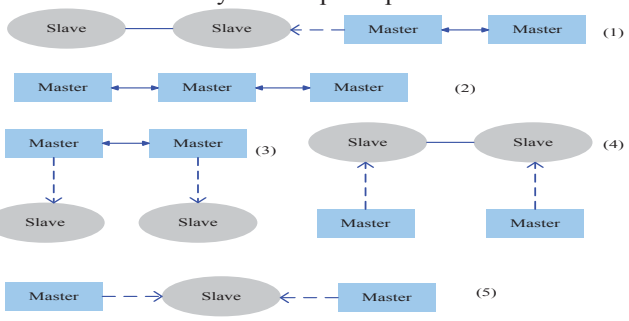

Figure 2. The situations of computation sequence

Based on master role and slave role of mashup components, we categorize the computation sequence into five situations:

- Situation 1: Slave-Slave-Master-Master

  Because there are Master-Master pattern, we compute the pair of Master-Master first. Then this pair play the master role to the second slave component, we compute them as Master-Slave pattern. At last, we compute the forward result and the first slave component as Slave-Slave pattern. The computation sequence is as follow:

  P(slave-slave-Master-Master) = P(slave-(slave-(Master-Master)))

- Situation 2: Master1-Master2-Mater3

  In this situation, we first find the master component which has the lowest data uncertainty. If Master1 or Master3 has the lowest data uncertainty, computation sequence is from the left to the right or from the right to the left. If the middle one has the lowest data uncertainty, then find the one between the other two components which has lower data uncertainty and compute this pair first.

- Situation 3: Slave1-Master-Master-Slave2

  This situation can also be seen as Slave1-Master-Slave2, and the computation sequence depends on the data uncertainty of Slave1 and Slave2. If the data uncertainty of Slave1 is higher than the data uncertainty of Slave2, the computation sequence is as follow:

  P(Slave1-Master-Master-Slave2) = P(Slave1- ((Master-Master)-Slave2))

  where P(Slave1)<P(Slave2). The situation first executes Master-Master computation and then executes Master -Slave computation.

- Situation 4: Master-slave-slave-Master

  In this situation, the computation sequence first executes Master-Slave computation and then executes Slave-Slave computation.

  P(Master-slave-slave-Master) = P((Master-slave)-(slave-Master))

- Situation 5: Master1-slave-Master2

  In this situation, there are two Master components and we assume that the data uncertainty of Master1 is higher than the data uncertainty of Master2. If Master1 and Master2 communicate separately with different parts of Slave component, we can transform the situation to Master1-slave1-slave2-Master2 situation where slave1 and slave2 are different parts of Slave component and P(slave1)=P(slave2)=P(Slave). If the parts of Slave component that Master1 and Master2 communicate separately with have the common part, the computation sequence is as follow:

  P(Master1-slave-Master2) = P(Master1-(slave-Master2))

VI. CONCLUSION

In this paper, we study the data uncertainty of mashup from two levels: mashup components and mashups. The data uncertainty of mashup component is a relative value in the set of all the homogeneous components. In the data level of mashup application, mashups can be seen as the composition of different data source with certain application relationships. So we give the data uncertainty computation of mashups based on these relationships and we show the computation sequence in different composition situations. We will further our work for the complex integration process in mashup application, analyze how the change of data uncertainty in certain mashup component affects the overall data uncertainty of mashups, and study the composition of mashup applications based on data uncertainty.

***Abstract*—Heterogeneously-licensed systems pose new challenges to architects and designers seeking to develop systems with appropriate intellectual property rights and obligations. In the extreme case, license conflicts may prevent a system's legal use. Our previous work showed that rights, obligations, and conflicts can be calculated. But architects benefit from fuller information than simply (for example) a list of conflicts. In this work we demonstrate an approach for presenting intellectual property results in terms of arguments supporting them. The network of argumentation provides not only an explanation of each conclusion, but also a guide to the tradeoffs available in choosing among design alternatives with different licensing results. The approach has been integrated into the ArchStudio software architecture environment. We present an illustrative example of its use.**

I. Introduction

An increasing number of development organizations are adopting a strategy in which software-intensive systems are composed of *heterogeneously licensed* (HtL) components, with different components governed by different software licenses. The components are either open source software (OSS) or proprietary software with open application programming interfaces (APIs), and are combined in an open architecture (OA) in which components with comparable interfaces can be substituted for each other [10]. Under this strategy the development organization becomes an integrator of components largely produced elsewhere, interconnected to achieve the desired result.

The resulting OA systems can achieve reuse benefits such as reduced costs, increased reliability, and potentially increased agility in evolving to meet changing needs. But rather than a single proprietary license as when acquired from a proprietary vendor, or a single OSS license as in uniformly-licensed OSS projects, the resulting system typically has no recognized single software license. Instead it has, strictly speaking, a *virtual license* [2] composed of each component's rights and obligations for that component under its governing license. The rights available for the system as a whole are the intersection of the rights sets for each component. In some cases the licenses may produce conflicting obligations and this intersection is empty, leaving a system that cannot legally be used, distributed, or modified. An emerging challenge is to realize the reuse benefits of HtL systems while managing virtual licenses to ensure that the desired system rights are available for an acceptable set of obligations.

In our previous work (summarized in Section IV) we described and implemented a novel approach for calculating conflicting obligations, unavailable rights, and virtual licenses in an architectural design context. Calculation is necessary because the number of entailments in a typical HtL system is large, the system's architecture is constantly evolving, its design-, distribution-, and run-time architectures are often distinct, component licenses evolve and components are relicensed, and the consequences of infringement can be substantial. Therefore identifying conflicts and virtual licenses through calculation is a substantial boon. But we soon realized that *explaining* them was of even greater value.

We present an approach in which arguments are used to explain the results of right and obligation calculations. The calculations proceed by elaborating a directed acyclic graph (dag) of inferences among rights to obligations for entities in the system architecture. In this work we reimplemented the software that performs the calculations so that the dag is retained in its entirety as the primary calculation product, containing within it the obligation conflicts, unavailable rights, and virtual license for the system under analysis. Then an explanation for a specific result corresponds to the traversal of a path through the dag, starting at the result in question and continuing until the question has been answered.

- *Conflicting obligations:* the traversal branches for each obligation to show the desired rights, license provisions, and architectural entities from which that obligation is produced, and at the root of the traversal shows in what ways the obligations conflict.
- *Unavailable rights:* for each such right, a traversal identifies the exclusive copyright right that subsumes the right in question, the architectural entity to which the right pertains, and why no right in the entity's license grants the right in question.
- *Virtual license:* traversals show the chains of inference by which each right and obligation is entailed by the system architecture, the stated license for each component, and the desired rights for the system as a whole.

The dag calculation algorithm follows the steps of legal

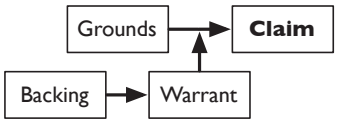

Fig. 1. A *claim*, supported by *grounds*, their pertinence to the claim justified by a *warrant*, whose validity is supported by *backing* (diagram after [14])

reasoning (formalized to support automation) by which an informed analyst would reason out the results. Thus the traversals follow inference paths that follow (in more detail) the paths by which an analyst reasons out the same conclusions.

II. Related Work

The most influential approach for structuring legal arguments is that of Toulmin, who classified the parts of arguments into claims, grounds, warrants, backing, qualifiers, and rebuttals, in a recursive structure with a diagrammatic notation outlined in Figure 1 [14]. His approach has spread beyond the area of legal arguments and is used in general rhetoric and computer science. Toulmin divides arguments into

1) *claims* asserted to be true;
2) for each claim whose truth is disputed, one or more *grounds* supporting it;
3) if it is disputed whether a claim's grounds suffice for it, then a *warrant* stating why the grounds entail the claim;
4) if the warrant is disputed, then *backing* supporting it.

If a ground or backing is disputed, then it is made the claim of a lower-level argument constructed in its support. The recursion of arguments continues as long as grounds or backings are in dispute, or until the original claim is abandoned. (Qualifiers and rebuttals address the degree of strength of arguments, and are not used in the present work.)

Hohfeld sought a theory by which to resolve the imprecise terminology and ambiguous classifications he found in use for legal relationships. In a seminal article published in 1913 and cited to the present day, he set forth a system of eight jural relations intended to express and classify all legal relationships between people. The first four regulate ordinary actions and are *right* ("may"), *no-right* ("cannot"), *duty* ("must"), and *privilege* ("need not"). Each relation has an *opposite* relation whose sense is its opposite, and a *correlative* relation whose sense is its complement. We use Hohfeld's first four jural relations as the basis of our representation of the enactable, testable provisions of software licenses (Section IV).

There has been much work on analysis of laws in AI over the past few decades. A widely-cited example is Sergot et al.'s re-expression of the British Nationality Act as a Prolog program; the resulting program applied the Act to any person's situation and characteristics to determine nationality [12].

A number of researchers have used argumentation to guide decision making, notably Haley et al. who propose an approach for using satisfaction arguments to evaluate and guide evolution of security requirements [7]. Decision choices for which no convincing argument is found are set aside in favor of choices for which stronger arguments have been identified.

III. Licensing Background

A. Intellectual Property (IP)

An individual can own a tangible thing, and have property rights in it such as the rights to use it, improve it, sell it or give it away, or prevent others from doing so, subject to some statutory restrictions. Similarly, an individual can own *intellectual property* (IP) of various types, and have specific property rights in the intangible intellectual property, such as the rights to copy, use, change, distribute, or prevent others from doing so, again subject to some statutory restrictions.

Software licenses are primarily concerned with copyrights Copyright is defined by Title 17 of the U.S. Code and by similar law in many other countries. It grants exclusive rights to the author of an original work in any tangible means of expression, namely the rights to

- reproduce the copyrighted work;
- distribute copies;
- prepare derivative works;
- distribute copies of derivative works; and
- (for certain kinds of work) perform or display it.

Because the rights are exclusive, an author can prevent others from exercising them, except as allowed by "fair use", or can grant others any or all of the rights or any part of them; one of the functions of a software license is to grant such rights, and define the conditions under which they are granted.

B. Software Licenses

Traditional proprietary licenses allow a company to retain control of software it produces, and restrict the access and rights that outsiders can have. OSS licenses, on the other hand, encourage sharing and reuse of software, and grant access and as many rights as possible.

Academic OSS licenses such as the Berkeley Software Distribution (BSD) license, the Apache Software License, and perl's Artistic License [1] grant nearly all rights and impose few obligations. Typical academic license obligations are simply to not remove the copyright and license notices.

Reciprocal OSS licenses impose an obligation that distributed modifications of reciprocally-licensed software be freely licensed under the same license. Examples are the Lesser General Public License (LGPL), Mozilla Public License (MPL), and Common Public License [1].

Some reciprocal licenses additionally require that software combined with the licensed software (for various definitions of "combined") also be freely licensed under the same license. We term such licenses *propagating*; they are also known as *strong copyleft* licenses. Examples are the General Public License versions 2 and 3 (GPLv2, GPLv3) [1].

Some OSS is *multiply-licensed*, or distributed under two or more licenses. The MySQL database software is distributed either under GPLv2 for OSS projects or a proprietary license for commercial projects. The Mozilla Disjunctive Tri-License licenses the core Mozilla components under any of three licenses (MPL, GPL, or LGPL).

C. Licenses and Software Architectures

Certain classes of architectural features affect the application and propagation of license provisions. The most common such features are listed below. A software architecture is composed of components, each of which is a "locus of computation and state" in a system, and connectors which link them and mediate interactions between them.

Software source code components—These can be

- standalone programs,
- libraries, frameworks, or middleware,
- inter-application script code such as C shell scripts, or
- intra-application script code, to creating Rich Internet Applications using domain-specific languages like XUL for the Firefox Web browser [6] or "mashups"[9].

The distinguishing characteristic of a source code component is that its source code is available and it can be modified and rebuilt. Each may have its own explicit license, though often script code connecting programs and data flows has no stated license unless the script is substantial or proprietary.

Executable components—These components are in binary form, with source code not available for access, review, modification, or possible redistribution [11]. If proprietary, they often cannot be redistributed, and so such components will be present in the design- and run-time architectures but not in the distribution-time architecture.

Software services—An appropriate software service can replace a source code or executable component.

APIs—These are not and cannot be licensed, but connections through APIs can be used to limit the propagation of some license obligations.

Software connectors—These are software elements providing a standard or reusable way of communication through common interfaces, such as High Level Architecture, CORBA, or Enterprise Java Beans. Connectors can also limit the propagation of some license obligations.

Methods of composition—These include linking as part of a configured subsystem, dynamic linking, and client-server connections. Methods of composition affect license obligation propagation, with different methods affecting different licenses. How and to what extent this occurs have not been resolved in court or in practice [5], [13].

Configured system or subsystem architectures—These are software systems used as atomic components of a larger system. Their internal architecture may contain subcomponents under several licenses, which may affect the rights and obligations for the configured (sub)system and the overall system containing it. To minimize license interaction, a configured system or subsystem architecture may be surrounded by what we term a *license firewall* [2], namely a layer of dynamic links, client-server connections, license shims, or other connectors that block the propagation of obligations.

D. Heuristics for Designing HtL Systems

HtL system designers have developed heuristics to guide architectural design while avoiding some license conflicts.

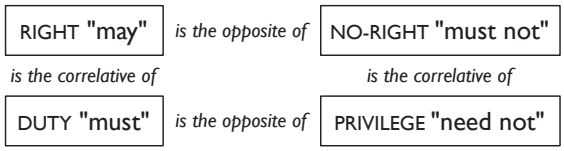

Fig. 2. Hohfeld's four basic relations

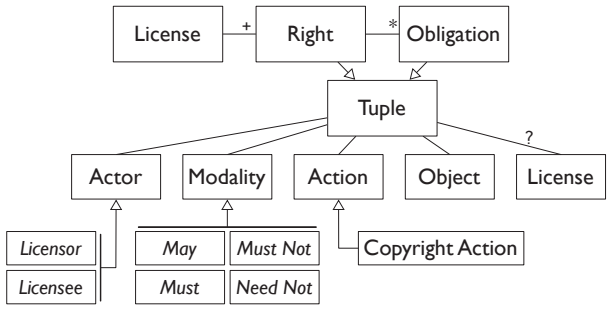

Fig. 3. Metamodel for software licenses

First, it is possible to use a reciprocally-licensed component through a license firewall that limits the scope of reciprocal obligations for specific licenses (depending on how the license provisions are interpreted). Rather than connecting conflicting components directly through static build-time links, the connection is made through a dynamic link, client-server protocol, license shim, or run-time plug-in.

A second approach used by a number of large organizations is to avoid using any components with reciprocal licenses.

Even using design heuristics such as these, keeping track of license rights and obligations across components that are interconnected in complex OAs quickly becomes cumbersome. Organizations wishing to follow a "best-of-breed" component selection policy, without regard to component licenses, face even steeper challenges. Automated support is needed to manage this multi-component, multi-license complexity.

IV. License Rights and Obligations

In our previous work [2] we developed an approach for expressing software licenses that is more formal and less ambiguous than natural language, and that allows us to calculate rights and obligations for an HtL system and identify conflicts arising from the rights and obligations of two or more component's licenses. Our approach is based on Hohfeld's eight fundamental jural relations [8], of which we use *right* ("may"), *duty* ("must"), *no-right* ("must not"), and *privilege* ("need not") (Figure 2). Each relation has a *correlative* relation, which in our context relates an obligation to its necessary right:

- if actor A must perform action X, then A requires the correlative right to perform it, expressed as "A may X";
- if actor A must not perform action X, then A requires the correlative right to not perform it, "A need not X".

We express rights and obligations as tuples (Figure 3):

<actor, modality, action, object, license>

The actor is either the "Licensee" or in a few cases "Licensor" for all the enactable, testable provisions of the licenses

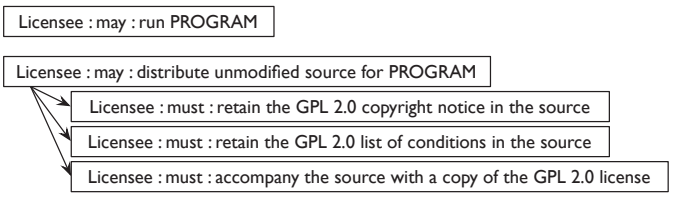

Fig. 4. Some tuples for the GPLv2 license

we have examined [3]. The modality is "may" or "need not" for a right and "must" or "must not" for an obligation. The action is a verb phrase acting on an object, describing what may, need not, must, or must not be done. The object is a module of the system or a related artifact such as a source file, the original version, documentation, and so forth. Typically a license right applies to any of a class of objects distributed under the license, such as any binary file or any modified source file; and the right's obligations will apply to the same object or a related object, such as the right's object's sources or the right's object's originals. For this reason we term rights and obligations as expressed in a license *abstract*, in contrast to a *concrete* right or obligation for one specific entity. Some actions are parameterized by a license as well.

Because copyright rights are exclusive to the copyright holder and licensees, the actions in copyright rights are distinguished from other actions; rights with those actions are only available through the object's license. Rights formed from all other actions are freely and immediately available, unless the object's license obligations restrict them.

A license is expressed as a set of rights, each right associated with zero or more obligations that must be fulfilled be granted it, and possibly a set of overall obligations that must be fulfilled for the license as a whole. Figure 4 sketches two rights from GPL version 2.0 (GPLv2), the first with no obligations and the second with three corresponding obligations.

The details of the license specification approach are described in our earlier work [2], [3].

V. Applying Licenses to Software

A. Calculating the Inference Dag

In order to obtain a particular desired right *r* for a specific module or other entity *e*, in other words a desired *concrete right*, one of two cases must hold:

1) *r* is *not* subsumed by any of the five copyright rights, and does not conflict with any general obligation of *r*'s license *L*. In this case *r* is freely available.
2) *r is* subsumed by an abstract right *R* of the license, with *e* likewise subsumed by *R*'s object. In this case all *R*'s obligations $O_1, O_2, \ldots, O_n$ must be fulfilled, with their objects replaced by whatever function of *e* they signify, in order for *r* to be granted. These could be *e* itself, all sources of *e*, the original version of *e*, and so forth. *n* may be zero, in which case *L* immediately grants *r*.

Figure 5 illustrates one step of the application of a license to obtain a desired concrete right *r*. In the license of *r*'s object

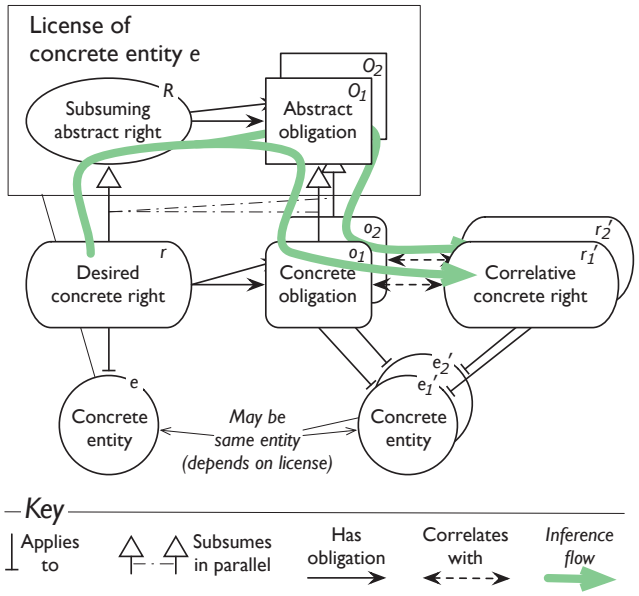

Fig. 5. A step in a rights/obligations inference

e, we search for an abstract right *R* subsuming *r*. The figure shows two obligations O_1 and O_2 of *R*, which we apply to *r*'s object *e* in order to obtain *r*'s concrete obligations o_1 and o_2. Depending on what kind of object O_1 has, o_1 could apply to *e* itself, in which case $e = e'_1$, or to an entity related to *e*, or (if *L* is a propagating license) to another module linked or otherwise connected to *e*. Finally, in order to fulfill o_1 we must have o_1's correlative right r'_1. The same considerations apply for O_2, of course. The heavy arrow shows the flow of inference from desired concrete right through to required concrete obligations and correlative rights.

If r'_1 (r'_2) is immediately available, its branch of the inference is complete. If not, the process recurses from r'_1 (r'_2).

The license rights and obligations for an entire system are calculated by repeating this process for every module of the system. If all modules are under the same license, analogous rights and obligations obtain for every module. If the system is heterogeneously-licensed, however, the calculation is much more varied, and if some of the modules are propagationally licensed then a right for one of those modules can produce obligations for other modules of the system. Such an architecture can easily result in license conflicts, as for example when a license propagates the obligation to be sublicensed under the same license to a proprietary component whose license forbids sublicensing. In such a case, the calculation will fail to produce a simultaneously satisfiable collection of obligations, and no rights will be available for the system as a whole.

Figure 6 shows in Toulmin form a portion of an example inference that produces a conflict, involving a component `e1` obtained under GPLv2 and modified, linked to a component `e2` obtained under the proprietary Corel Transactional License (CTL) [1]. The architectural connection between `e1` and `e2` is one that is interpreted for this inference as propagating

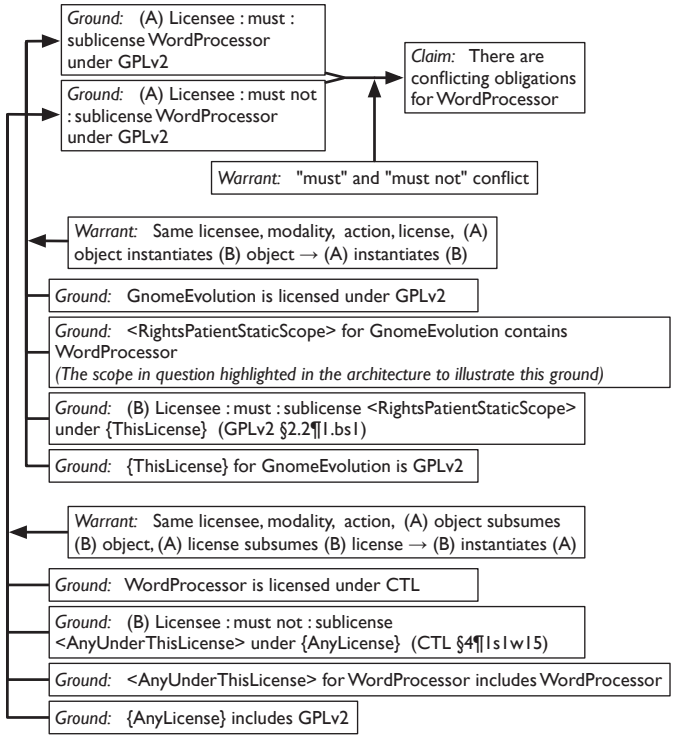

Fig. 6. Toulmin-structured arguments supporting (and explaining) a typical conflict between obligations for a GPLv2 and a proprietary component

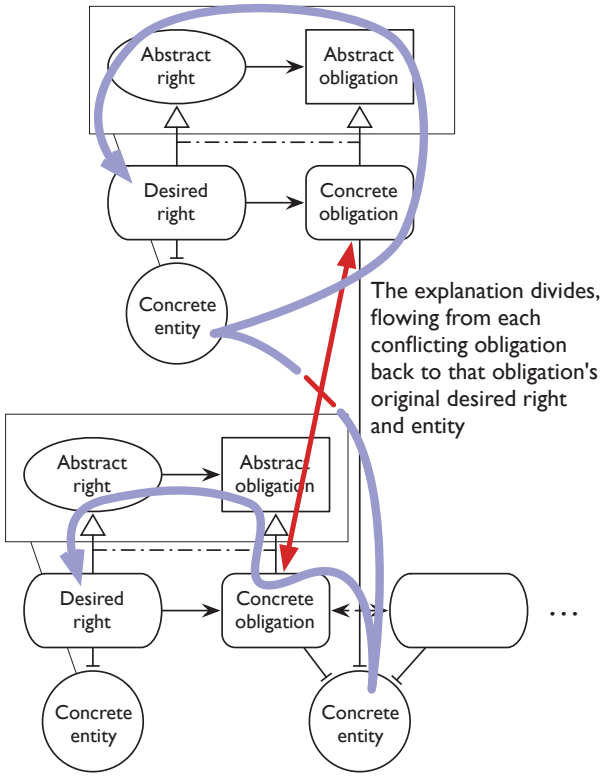

Fig. 7. Divided explanation flow for a conflict between two obligations

GPLv2 obligations, such as a static link. The right to distribute copies of the containing system is desired. In our prototype implementation (Figure 8) these arguments are presented in outline form, with the claim as the root of the outline and its grounds and warrant as its subheads, to be expanded as desired if further explanation is needed. A typical use would be:

1) Why does the WordProcessor component need to be sublicensed under GPLv2?
2) It is in the static-linked scope of the GnomeEvolution component; that component is annotated with the GPLv2 license; and GPLv2 obligates sublicensing under GPLv2 (GPLv2 §2.2¶1.bs1).
3) Why can't the WordProcessor component be sublicensed under GPLv2?
4) The WordProcessor component in the architecture has been annotated with the CTL license, and CTL forbids sublicensing under any license (CTL §4¶1s1w15).

B. Explanation by Argumentation

Figure 7 shows the two explanation flows for a conflict between obligations. Each flow begins at the conflict and explains how one half of the conflicting pair came to be. The connection between the pair is straightforward, as they are identical except for their modalities which are always "must" for one and "must not" for the other.

The flow and the required explanations are analogous for a right-obligation conflict, with the right and obligation again identical except for their modalities, which are always opposites, either "may" and "must not" or "must" and "need not".

After examining the kinds of information that are available in the vicinity of a problem (a conflict or unavailable right), we realized the inferences leading up to it provide the clearest insight into what the problem signifies and why it is present.

- The chains of inference leading up to the problem constitute precisely the portion of the calculation relevant to the problem. No other parts of the calculation—or of the applications of license provisions, determined by the architecture and its annotations, that the calculation identifies—affect whether the problem is present or not.
- The inferences place the problem in the context of licenses, components and their annotations, and architectural configuration — the context in which a designer using the tool is already working.
- Each chain of inference, followed in reverse, provides an unfolding explanation for the problem's presence, which an analyst can explore as far as is helpful in providing understanding and insight.

Each step of a chain of inference is a point at which it can be broken—by replacing a component with one differently licensed, replacing one or more connectors to firewall off a propagating obligation, replacing a build-time component with one provided by users at run time, or other design decisions.

C. Automation

The license metamodel, calculation, and an assortment of license interpretations are implemented in a Java package. The

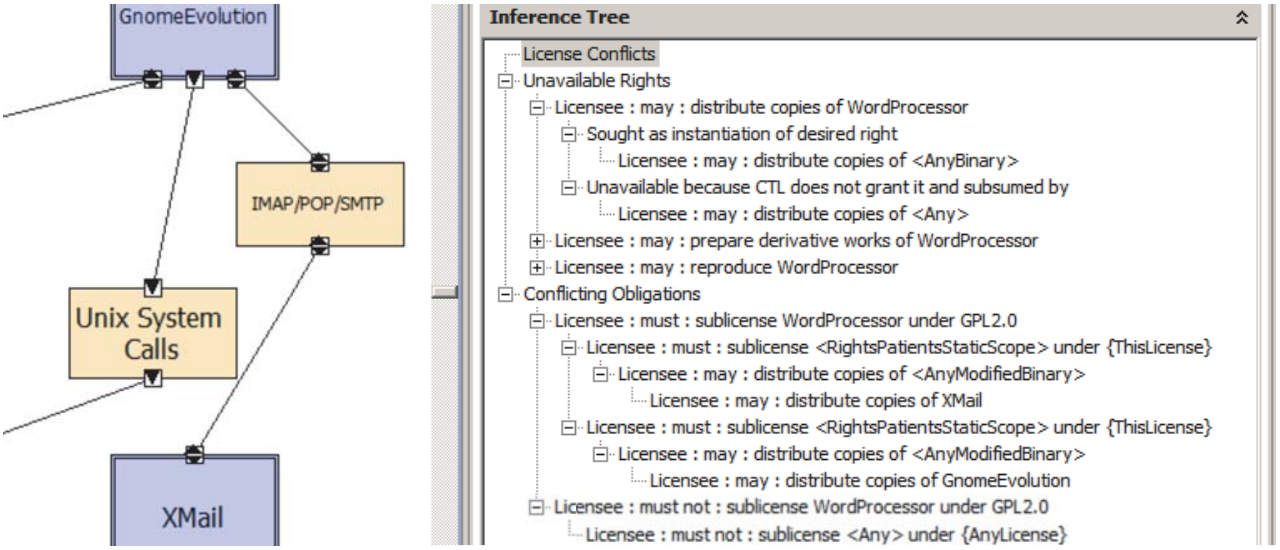

Fig. 8. Prototype explanation results for a CTL-GPL2.0 conflict: (at top) unavailable rights (partially collapsed), (middle) two conflicting obligations.

calculation builds the entire dag, which is then available for presentation in whatever ways are desired. Each abstract right and obligation in a license interpretation has its provenance in the license or interpretation for use in explanations. The package supports the addition and use of new interpretations.

The package is connected into the system design context by its integration into an ArchStudio 4 plugin [4]. The plugin maps features of software architectures onto the license architecture abstraction needed for the virtual license calculation and displays results in the context of the architecture.

The argument grounds drawn from the texts of licenses are implemented through URLs hyperlinking into our collection of software licenses tagged for reference with §-¶-sentence-word numbers [1]. Each URL cites the sentence or phrase from which a right or obligation arises. Word-level `id`s allow references to, for example, #S2.2p1.bs1w11 for the phrase beginning at word 11 of that sentence.

VI. Conclusion

HtL system design and development provide important benefits but impose new demands difficult to meet using only manual methods and human insight. Our approach for supporting HtL development and acquisition automates the calculation of HtL system virtual licenses. We have integrated it into a software architecture tool so it can be applied at the point in the development process when the necessary information is available and the relevant design decisions are made. A key benefit it provides is the automated calculation of license conflicts, desired but unavailable rights, and virtual licenses. But explaining them is of even greater value.

We present a novel approach that presents each conflict in the form of structured arguments showing why each conflict exists and (by implication) points of attack for eliminating it. These arguments provide an informative presentation that brings together all the available information in a compact, evocative form that is easier to interpret, act on, and verify.

***Abstract*— Software architecture is recognized as a critical element in the successful development and evolution of software-intensive systems. Despite the important role of architecture representation and modeling many existing systems like legacy or eroded ones do not have a reliable architecture representation. In this paper we present an approach for architecture recovery from object-oriented code. It's based on a genetic algorithm which uses a fitness function measuring the semantic-correctness of software components. Following our model, architecture which is a partition of classes is considered as a chromosome. A group of classes is a gene. This algorithm gives satisfactory results in terms of consistency and adequacy metrics.**

Keywords- Component; software architecture; recovery; component based; object oriented; reverse engineering

I. INTRODUCTION

Software architecture is recognized as a critical element in the successful development and evolution of software-intensive systems [5]. Software architecture expresses the overall structure of a system in an abstract, structured manner. The main goal of a software architectural representation of a system is to identify the major components that constitute this system, and the interactions between these components [1]. According to Garlan [6], software architecture plays an important role in at least six aspects of software development: understanding, reuse, construction, evolution, analysis and management. Despite the important role of architecture representation and modeling, many existing systems do not have a reliable architecture representation. Indeed these systems could have been designed without an architecture design phase, as it is the case of most legacy systems. For other systems, the available representation can diverge from the system implementation. This appears, first, during the implementation phase due to gaps between the expected architecture and the implemented one. These gaps become greater because of lack of synchronization between software documentation and implementation. Taking into account the previous considerations, it is obvious that an approach of architecture recovery allows architects and developers to take advantage of all the benefits of having an architecture model available. In this context, we propose an approach to extract a component-based architecture from object-oriented systems. Our goal is to decrease the need for human expertise which is expensive and not always available. Our process aims at selecting among all the architectures which can be abstracted from a system, the best one according to the semantic-correctness of architecture. Based on the norm ISO 9126 [10], we formulate these characteristics as measurable properties and specify the recovery process as a balancing problem of these ones. Based on this formulation, we developed a recovery architecture process exploiting a hierarchical clustering algorithm. Nevertheless, the result of this process (i.e. architectures) was not completely satisfactory. We studied the process on several case studies (e.g. Jigsaw, ArgoUML, Eclipse, etc.). The results were sometimes offset from the known architectures. This is due to the nature of the clustering algorithm. In fact, this heuristic algorithm is memory less. For some systems, this feature may deter the clustering process from the best architectures. It explores only a limited number of possible ones. It is not a meta-heuristic and it does not use the space exploration of all possible architectures. Thus, our objective in this paper is to propose an alternative formulation of our approach based on a genetic algorithm (GA). This choice is due to the characteristics of this type of algorithm. A GA allows us to consider architecture recovery as a metaheuristic optimization problem. It aims to explore the solution space to identify the best possible. GAs were introduced in the late 1960's by John Holland [7]. They are based on the Darwinian theory of evolution whereby species compete to survive and the fittest get a higher chance to remain until the end and produce progeny. The basic idea of a GA is to start from a set of initial solutions, and to use biologically inspired evolution mechanisms to derive new and possibly better solutions.

The remainder of this paper is structured as follows. Section 2 presents principle of our architecture recovery approach: semantic-correctness driven. The GA encoding of the recovery process is presented in section 3. Case studies are presented in section 4. They present the results of our approach using GA and compare these results to the clustering-based ones. Section 5 discusses related work. Conclusion and future works are given in section 6.

II. SEMANTIC-CORRECTNESS DRIVEN ARCHITECTURE RECOVERY : AN OVERVIEW

In our approach, recovering a component-based architecture of an object oriented system consists of using its implementation code in order to identify the architectural elements. As first step toward this goal, we defined a mapping model of object

oriented concepts (i.e. classes, methods, interfaces, packages, etc.) and architectural ones (i.e. components, connectors, interfaces, etc.). It defines architecture as a partition of the system classes. Each element of this partition represents a component. These elements are named "shape" and include classes which can belong to different object-oriented packages. A shape is composed of two sets of classes: the "shape interface" includes classes linked with others from the outside of the shape, e.g. a method call to the outside; and the "center" composed of the remainder classes of the shape. We assimilate component to shape and component interfaces to "shape interface". Connectors are all links existing between components. Consequently, the architecture configuration is the set of shapes constituting a partition of the system classes. As a result of these considerations, the search-space of architecture recovery problem is composed of all architectures which are partitions of the system classes. This means that, in a system which contains *n* classes, the search-space contains *O (n!)* potential architectures.

Thus to select the best architecture compared to its semantic correctness, we propose to define fitness function measuring this characteristic. An architecture is semantically correct if its elements (components, connectors and configuration) are. We limit ourselves here to study component semantic-correctness and define function to measure it. This study is based on the most commonly admitted definitions of software component rather than architectural one. Indeed architectural component constraints are included in the software component ones. In addition these supplementary constraints make easier a migration from an object-oriented system to a component-based one.

A. Semantic characteristics of a software component

Szyperski defines in [17] a component as a unit of composition with contractually specified interfaces and explicit context dependencies only. A software component can be deployed independently and is subject to composition by third parties. In [9] Heinemann and Councill define a component as a software element that conforms to a component model and can be independently deployed and composed without modification according to a composition standard. In [12] Luer makes a distinction between component and deployable component. He defines a component as a software element that (a) encapsulates a reusable implementation of functionality, (b) can be composed without modification, and (c) adheres to a component model. A deployable component is (a) prepackaged, (b) independently distributed, (c) easily installed and uninstalled and (d) self-descriptive.

In combining and refining the common elements of these definitions and others commonly accepted ones [11], we propose the following definition of a component: A component is a software element that (a) can be composed without modification, (b) can be distributed in an autonomous way, (c) encapsulates an implementation of functionality, and (d) adheres to a component model. In our approach, the definition of a component model is the Luer one [12]: a model component is the combination of (a) a component standard that governs how to construct individual components and (b) a composition standard that governs how to organize a set of components into an application and how those components globally communicate and interact with each other. As compared to the definitions of Luer and Heineman and Councill, we intentionally do not include the criterion that a component must adhere on a composition theory and the properties of component self-descriptive, pre-packaged and easy to install and uninstall. These are covered through the criterion that a component must adhere to a component model and does not need to be repeated. In conclusion, according to our software component definition, we identify three semantic characteristics of software components: composability, autonomy and specificity. The specificity of a component means that it must contain a limited number of functionalities.

B. Refinement model of the semantic correctness

In the previous section, we have identified three semantic characteristics that we propose to evaluate. To do so, we adapt the characteristic refinement model given by the norm ISO-9126 [ISO]. According to this model, we can measure the characteristic semantic correctness by refining it in the previous three semantic characteristics which are consequently considered as sub-characteristics.

1) From characteristic to properties

Based on the study of the semantic sub-characteristics, we refine them into a set of component measurable properties. Thus, a component is autonomous if it has no required interface. Consequently, the property number of required interfaces should give us a good measure of the component autonomy. Then, a component can be composed by means of its provided and required interfaces. However, a component will be more easily composed with another if services, in each interface, are cohesive. Thus, the property average of service cohesion by component interface should be a correct measure of the component composability. Finally, the evaluation of the number of functionalities is based on the following statements. Firstly a component which provides many interfaces may provide various functionalities. Indeed each interface can offer different services. Thus the higher the number of interfaces is, the higher the number of functionalities can be. Secondly if interfaces (resp. services in each interface) are cohesive (i.e. share resources), they probably offer closely related functionalities. Thirdly if the code of the component is closely coupled (resp. cohesive), the different parts of the component code use each other (resp. common resources). Consequently, they probably work together in order to offer a small number of functionalities. From these statements, we refine the specificity sub characteristic to the following properties: number of provided interfaces, average of service cohesion by component interface, component interface cohesion and component cohesion and coupling.

2) From properties to metrics

According to our object-component/architecture model, component interfaces are assimilated to shape interface. Therefore, the *average of the interface-class cohesion* gives a correct measure of the *average of service cohesion by component interface*. Secondly the *component interface cohesion*, the *internal component cohesion* and the *internal*

component coupling can respectively be measured by the properties *interface class cohesion*, *shape class cohesion* and *shape class coupling*. Thirdly in order to link the *number of provided interfaces* property to a shape property, we associate a component provided interface to each shape-interface class having public methods. Thanks to this choice, we can measure the number of provided interfaces using the *number of shape interface classes having public methods*. Finally, the *number of required interfaces* can be evaluated by using coupling between the component and the outside. This coupling is linked to shape external coupling. Consequently, we can measure this property using the property *shape external coupling*. In order to measure these properties, we need to define metrics. The properties *shape class coupling* and *shape external coupling* require a coupling measurement. We define the metric *Coupl(E)* which measures the coupling of a shape *E* and *CouplExt(E)* which measures the coupling of *E* with the rest of classes. They measure three types of dependencies between objects: method calls, use of attributes and parameters of another class. Moreover they are percentages and are related through the equation: $CouplExt(E) = 100 - Coupl(E)$. Due to space limitations, we do not detail these metrics. Shape properties *average of interface-class cohesion*, *interface-class cohesion*, and *shape-class cohesion* require a cohesion measurement. The metric "Loose Class Cohesion" (LCC), proposed by Bieman and Kang [2], measures the percentage of pair of methods which are directly or indirectly connected. Two methods are connected if they use directly or indirectly a common attribute. Two methods are indirectly connected if a connected method chain connects them. This metric satisfies all our needs for the cohesion measurement: it reflects all sharing relations, *i.e.* sharing attributes in object oriented system, and it is a percentage. Consequently, we use this metric to compute the cohesion for these properties. The refinement model is summarized in Fig.1.

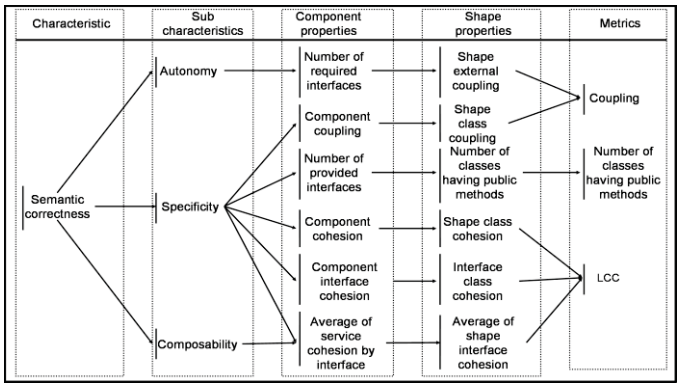

Fig.1. Refinement model of the semantic-correctness characteristic of component

3) Evaluation of the semantic correctness

According to our refinement model of semantic-correctness of component, we define the functions *Spe*, *A*, *C* which measure respectively specificity, autonomy and composability of this component. In these functions *nbPub(I)* is the number of interface classes having a public method and IiI is the shape interface cardinality.

$$Spe(E) = \frac{1}{5} \cdot \left(\frac{1}{|I|} \cdot \sum_{i \in I} LCC(i) + LCC(I) + LCC(E) + Coupl(E) + nbPub(I) \right)$$

$$A(E) = couplExt(E) = 100 - Coupl(E)$$

$$C(E) = \frac{1}{|I|} \sum_{i \in I} LCC(i)$$

The evaluation of the *semantic correctness* characteristic is based on the evaluation of each sub-characteristic. That is why we define this function as a linear combination of each sub-characteristic evaluation function (*Spe, A*, and *C*):

$$S(E) = \frac{1}{\sum_i LCC(i)\mu_i} \left(\mu_1 Spe(E) + \mu_2 C(E) + \mu_3 A(\right.$$

This form is linear because each of its parts must be considered uniformly. The weight μ_i associated with each function allows the software architect to modify, as needed, the importance of each sub-characteristic.

III. GENETIC MODEL FOR ARCHITECTURE RECOVERED FROM OBJECTI-ORIENTED CODE

GA starts derivations from an initial solution called the initial population and then generates a sequence of populations. Each derived population is obtained by "mutating" the previous one. Elements of the obtained solutions are called chromosomes. The fitness of each chromosome is measured by an objective function called the fitness function. Each chromosome (possible solution) consists of a set of genes. At each generation, the process consists to apply some genetic operators which are crossover, mutation and selection in order to generate the next generation. On each chromosome, the algorithm applies two operators: crossover and mutation. Each operator is applied following a specific probability given as an input parameter of the algorithm. During crossover, two chromosomes are selected using a selection method that gives priority to the fittest ones; they exchange some of their genes giving birth to two other chromosomes. Each selected pair of chromosomes produces a new pair of chromosomes that constitute the next generation. Mutation consists of changing randomly one or more genes in a chromosome. Finally a selection is operated on chromosomes to choose the next generation. This selection can increase or reduce or keep stable the size of the population. The algorithm stops if a convergence criterion is satisfied or if a fixed number of generations is reached. The implementation of GA to recover architecture requires specifying how solutions are encoded into chromosomes, how the three genetic operators crossover, mutation and selection are defined and which fitness function and initial population to be used. As we have already defined the function in the section II.B.3, we address the remaining questions in the following sections.

A. Encoding architecture as chromosome

Our genetic model of architecture must adhere to our object-component/architecture mapping model indicating that

an architecture is a partition of classes (cf. section II). This can be translated following different possible formulations. One of these formulations is to represent architecture as a chromosome. Thus, in this model a chromosome is a partition of classes. Another formulation is to model shape as chromosome and architecture as the whole population. This choice makes difficult to check partition property. Instead of the basic idea of GA which aims to optimize one element in a population, this model aims to optimize one population. We opt for representing architecture as a chromosome. Therefore this requires defining the genes which constitute the chromosomes. Again several options are available. Thus a gene may represent a class and the value of the gene may represent the shape which contains this class. An alternative formulation would be to represent a shape as a gene and then the value of the gene would be a set of classes. We opt for the second formulation because it makes easier to check the partition property. Indeed the union of the gene values must be all the system classes and each intersection of gene values must be empty.

B. *Definition of the genetic operators*

In order to apply GA we need to define the genetic operators. These are the selection, the crossover and the mutation operators. The process of evolution starts by selecting several pair of chromosomes whose the number vary according to a probability *PC*. Then the crossover is applied on each pair to generate two new chromosomes. The mutation is applied to each chromosome (new and old) with the probability *PM*. *PC* and *PM* are given as given as parameters of GA. Finally some chromosomes are selected for the next generation. We present in the following each of these three operators.

1) *Selection operator*

There are two selection operators which are used in GA. The first one selects the pair of chromosomes for the crossover and the second selects the next generation among the chromosomes. The selection of the chromosome pair is done according to the roulette-wheel technique [7]. Each chromosome is assigned a portion of the wheel that is proportional to its fitness. A marble is thrown and the chromosome where the marble halts is selected. The selection of the chromosomes for the next generation is done according to two criteria: the age of the chromosomes and their fitness. The new chromosomes are automatically added to the next generation. As we decided to keeps the population size constant, the other chromosomes are selected among the old chromosomes according to the fitness function.

2) *Crossover operator*

A standard way to perform the crossover operation on chromosomes is to cut each of the two parent chromosomes into two subsets of genes (shapes in our case). Two new chromosomes are created by interleaving the subsets. If we apply such operation, it is possible that the resulting chromosomes can no longer represent well-defined partitions. Two specific problems can occur. If the intersection of two shapes is not empty, then the solution is inconsistent. The second problem is when the solution is incomplete. This occurs when the union of all the shapes does not contain all the system classes. In both cases, the architecture represented by the chromosome is not even a partition. Figure 2(a) illustrates these two situations. To preserve the consistency and the completeness of the offspring, we propose a crossover operator based on the operator defined for grouping problems [4]. To obtain an offspring, we select a random subset of shapes from one parent and add it to the set of shapes of the second parent. By keeping all the shapes of one of the parents, completeness of the offspring is automatically ensured. To guarantee consistency, we eliminate from the older shapes, the classes contained in the added shapes. Figure 2(b) illustrates the new crossover operator.

3) *Mutation operator*

Mutation is a random change in the genes that happens with a small probability. In the case of our architecture recovery model, the mutation operator randomly moves some classes from one shape to another one. This mutation operator keeps the partition property safe.

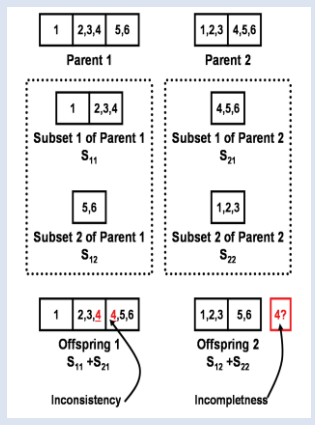

Fig.2 (a) insufficient of the standard crossover

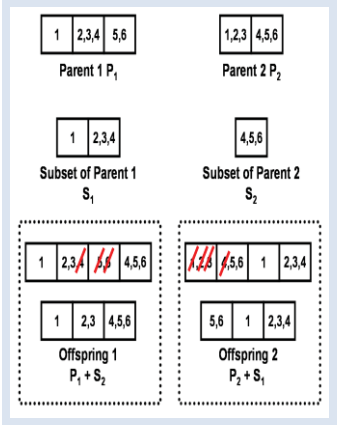

Fig.2 (b) Crossover that preserves consistency and completeness

C. *Choice of the initial population*

The initial population is the set of chromosomes which is used at the start of the GA. The choice of this population is often randomly made. Nevertheless better the initial population is better the solutions is. We opt for an initial population which represents partition obtained by the strongly-connected components of the system classes. In this graph whose vertices are the system classes, there is an arc between two vertices A and B if the class A uses the class B, i.e. uses an attribute, a parameter or a return variable whose type is B and creates or uses an object whose type can be B. A Strongly-connected component is a subset of the graph vertices where any vertex can be reached from any other vertex by a path. These strongly-connected components are a partition of the graph vertices and consequently a partition of the system classes. This partition is an approximation of the system architecture. We use it as an initial chromosome for our GA.

IV. CASE STUDY

As case studies, we validate the genetic algorithm implementation of our architecture recovery process on many systems with different sizes: small systems whose number of classes is less than 50 (e.g. JPhotoAlbum with 17 classes),

systems of medium size where the number of classes is between 50 and 500 (e.g. Jigsaw with 300 classes) and larger systems with more than 1,000 classes. (e.g. ArgoUML with over than 1500 classes). In most cases, the results show that the recovered architectures are closer to the known architectures than those obtained by the clustering algorithm. The difficulty was to choose the adequate parameters for GA. Due to space limitation, we give below only the case study of the Jigsaw system which is a Java based web server.

A. GA parameters

To execute the GA we have to determine some parameters. These are the elements of the initial population, the rate of crossover and mutation, the size of the initial population, and the number of generation. We launch several tests in order to analyze the impact of each parameter on the result. Firstly, we choose to use an initial population based on randomize partitions plus one partition calculated from the strongly-connected components of the system classes. Secondly, the tests realized show that the elements of the population become similar all along the process. This is due to our crossover operator. To avoid having only one element in the population after some generation, we choose a great rate of mutation. Indeed we choose to put the mutation and the crossover rate to 80 %. Nevertheless, this choice of rate is not enough to palliate totally the activity of the crossover operator. Consequently we choose a big initial population (i.e.100) which reduces the risk to obtain a generation composed of only one duplicated element. In order to keep a correct execution time for the test, we choose to do 100 generations.

B. Results

Fig.3 presents the recovered and the known architectures of Jigsaw. The comparison of these architectures shows that most of components of the recovered architecture are the same or sub-components of the known ones. Therefore the obtained solution is relevant according to the known architecture of Jigsaw. The recovered architecture has fitness function score of 80.2 %. This shows the correlation between our fitness function and the relevance of the recovered architecture solution compared to the expected one.

We validate the consistency of our approach by measuring the similarity of the recovered architectures of Jigsaw. We use the similarity measure proposed by Mitchell [18]. For each link between two classes it measures the number of solutions (architectures) for which this link is included in a component. To obtain the percentage of inclusion in a component, this value is then divided by the number of compared solutions. The different results are then aggregated at the levels: {[0, 0], (0, 10], (10, 75), [75, 100] }. These levels correspond to a similarity degree zero, low, medium and high.

Table 1 shows degree of similarity obtained over 99 executions of the recovery process. It shows that 81% of classes are in the zero or high categories. This demonstrates that the vast majority of classes are respectively always separated or together. Only 6.4% of class relationships are in the category medium. This shows that class neighborhoods are stable. Changes are due to classes that are on the borders of two components: the content of these classes is highly dependent on two distinct components. Therefore a significant portion of these class methods can be specified as connectors.

Zero (%) $S = 0\%$	Low (%) $0\% < S <= 10\%$	Medium (%) $10\% < S < 75\%$	High (%) $S <= 75\%$
22.9	12.6	6.4	58.1

TAB 1. A measure of degree of similarity of obtained solution on Jigsaw

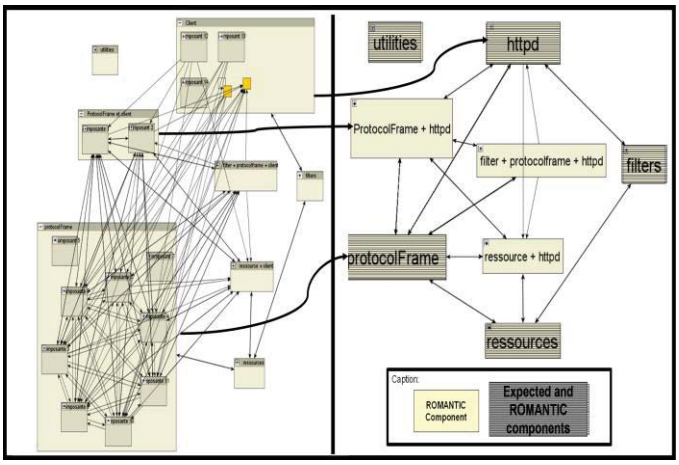

Fig.3 Recovered and known architectures of Jigsaw system

The result of clustering and genetic algorithms is significantly different. This difference is due to the way how the process explores the solution space. On the one hand, clustering explores one solution per iteration. On the other hand, GA explores several solutions (100 in our test) per iteration and the number of genetic operations done by iteration is limited to 2 operations by element of the population. It is clear that GA explores a bigger space than clustering algorithm. GA has a better ratio between the execution time and the quality of the resulting solution.

V. RELATED WORK

Various works are proposed in literature in order to recover architecture from an object-oriented system [15]. We distinguish these works according to two criteria: the input and the technique. Firstly the inputs of the recovery approaches are various. Most often it works from source code representations, but it also considers other kinds of information which for most of them are non-architectural. We can cite, for example, human expertise, which is used in an interactive way in order to guide the process [13], and physical organization, e.g. files, folders and packages [8]. Some works use architectural input. Medvidovic [13] uses styles in Focus in order to infer a conceptual architecture. Finally most works are based on the human expertise: some use the expertise of the architect which uses the tools as an input whereas others use the expertise of the one which proposed this approach. In our approach we use architectural semantic in order to reduce this need of human expertise. Secondly the techniques used to recover architecture

are various and can be classified according to their automation level. Firstly some approaches are quasi manual. For example, Focus [13] proposes a guideline to a hybrid process which regroups classes and maps the extracted entities to conceptual architecture obtained from an architectural style according to the human expertise. Secondly most approaches propose semi-automatic techniques. It automates repetitive aspects of the recovery process but the reverse engineer steers the iterative refinement or abstraction, leading to the identification of architectural elements. Thus ManSART [8] tries to match source code elements on the architectural styles and patterns defined by reverse engineers. Our approach is quasi-automatic too. The main difference with other quasi-automatic approaches is that it refines the commonly used definitions of components into semantic characteristics and refinement models whereas others works use the expertise of the authors in order to define rules driving the process. Some works aim to find the best grouping of elements to subsystems, i.e., the best clusters of an existing software system. Some of these works use a genetic algorithm to compute the best partition [3, 14]. For example, in [14] the problem representation uses chromosomes where each gene represents a class and contains the number of the corresponding cluster. Among these approaches of software clustering, the work of Mancoridis and Mitchell [3] is close to our approach. They introduced the concept of software modularization as a clustering problem for which search is applicable. Their tool Bunch uses a variety of search algorithms. Result is a graph of dependence between modules. This is not an architectural view of the system.

VI. CONCLUSION

We presented in this paper an approach of architecture recovery of object-oriented systems. Architecture recovery is formulated as a search-based problem based on a genetic algorithm (GA). To use genetic algorithms, we adapted our object-component/architecture model to manipulate the architectures (solutions) as chromosomes and group of classes as genes. The properties of this algorithm make it particularly efficient in cases where the computation time is less important compared to the quality of the result. Case studies show that fitness function score is proportional to the relevance of the obtained architectures compared to the expected ones.

As a perspective of this work, we intend to define a method to combine, for a given system, the results obtained by using the genetic implementation of our architecture recovery process with those obtained by the use of the implementation based on simulated annealing [16]. Our goal is to get more relevant architectures in all use cases.

***Abstract*—Software asset management (SAM) represents an important role for software development and maintenance. Many software companies have been using a SAM system to help to control costs and optimize software investments across their organization and throughout all stages of their life cycles. During all the process in SAM, how to classify the software assets reasonably and build a classification to help developers find their desired software asset effectively is an import part. However, how to build a reasonable classification is a dilemmatic problem for SAM system managers. Because it is difficult for them to find a Hierarchical Classification Structure (HCS) with good super-ordinate and sub-ordinate word relationships, at the same time, it is also difficult for them to build a Hierarchical Classification Structure (HCS) using the words selected by themselves. In this paper, we proposed an ontology based HCS modeling method for SAM system managers. With this method, the managers can build an understandable HCS for their users to support the browsing of software assets. We also present a case study to illustrate the availability of our method.**

Keywords-software asset management; ontology; classification; browsing-based restrieval;

I. INTRODUCTION

Software asset management (SAM) represents an important role for software development and maintenance. Administered through an ongoing plan, SAM makes it easier to identify what you have, where it's running, and whether redundancy may exist [1]. Many software companies have been using a SAM system to help to control costs and optimize software investments across their organization and throughout all stages of their life cycles. A well-deployed SAM system can help companies cut costs, improve security and compliance, and anticipate future software needs. SAM system also helps organizations accurately capture the costs and benefits associated with IT projects that enable a competitive advantage.

During all the process in SAM, how to classify the software assets reasonably and build a Hierarchical Classification Structure (HCS) to help the developers to find their desired software asset effectively by browsing–based retrieval is an import part. Because, as we have known, the browsing–based retrieval is more instructive for developers and easier for them to find new assets, more and more developers prefer to find their desired assets by browsing the assets library by following a HCS.

However, how to build a reasonable HCS is a dilemmatic problem for SAM system managers. Because, strictly speaking, in a good HCS, the relationship between each super-ordinate word and sub-ordinate word should be an "is-a-kind-of" relation. However, it is usually very difficult for system managers to find a strict taxonomy with only this kind of relation to be used as a HCS directly. At the same time, it is also very difficult for them to build a HCS from scratch using the words selected by them, because they could not make sure whether the relationship among all the selected words is appropriate to be used in a HCS or not.

In this paper, we proposed an ontology based HCS modeling method for SAM system managers. In our method, an ontology is proposed for HCS building. This ontology confined the kinds of relationship between each super-ordinate word and sub-ordinate word in the HCS. Using the instances defined according to this ontology the system managers can build a HCS with controlled understandability (in another paper [2], we gave a HCS generating algorithm to support building the HCS automatically). For the relationships among the words in HCS are defined apparently, the understandability of the whole HCS can be controlled. Furthermore, it becomes easier for the system managers to make it clear that which part of HCS dragged down the understandability of the whole HCS, and then it becomes easier for them to make some improvements.

The rest of this paper is organized as follows: section Ⅱ presents the motivation of our paper with a real using example; section III discussed the different levels of understandability and the corresponding relationships in HCS; Section IV presented our ontology and the HCS building process; In section V, we presented a case study to illustrate the availability of our method; Section VII draws the conclusion for our work.

II. MOTIVATION EXAMPLE

In SAM systems, the HCS usually help the developers to find their desired software asset by browsing–based retrieval

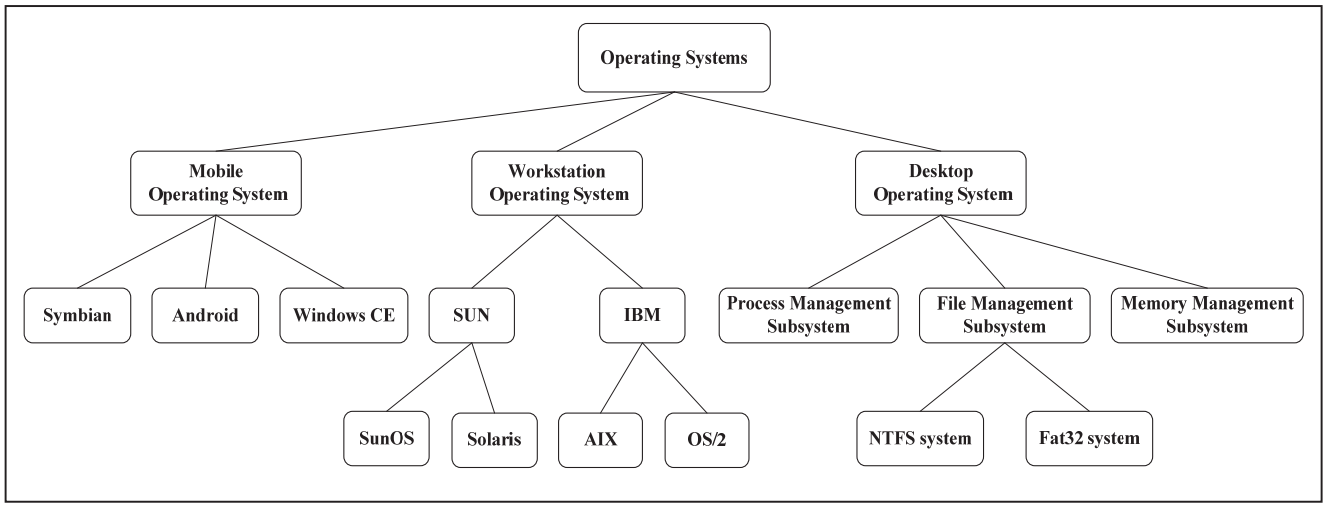

Figure 1. Example of a HCS.

[3][4][5]. HCS is a hierarchical tree structure, in which each node is labeled with a word and represents a set of assets based which related to this word. Navigated by HCS, the browsing retrieval process becomes a process to follow a route in the HCS[6][7]. In a certain browsing-based retrieval step, the developer is usually presented with a screen containing many word-links (e.g. a hyper-link which is labeled by a word in HCS). Each word-link represents a sub-node of a certain node in the HCS. After an overview of the screen, the developer selects a link that he or she thinks the desired assets should be contained, and clicks on the link. This will result in a step of retrieval, in which all the software assets that related to this word are returned as retrieval results. Then the developer can review all the returned assets to check whether there are the desired assets among them or not. If he or she locates all the desired assets, the retrieval process will end; if the returned results are not so confined that the developer cannot find the desired assets, he or she will continue the retrieval process. In the next step, some further links, which represent the sub-nodes, are displayed on the next screen. The developer will keep on the same clicking, retrieving and reviewing until the set of retrieved assets is so confined that the retriever can easily determine whether or not the desired assets as are contained in this retrieved asset set.

From the above analysis, we can see that during the browsing-based retrieval process, developers usually using the HCS to make it clear what assets are there in the SAM system. In each retrieval step, when developer selects a word-link from the screen, he or she always assumes that the word-link could lead him or she to find the desired assets, in other words, the desired assets should be "contained" in the link. For example, for a sample HCS, as Figure 1 shows, that presents a classification for the assets from the "Operating System" aspect [8][9][10]. During the browsing process navigated by this HCS, if a developer selects and clicks the link labeled by "Mobile Operating System", it shows that he or she considers the desired assets are related to the word "Mobile Operating System", or the desired assets should be "contained" in the assets set related to the word "Mobile Operating System". If, in the next step, the developer selects and clicks the link labeled by "Android", it also shows that he or she thinks the desired assets should be contained in the assets set related to the word "Android". So, we can say that, in the corresponding retrieval step, the developer holding an assumption: the assets set related to the word "Mobile Operating System" should include the assets set related to the word "Android". In fact, this assumption is very important. It just because of holding this assumption, the developers could be navigated by the HCS to find their desired assets.

However, what kinds of semantic relationships between each super-ordinate word (e.g. "Mobile Operating System") and sub-ordinate word (e.g. "Android") in the HCS could make the retriever consider "the assets set related to the super-ordinate word should include the assets set related to the word sub-ordinate word? This is a dilemmatic problem for SAM system managers.

Strictly speaking, the "is-a-kind-of" is a good candidate kind of relationship for each super-ordinate and sub-ordinate word pair in the HCS, just like the words defined in some predefined taxonomy ontologies. For example, as Figure 1 shows "Android" is-a-kind-of "Mobile Operating System", so, by these two words developers could be navigated. However, it is really very difficult for SAM system managers to find practicable predefined taxonomy ontology to be used as a HCS. Also, it is very difficult for system managers to build a HCS using only "is-a-kind-of" relationship. For, different from taxonomy ontology, HCS is a tool used to navigate the discovery of the software assets, but not used to present taxonomy knowledge.

At the same time, it is also very difficult for system managers to build a HCS from scratch using the words selected by themselves, because, in the literature, there still no method discuss about what kinds of relationships could make the retriever consider "the assets set related to the super-ordinate word should include the assets set related to the word sub-ordinate word. So, how to modeling the word relationships in HCS and how to build an understandable HCS is remained quite a problem for SAM system.

III. OUR APPROACH

In this paper, we proposed an ontology based HCS modeling method for SAM system managers. An upper level ontology is proposed to confine the kinds of relationship between each super-ordinate and sub-ordinate word pair in the HCS. Using the instances defined according to this ontology, the managers can build an understandable HCS for their users to support the browsing of software assets. In this section, we will discuss the different levels of understandability of HCS, and then present the upper level ontology used to modeling the HCS. From this section on, we will call the developers that are retrieving the SAM system as retrievers.

A. Retriever Assumptions and Relationships Analysis

As we have discussed in section II, during the retrieving process, the retrievers are always holding some assumption: the assets set related to the super-ordinate word should include the assets set related to the sub-ordinate word. And, because of holding this assumption, the developers could be navigated by the HCS to find their desired assets. In fact, besides of this assumption, there are several other assumptions holding by the developers during the retrieval process. According to the degrees of strictness of this assumption, we classified them into 4 different levels, named Retriever Assumption 1-4：

Retriever Assumption I: During the retrieving process, the retrievers are always assuming that the assets set related to the super-ordinate word should include all the assets related to the sub-ordinate word.

In our method, in order to modeling the right semantic that meets Retriever Assumption I. we defined three kinds of relationships for each super-ordinate and sub ordinate word pair:

IsaKindof: for word W_1 and word W_2, if the concept represented by W_1 is a specialization of concept represented by W_2, and the concept represented by W_2 is a generalization of concept represented by W_1, then we have W_1 is a kind of W_2, denoted as: W_1 *IsaKindof* W_2 .

For example, in Figure1, "Android" is a kind of "Mobile Operating System". According to the definition of IsaKindof relationship, we have: *"Android" IsaKindof "Mobile Operating System"*. During the retrieving process, if the retrieval result had been confined to the assets set related to "Mobile Operating System", then the words "Android" means the assets set that related to the "Android Mobile Operating System", this set is included in the set of assets related to the super-ordinate word ("Mobile Operating System"), so we can see, the semantic of *"Android" IsaKindof "Mobile Operating System"* can meet the definition of Retriever Assumption I.

IsaPartof: for word W_1 and word W_2, if any instance of the concept represented by W_1 is a part of some instance of the concept represented by W_2, then we have W_1 is a part of W_2, denoted as: W_1 *IsaPartof* W_2 .

For example, in Figure1, "File Management Subsystem" is a part of "Desktop Operating System". According to the definition of IsaPartof relationship, we have: *"File Management Subsystem" IsaPartof "Desktop Operating System"*. During the retrieving process, if the retrieval result had been confined to the assets set related to "Desktop Operating System", then the words "File Management Subsystem" means the assets set that related to the "File Management Subsystem in Desktop Operating System", this set is included in the assets set related to the super-ordinate word ("Desktop Operating System"), so we can see, the semantic of *"File Management Subsystem" IsaPartof "Desktop Operating System"* can meet the definition of Retriever Assumption I.

[Attribute]Is: for word W_1, attribute A_1 and word W_2, if A_1 is an attribute of W_1 (denoted as: $W_1.A_1$), and if the word W_2 is a kind of $W_1.A_1$, in other words, if W_2 *IsaKindof* $W_1.A_1$ then we have W_1 *[*A_1*]Is* W_2**.**

For example, in Figure1, "Manufacturer" is an attribute of "Workstation Operating System" (although the words "Manufacturer" is not appeared in the HCS), and "IBM" is a kind of "manufacturer" of "Workstation Operating System". According to the definition of [Attribute]Is relationship, we have:*"Workstation Operating System" [Manufacturer]is "IBM"*. Here the word "IBM" means the workstation operating systems that were manufactured by IBM. During the retrieving process, if the retrieval result have been confined to "Workstation Operating System", then the words "IBM" means the assets set that related to the "Workstation Operating System that manufactured by IBM", this set is included in the assets set related to the super-ordinate word ("Workstation Operating System"), so we can see, the semantic of *"Workstation Operating System" [Manufacturer]Is "IBM"* can meet the definition of Retriever Assumption I.

So, the above three kinds of relationship (***IsaKindof, IsaPartof, [Attribute]Is***) give the right semantic that meets Retriever Assumption I. Based on Retriever Assumption I, we defined the Retriever Assumption II and III:

Retriever Assumption II: During the retrieval process in one aspect, the retrievers are always assuming that the desired assets are only belonging to one subset. In other words, in each retrieving step, when selecting the next work-link, the retrievers are always assuming that, the desired assets are only related to only one sub-ordinate word.

If there are two sub-ordinate words, and each of them looks likely to be related to the desired assets, then the retriever will be confused by which should be selected as the next one. For example, in Figure1, if a retriever selected to search desired assets from the "Operating System" aspect, and had selected "Operating System" in the first step, and then faces with three sub-ordinate words ("Mobile Operating System", "Workstation Operating System" and "Desktop Operating System"), and if the assets he or she desired are likely to be included in any one of them or any two of them, the retriever may be confused by which one should be selected.

Therefore, we defined the forth kind of relationship which used to modeling the right semantic that meets Retriever Assumption II:

DisjointWith: for word W_1 and word W_2, if there hasn't any common instance for the concept represented by W_1 and the concept represented by W_2, then we have W_1 disjoint with W_2, denoted as: W_1 *DisjointWith* W_2 . To facilitate representation,

for a words set $W_S = \{W_i, i \in \{1,2,...,n\}\}$, if for any two words W_i and W_j in the set, we have W_i *DisjointWith* W_j, then we can donate the relationship as: *DisjointWith*$\{W_i, i \in \{1,2,...,n\}\}$ or *DisjointWith* W_S.

For example, for the words "Symbian", "Android" and "Windows Mobile" in Figure1, if there haven't any common instance for the concept represented by each of them. According to the above definition, we have: *DisjointWith {"Symbian","Android", "Windows Mobile"}*. Which means the assets sets related to word "Symbian", "Android" and "Windows Mobile" is isolated to each other; there isn't any intersection between each pair of them. In this case, during the retrieving process, if a retriever selected to search from the Operating System aspect, and confined the retrieval result to the assets related to "Mobile Operating System", he or she could make a clear choice of which should be selected. So, we can see that the semantic of *DisjointWith {"Symbian", "Android", "Windows Mobile"}*. can help us to build HCS that meets the definition of Retriever Assumption II.

Retriever Assumption III: During the retrieval process in one aspect (e.g. the Operating System aspect), on each retrieving step, if the current word-link include many sub-ordinate word-links, the retrievers are always assuming that the desired assets must related to at least one of them, but not exist as a isolated leaf.

For example, in Figure1, if a retriever selected to search desired assets from the "Operating System" aspect, and had selected "Desktop Operating System" in the first step, and then faces with three sub-ordinate words ("File Management Subsystem", "Memory Management Subsystem" and "Process Management Subsystem"), the retriever may hold a assumption: all the assets related to "Desktop Operating System" had been divided into three subsets, which related to three sub-ordinate words separately. And, no isolated outside of these three subsets.

Therefore, we defined the fifth kind of relationship which used to modeling the right semantic that meets Retriever Assumption III:

CoveredBy: for word W_1 and a words set $W_S = \{W_i, i \in \{1,2,...,n\}\}$, if any instance of the concept represented by W_1 must belongs to at least one instances set of the concept represented by some W_i in W_S, then we have W_1 is covered by W_S, denoted as: W_1 *CoveredBy* W_S .

For example, in Figure 1, if in the current SAM system, all the assets related to "Desktop Operating System" are divided into three subsets, and each subset related to three sub-ordinate words ("File Management Subsystem", "Memory Management Subsystem" and "Process Management Subsystem") separately, And there isn't any isolated asset outside of these three subsets. Then we have: *"Desktop Operating System" CoveredBy {"File Management Subsystem", "Memory Management Subsystem", "Process Management Subsystem"}*.

Besides the three assumptions mentioned above, we proposed a supplementary retriever assumption for retriever, which could be referenced in HCS building:

Retriever Assumption IV: During the retrieval process in one aspect (e.g. the Operating System aspect), in any consecutive two-step retrieving, the retrievers may assume that the two step's retrieving are navigated by the same kind of relationships.

For example, in Figure 1, if a retriever selected to search desired assets from the "Operating System" aspect, and had selected "Mobile Operating System". For the relationship between "Mobile Operating System" and "Operating System" is IsaKindOf, so the retriever maybe assume that, the relationship in the next step is as same as the relationship in the last step.

We proposed 4 retriever assumptions above, as we can see that, different retriever assumptions could be superimposed together in one HCS. And, the more assumptions the HCS meets, the more understandable it is. So, in order to help the SAM system managers to build more understandable HCS, based on the relationships we mentioned above, we proposed an upper level ontology to guide the HCS modeling.

B. Upper Level Ontology for HCS Modeling

According to the above analysis, we proposed an upper level ontology for HCS modeling.

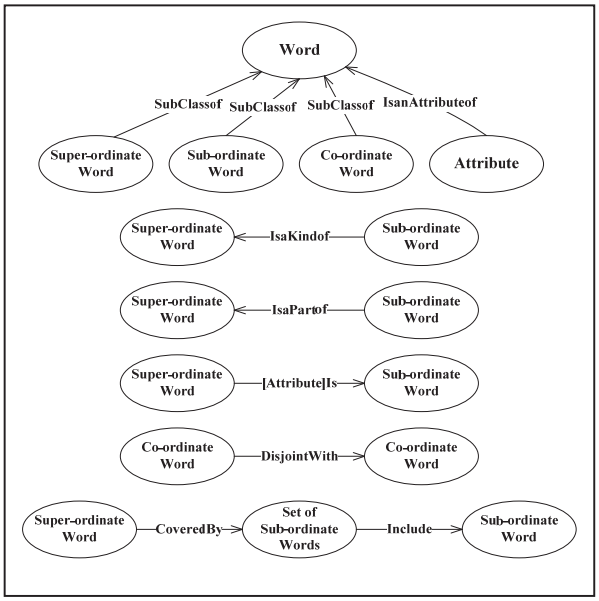

Figure 2. Upper Level Ontology for HCS Modeling.

As Figure 2 shows, the upper level ontology consists of 4 elements: Words, Attributes, Relations and Axioms. In which:

- **Words** represents a set of words that will be used in HCS; there are 3 kinds of words (Super-ordinate word, sub-ordinate word, co-ordinate word).
- **Attributes** is a collection of some small attribute sets, and each small set in the collection includes all the attributes of one word;
- **Relations** represents a set of relationships among different kinds of words, only 5 kinds of relationships (as mentioned in above) can be used in the instance

level ontology to represent the relationships between each words pair ;

Beside the above 5 kinds of relationships, in order to facilitate the representation of attribute, we defined *IsanAttributeOf* as a supplementary relationship :

Wp IsanAttributeOf Wq: to represent that the word Wp is an attribute of the word Wq.

e.g. "Manufacturer" IsanAttributeOf "Workstation Operating System";

- **Axioms** represents a set of axioms; each of them is a constraint on the words or relationships (e.g. about the transferability, symmetry, etc). Each constraint can be expressed in Prolog-like rule [11].

As an example, the following is an instance ontology for the HCS in operating system aspect showed in Figure1:

TABLE I. AN INSTANCE ONTOLOGY FOR OPREATING SYSTEM ASPECT

Operating System = {Words; Attributes; Relations; Axioms}

Words = {
"Operating System", "Mobile Operating System", "Workstation Operating System", "Desktop Operating System", "Symbian", "Android", "Windows Mobile", "SUN", "IBM", "SunOS", "Solaris", "AIX", "Operating System/2", "Process Management Subsystem", "File Management Subsystem", "Memory Management Subsystem", "NTFS system", "Fat32 system"
}

Attributes ={
"Manufacturer" IsanAttributeOf "Workstation Operating System";
}

Relations ={
"Mobile Operating System" IsaKindOf "Operating System";
"Workstation Operating System" IsaKindOf "Operating System";
"Desktop Operating System" IsaKindOf "Operating System";
"Symbian" IsaKindOf "Mobile Operating System";
"Android" IsaKindOf "Mobile Operating System";
'Windows Mobile" IsaKindOf "Mobile Operating System";
"Mobile Operating System" CoveredBy {"Symbian", "Android", "Windows Mobile"};
"DisjointWith {"Symbian", "Android", "Windows Mobile"};
"IBM" IsaKindOf "Manufacturer";
"SUN" IsaKindOf "Manufacturer";
"Workstation Operating System" [Manufacturer]Is "SUN";
"Workstation Operating System [Manufacturer]Is "IBM";
DisjointWith {"SUN", "IBM"};
"SunOS" IsaKindOf "SUN";
"Solaris" IsaKindOf "SUN";
"AIX" IsaKindOf "IBM";
"Operating System/2" IsaKindOf "IBM";
"Process Management Subsystem" IsaPartOf "Desktop Operating System";
"File Management Subsystem" IsaPartOf "Desktop Operating System";
"Memory Management Subsystem" IsaPartOf "Desktop Operating System";
"Desktop Operating System" CoveredBy {"Process Management Subsystem", "File Management Subsystem", "Memory Management Subsystem"};
"NTFS sytem" IsaKindOf "File Management Subsystem";
"Fat32 sytem" IsaKindOf "File Management Subsystem"
}

Axioms = {
$\exists w_p$ *IsaKindof* $w_q \rightarrow \neg\exists w_q$ *IsaKindof* w_p;
$\exists w_p$ *IsaPartof* $w_q \rightarrow \neg\exists w_q$ *IsaPartof* w_p;
$\exists w_p$ *[Attribute]Is* $w_q \rightarrow \neg\exists w_q$ *[Attribute]Is* w_p;
$\exists w_p$ *CoveredBy ws* $\rightarrow \neg\exists$ *ws CoveredBy* w_p;
$\exists w_p$ *DisjointWith* $w_q \leftrightarrow w_q$ *DisjointWith* w_p;
$\exists a_r$ *IsanAttributeof* $w_p \wedge \exists w_q$ *IsaKindof* $w_p \leftrightarrow a_r$ *IsanAttributeof* w_q;
$\exists w_q$ *IsaKindof* $w_p \wedge \exists w_p [w_p.a_r]$ *Is* $w_s \leftrightarrow w_q [w_q.a_r]$ *Is* w_s;
$\exists w_q$ *IsaKindof* $w_p \wedge \exists w_r$ *IsaPartof* $w_p \leftrightarrow w_r$ *IsaPartof* w_q;
$\exists w_q$ *IsaKindof* $w_p \wedge \exists w_r$ *IsaKindof* $w_q \rightarrow w_r$ *IsaKindof* w_p;
$\exists w_q$ *IsaPartof* $w_p \wedge \exists w_r$ *IsaPartof* $w_q \rightarrow w_r$ *IsaPartof* w_p;
$\exists w_p$ *DisjointWith* $w_q \wedge \exists w_r$ *IsaKindof* $w_q \rightarrow w_r$ *DisjointWith* w_p;
$\exists w_p$ *DisjointWith* $w_q \wedge \exists w_r$ *IsaPartof* $w_q \rightarrow w_r$ *DisjointWith* w_p;
}

In practice, this ontology can be represented in any ontology representation language, such as the RDF(S), the DAML+OIL and so on.

Using the proposed upper level ontology can help the SAM system managers to define the relationships among words clearly. As we have discussed, in order to build more understandable HCS, we should try to make every super-ordinate and sub-ordinate word pair meets more retriever assumptions. In the following section we will use a case study to illustrate the using of the proposed ontology.

IV. CASE STUDY

This section uses a case study to illustrate the availability of our ontology. In this case study, we will present how the HCS in the Figure1 are built up step by step, in this process, as we can see that, with more retriever assumption been met, the understandability of the HCS will be improved step by step.

In the first step, we build a HCS that only meets retriever assumption I. During the modeling of this HCS, we only used 3 kinds of relationships: *IsaKindOf, IsaPartOf, [Manufacturer]Is*. We can see that, though the HCS is usable, and meets retriever assumption I, it is still not easy to be understood, for the sub-ordinate words of "Operating System" are so diversiform that confusing the retrievers.

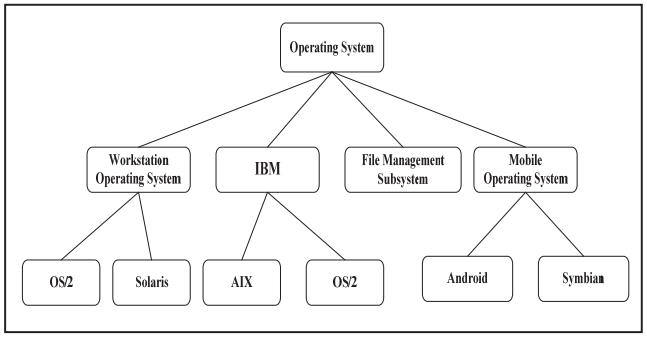

Figure 3. HCS Meet Retriever Assumption I

In the second step, we try to add the relationship of *DisjointWith* to the model of HCS, and try to make the HCS to meet retriever assumption II. As Figure 4 shows, the

understandability is better than Figure 3, for in each retrieving step, the retriever only need to select only one sub-ordinate word-link, but do not need to make trade-offs among several possible word-links, so it becomes more clear and straight for retrievers.

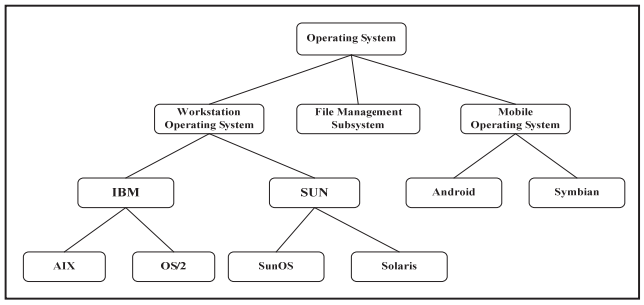

Figure 4. HCS Meet Retriever Assumption II

In the third step, we try to add the relationship of *CoveredBy* to the model of HCS, and try to make the HCS to meet Retriever Assumption III, and the HCS becomes to as Figure 1 shows. We can see that, the understandability is better than Figure 4, for in each retrieving step, the retriever only need to select the next sub-ordinate word-link, but do not need to care about whether the desired asset is an isolated leaf, and isn't related to any sub-ordinate word-link.

However, for the HCS in Figure 1, there is still room for improvement, because it doesn't meet the Retriever Assumption IV. In order to make the HCS to meet Retriever Assumption IV, we could delete the words "IBM" and "Sun" from the HCS, just as Figure 5 shows.

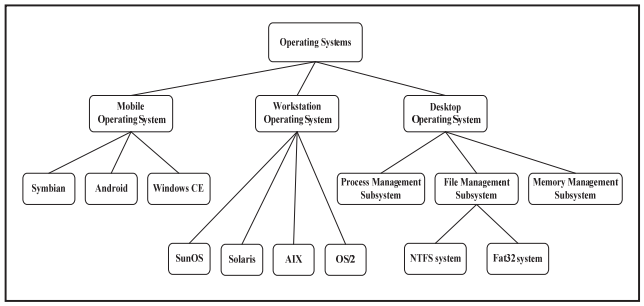

Figure 5. HCS Meet Retriever Assumption II

So, we can see that, different retriever assumptions could be superimposed together, the more assumptions the HCS meets, the more understandable it is. By using more kinds of relationships, we can improve the understandability step by step.

V. DISCUSSION AND CONCLUSION

Software asset management (SAM) represents an important role for software development and maintenance. In SAM, how to classify the software assets reasonably and build a Hierarchical Classification Structure (HCS) and help the developers to find their desired software asset effectively by browsing–based retrieval is an import part. However, how to build a reasonable HCS is a dilemmatic problem for SAM system managers.

In this paper, we analyzed the different level of understandability of HCS，proposed 4 retriever assumptions, and discussed the kinds of relationship between each super-ordinate and sub-ordinate word in the HCS. We proposed an ontology based HCS modeling method for SAM system managers, which an ontology is proposed for HCS building. This ontology confined the kinds of relationship between each super-ordinate and sub-ordinate word in the HCS. Using the instances defined according to this ontology, the system managers can build a HCS with controlled understandability. And, if more kinds of relationships are used in the modeling, more assumptions in the HCS will be met, and more understandable the HCS is. Also, this ontology can be combined with the HCS generating method (we published in 2007[2]), to build a HCS automatically. Besides these, our method make it easier for the system managers to make it clear that which part of HCS dragged down the understandability of the whole HCS, and then it becomes easier for them to make some improvements.

Mapping Non-Functional Requirements to Cloud Applications

David Villegas and S. Masoud Sadjadi
School of Computing and Information Sciences
Florida International University
Miami, Florida
{dvill013, sadjadi}@cs.fiu.edu

***Abstract*—Cloud computing represents a solution for applications with high scalability needs where usage patterns, and therefore resource requirements, may fluctuate based on external circumstances such as exposure or trending. However, in order to take advantage of the cloud's benefits, software engineers need to be able to express the application's needs in quantifiable terms. Additionally, cloud providers have to understand such requirements and offer methods to acquire the necessary infrastructure to fulfill the users' expectations. In this paper, we discuss the design and implementation of an Infrastructure as a Service cloud manager such that non-functional requirements determined during the requirements analysis phase can be mapped to properties for a group of Virtual Appliances running the application. The discussed management system ensures that expected Quality of Service is maintained during execution and can be considered during different development phases.**

I. Introduction

The emergence of cloud computing responds to a increasing trend in web application emergence and utilization. The wide adoption of Internet has resulted in systems that need to accomodate millions of users [1] and provide capabilities that until now were only required by critical, high availability or high throughput software. The practice of Software Engineering provides methodologies to ensure such characteristics are met, but it is necessary to review how they fit in this new paradigm. In this paper, we explore the applicability of traditional processes to the incipient field of cloud computing from the perspective of our research in an Infrastructure as a Service (IaaS) cloud manager.

Internet has resulted in rapid cycles of software development, deployment and consumption by users. The rising number of subscribers, better network connectivity and bandwidth, and the growing connectedness between users have created new dynamics where applications can be rapidly discovered and consumed. However, the benefits produced by these circumstances are hindered when expected requirements are not met. Nowadays, cloud computing is often employed as a solution to this problem. Capabilities such as pay-per-use, scalability or elastic provisioning of resources can help to overcome these new challenges. Nevertheless, application developers need to recognize how to apply Software Engineering methods to the cloud in order to successfully map their needs to fulfill service expectations.

There are two interrelated points that we believe have to be considered to successfully make use of clouds to develop applications that respond to the new demands generated in this field. First, developers must understand which non-functional requirements take renewed importance in cloud applications so that they can be accounted for during the requirements analysis phase. Second, cloud providers need to define better guarantees for their services, so developers can design their systems accordingly. We believe that providing a solution to these problems will result in a more dependable use of clouds to confront the new challenges of this era.

In this paper we consider the concept of *Distributed Ensembles of Virtual Appliances* (DEVAs), introduced in [2], as a model to represent complex systems with Quality of Service (QoS) guarantees. We discuss how a software architecture can be mapped to a DEVA, and how through the use of performance modeling and prediction we can make certain assurances about its behavior in the cloud in order to address its non-functional requirements. We finally present a case study were we demonstrate the feasibility of our approach to model the expected number of requests per second and response time of a web application hosted in the cloud.

II. Background

We define a cloud application as any software that runs on a distributed system that complies with the definition of a *cloud*. Such systems ([3], [4]) possess certain common capabilities such as on-demand provisioning, resource elasticity or pay-per-use billing model. Therefore, cloud applications can be deployed on remote resources with a minimal cost, and scaled dynamically when user demand grows.

We consider three main actors in our scenario: application users, application providers, and cloud providers. In this proposed division, application providers also have the role of cloud users, even though in certain cases it would be possible that application and cloud providers are the same individual or organization. The cloud is usually divided in Software, Platform and Infrastructure as a Service [3] —SaaS, PaaS and IaaS respectively. Application providers are in charge of implementing the SaaS layer, while the PaaS and IaaS layers are supplied by cloud providers.

A DEVA [2] is a group of Virtual Appliances and virtual network devices, where individual and composite policies can be defined for elements. Virtual Appliances [5] are Virtual

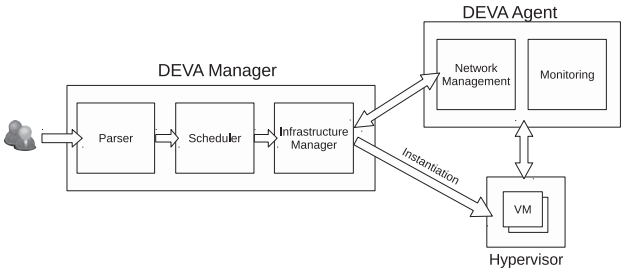

Fig. 1. General architecture

Machines with specific functions, usually containing a particular software and configuration; for simplicity, we'll use the more general term VM to refer to them. Figure 1 illustrates the architecture of the DEVA Manager. A user sends a specification for a list of VMs and their associated QoS requirements, which may consist of CPU, memory and required software for individual VMs, and network bandwidth and latency for the network links. Then, the Manager instantiates the ensemble across heterogeneous resources, which may be located in different administrative domains. A group of agents monitors each VM's behavior and provides the requested QoS and network isolation.

III. Requirement analysis and architectural design

In Software Engineering, the requirements analysis phase is in charge of determining the functional and non-functional requirements of the system based on the client's needs. In particular, non-functional requirements [6] describe the characteristics of the system not related to its functionality. These requirements shape the architecture of the system during the design phase.

In this paper we target a class of applications that are specially suited to be hosted in the cloud and have a prevalent set of non-functional requirements. Identifying them allows developers to ensure that they are addressed during the requirement analysis phase, and establish a set of requisites that must be met by cloud providers in order to quantify their service and ascertain the application goals are met successfully. We enumerate the most salient ones next.

Response time

This requirement describes how much time it takes from the moment a user sends a request to the system, until a complete response is provided. In web applications, this comprehends request transmission and processing, and response transmission. The factors that account for it are resource capabilities —processing power, memory, disk, network latency and bandwidth— and the load produced by other processes running in the server or the number of concurrent requests. For complex requests, this may also involve calls to external systems, or to other subsystems, in which case the host's internal network characteristics and other resources' load may be taken into account.

Uptime

The total time the service is available. It may be expressed as a percentage. When considering this requirement, it is necessary to take into account the provider's own uptime. For example, if a provider has an uptime of 99.5%, it would be impossible to deploy an application with a higher uptime. Other factors involve the recoverability of the system (*i.e.,* how much time it takes to restart the service after a failure happens).

Requests per unit of time

This requirement describes the number of requests the system can handle successfully per unit of time, and can also be referred to as the system's throughput. Resource allocation and usage has an impact in this parameter. Additionally, the number of requests can have an impact in the response time requirement (*i.e.,* a high number of requests will result in a deterioration of the overall response time).

Fault tolerance

One of the system's properties is how it can withstand errors, either hardware or software-based. In the case of cloud, non-software errors can be generated either at the physical or the virtual machines hosting the service. While the first case is usually out of the developer's control, virtual machine faults can be handled by different means, for example by spawning new instances, or having backup VMs to respond to failures.

Security

Security is another requirement that can be applied to the cloud provider or to the developed system. In the first case, the application developer is under the provider's security measures such as physical infrastructure access policies or network isolation mechanisms. Alternatively, security in the instantiated VMs must be handled by the cloud user.

Operational cost

In traditional systems, hardware was determined based on the application's initial requirements. Changes in requirements would typically result in costly upgrades involving the acquisition of new physical machines and installation and configuration of the application to run on them. In cloud systems, resources can be upgraded almost instantaneously, meaning that cost can be considered a changing variable. This allows defining tradeoffs to architectural (static) and operational (dynamic) behavior.

During the requirements analysis, it is the job of the software engineer to give appropriate values to each of the non-functional requirements according to the user's expectations. Each of these parameters needs to be reflected in one or more architectural decisions and tradeoffs.

IV. Mapping Requirements to DEVAs

The original implementation of the DEVA Manager accepts three types of parameters: nodes (VMs and virtual network devices), edges between nodes, and element annotations. Basic annotations describe node and edge characteristics such as VM processor power or memory size, and link bandwidth and latency, respectively.

An application developer could map the assigned non-functional requirement values to any of the discussed DEVA parameters in order to ensure the application's operational guarantees. For example, the number of desired requests per second would influence the assigned latency for the links between VMs; alternatively, the targeted response time could translate to a minimum processing power for the VMs in the ensemble.

However, this process is complicated and error-prone: the relationship between non-functional requirements and low level values is in many cases difficult to determine, and many factors can take part in the fulfillment of one individual parameter. Thus, we propose an extension to our system where non-functional requirements can be directly mapped to the execution platform, not only during the deployment phase, but also along the whole design process.

Our proposed approach in this paper extends DEVA annotations with new high-level values that correspond to non-functional requirements. An underlying application-dependent model is in charge of translating high-level parameters to low-level ones, and performing the required operations on the appropriate elements. We describe our system design next, and discuss its implementation.

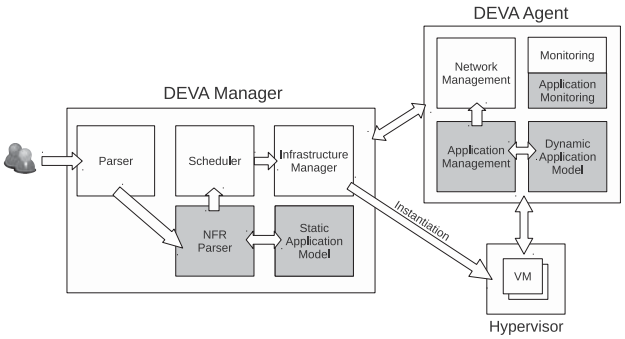

Fig. 2. Extended architecture

A. Processing annotations for DEVAs

Once the user defines a set of nodes, edges and annotations, a request is sent to the DEVA manager, which parses it and assigns the virtual resources to physical hosts that can comply with the requested QoS parameters. At each host, a number of VMs and virtual network links are created so that the ensemble appears as an isolated group of machines with dedicated resources. Additionally, a set of DEVA Agents are in charge of monitoring the infrastructure usage and ensuring global and individual QoS.

Requirements in the request are realized in two phases: first, the scheduling module of the manager chooses the target resources so that the ensemble requirements can be met. This implies selecting hosts with enough free memory and CPU for the VMs and ensuring the underlying physical network will be able to support the requested bandwidth and latency. Second, control measures are applied to constraint resource usage so that shared requests don't interfere among them. VM resources are adjusted by a Virtual Machine Monitor such as Xen or VMWare running in the target host, while network resources are controlled by a DEVA Agent. Agents apply shaping and monitoring to manage network QoS.

In order to implement high-level annotations representing non-functional requirements, we need to extend the DEVA manager and agents so that the new parameters can be translated into the existing ones. Figure 2 shows the system architecture with the new components in a darker shade.

First, the manager needs to translate non-functional requirements into values that can be considered as part of the scheduling process. We provide a non-functional requirements (NFR) Parser that is in charge of converting high-level values to low-level ones. For this, a Static Application Model is employed. Such model is dependent on the type of application, and can be defined either theoretically or empirically. We define a global annotation for the request, where the user can specify the application type. The value of this annotation will determine the model to use in the scheduler.

The Non-Functional Requirements Parser generates a set of requirements for nodes and connections based on the translated parameters, and these are fed to the scheduler, which takes them into account to generate a list of physical machine candidates. Each of the candidates is assigned a number of VMs to host. Finally, the Infrastructure manager, implemented in our system by OpenNebula [7], sends instantiation requests to Hypervisors and the DEVA Agents in charge of the dynamic behavior of the application.

After VMs are instantiated, DEVA Agents create a virtual network in the hosting machines. In our proposed architecture, we extend the system by adding three new components in the agents: First, we define an additional monitoring module with application dependent rules. While the basic component reads values such as CPU, memory and bandwidth usage, new values need to be contemplated in order to track non-functional requirements compliance. Examples of this are requests per second for a web server or database transactions for a database server. The application-dependent monitoring module can be extended based on different applications. All agents send the monitored data to the DEVA Manager, where the data is aggregated to determine high-level actions.

The second change in the DEVA Agents consists in an Application Management module similar to the existing Network Management component. While the later one is in charge of determining low-level actions to maintain network QoS, the new subsystem needs to consider high-level requirements and send them as an input to the other module. The third modification of the agent, the Dynamic Application Model, provides

the mapping based on a model of the application's behavior. Contrarily to the Non-Functional Requirements Parser and the Static Application Model, the components in the agent can also consider the runtime state of the application.

B. Model-based translation of non-functional requirements

There are two modules with the task of translating non-functional —high level— to infrastructure or low-level requirements. As stated in the last section, the first one considers the static behavior of the application and provides the necessary criteria to the scheduler, while the second one takes into account the dynamic state of the application. There are different approaches in the literature to modeling application performance such as [8] or [9], which can be divided into the categories of empirical, theoretical and on-line simulation models.

The first category corresponds to those models created from the application's off-line execution. Requirements can be inferred by observing the behavior of the system under different conditions and creating a model that can be later used to obtain approximate parameters to provide to the underlying management system. These models are usually measured by treating the application as a black-box (*i.e.*, without employing any knowledge of the internal implementation or design).

The second category consists of creating a mathematical model to relate the application's characteristics to its requirements. In this case, knowledge about the internal implementation is used to quantify the application's behavior based on available resources.

Finally, some models perform on-line (runtime) simulation of the application in order to find its behavior for a certain input. Simulations can be either event-based, for which an abstract model is created to approximate the behavior under certain conditions, or real-time, where a part or the whole application is executed to predict how the real system would behave.

Our system does not make any assumptions about the models used to map non-functional requirements to low-level ones. In fact, any of these could be employed either for the static or the dynamic modules in the manager and the agents. The basic prerequisite is that the used model understands the application's requirements and is able to determine a set of values that can be expressed via DEVA annotations. Some models may consider individual components of the system separately, while others contemplate complex relations between modules and how changes in one may affect others.

C. Non-functional requirements fulfillment

The modules added to the system allow the translation of non-functional requirements to low-level ones by using an application model. However, the DEVA Manager and agents need to perform the appropriate actions in order to fulfill the requested requirements. We classify these actions in two areas: resource allocation, and resource control. These categories also correspond to static and dynamic management, respectively.

The first type of actions is decided and enforced by the DEVA Manager based on the initial ensemble request and the model mapping. After parsing the user's input, non-functional requirements are translated into a set of low-level QoS values, which can be in turn used by the scheduler component to assign virtual elements to physical infrastructure. In our implementation in [2], the scheduler executes a metaheuristic algorithm to iteratively choose a near optimal placement of the requested DEVA in the available resources. This mapping would ensure that non-functional requirements are met by employing the appropriate infrastructure. Additionally, the DEVA Manager sends a description of the requested network links to each agent. Agents perform traffic isolation and shaping operations on the physical links to multiplex their usage among ensemble members, and when needed, create tunnels between physical hosts in different domains to build a virtual overlay network.

However, static allocation is not enough to respond to the runtime behavior of the application. While some values can be applied during the instantiation phase, most of the non-functional requirements need to be considered in terms of the application's dynamic usage. The DEVA agent is in charge of monitoring the system's running state and execute the appropriate control mechanisms. In many cases, these actions have associated trade-offs which need to be considered. Examples of control mechanisms run by the agents are dynamic bandwidth or CPU adjustment, provisioning of additional VM instances or VM migration.

V. Experimental Validation

In order to validate the proposed architecture, we have implemented a prototype extending the original DEVA Manager and agent. There are two main goals for this section:

1) Demonstrate the feasibility of translating high-level, non-functional requirements into a deployed ensemble of VMs.
2) Show how high-level QoS requirements are met during a DEVA lifecycle.

The experiment includes provisioning a test application through the DEVA Manager in order to determine how a set of non-functional requirements defined through the requirements analysis phase can be fulfilled during runtime. We have developed a three-tiered web application to illustrate the process.

A. The Chirper Application

In our test scenario, an fictitious company wants to develop an internal messaging systems so that their employees can communicate without having to use third party applications. They decide to deploy this solution in their private cloud so that they can take advantage of their in-house resources. The application, which we call *Chirper*, stores profile information for users, and enables them to post short messages to a common virtual board and query others' messages.

The application has two main components: the first one is a web server running the CherryPy[1] python web server;

[1] http://www.cherrypy.org

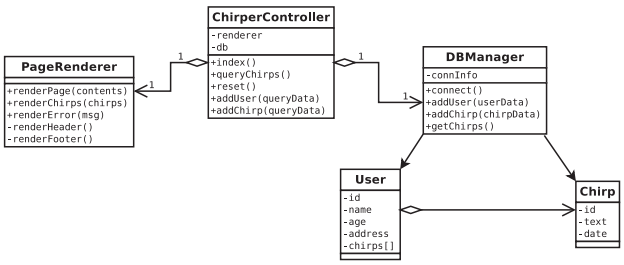

Fig. 3. Chirper class diagram

the second is a PostgreSQL[2] database with the users and messages information. The application will be accessed from the company's intranet.

As the first step, we perform the requirements elicitation to come up with the different functional and non-functional requirements. In this case, users need to be able to register in the application through a form, and then query either a specific user entries or last 50 messages in the database. We focus on a subset of the typical non-functional requirements explained in Section III: after exploring their users' behavior, our fictitious company estimates that the application should be able to respond to a peak of 40 requests per second, and that any request should be served in less than 500 milliseconds through the internal network.

In the second step, we define the application's architecture and implement it. In our approach, we follow the Model-View-Controller (MVC) architecture: a front-end interface where the user can interact with the system, a controller to submit and request data to the database, and the database layer itself. Figure 3 shows a class diagram of the system. The application receives requests through different URLs, which are mapped by CherryPy to the appropriate functions in the Chirper-Controller object. This class handles each request separately, performing input validation, then retrieving the requested information by calling the DBManager class, and finally rendering the response through the PageRenderer instance. The DBManager uses the SQLObject[3] Object-Relational Mapping (ORM) library to access the PostgreSQL database and perform selection and insertion operations. Finally, the PageRenderer class has methods to produce HTML code to return to the user.

In order to simplify scalability and be able to assign physical resources separately to each of the components, the web and database servers are deployed as different Virtual Appliances. Each of the VMs runs CentOS 5.3 and the software requirements needed by the application, which consist of Python 2.4 and CherryPy 3.2 for the Web appliance, and PostgreSQL 8.4 for the Database appliance. When the VMs are provisioned in the cloud, the DEVA Manager is able to define the resource allocation by sending commands to the VM Hypervisor and the DEVA agents. There are three main parameters that can be configurable once the VMs are instantiated in the infrastructure: maximum CPU share assigned to a VM, amount of memory, and bandwidth allocation between pairs of VMs.

[2]http://www.postgresql.org
[3]http://www.sqlobject.org

B. Performance Modeling

Once the application complies with the specified functional requirements, a model is created to account for the expected performance. In this example, a simple black-box model is defined by benchmarking the application externally. We deploy both appliances in the private cloud, consisting of a cluster of machines with Pentium 4 processors and 1 GB of memory running the Xen 3.0 hypervisor, and a third VM to act as a user. Physical machines are interconnected with 1 Gbps ethernet links and a dedicated network switch.

Initially, each VM is assigned a quota of 100% of the CPU, 1GB of disk, and 768 Mb of RAM. We run the Apache Benchmark tool to send 1000 requests with a level of concurrence of 10 to the service for each tested configuration. CherryPy is set up to spawn 10 serving threads without page caching mechanisms. We measure the request time and number of requests served per second for the operation of querying the last 50 messages in the database. We consider CPU and bandwidth as the VMs' configuration parameters. Memory allocation was discarded since the application doesn't require a high amount of main memory and consequently its performance doesn't depend on this parameter (our tests demonstrated 40 Mb were enough for the application to function at maximum capacity).

In the first set of runs, we calculate the application's behavior depending on the CPU quota. After running the tests, we determined that the Database appliance is not CPU bound, and therefore, there is no difference in performance with different values. Figure 4 shows the number of handled requests per second and the milliseconds taken for each request when the CPU allocation for the Web appliance is changed from 25% to 100% in intervals of 25%. As the figure shows, the number of served requests per second is directly proportional to the CPU allocation, while the time taken to respond to each request decreases with a higher CPU quota.

As the second set of measurements, we explore the application's behavior in relation to the allocated bandwidth. There are two links considered in this benchmark: the incoming connection to the Web appliance, and the private connection linking it to the database. Each of them can be constrained and isolated independently by the DEVA agents in the hosting machines. By doing this, each DEVA can perform independently of the rest, and network traffic from different applications is separated so that different VMs can multiplex the physical channel. We test the application with symmetric network assignments —*i.e.* same incoming and outgoing rate— from 100 Kb/s to 500 Kb/s with increments of 100 Kb/s. Figure 5 shows the results in requests per seconds and milliseconds per request for the incoming link (*in*) and the private one connecting both VMs (*priv*).

As it can be observed, the number of served requests per second depends on the available bandwidth, up to approximately 550 Kb/s for the incoming link (not shown in the graph)

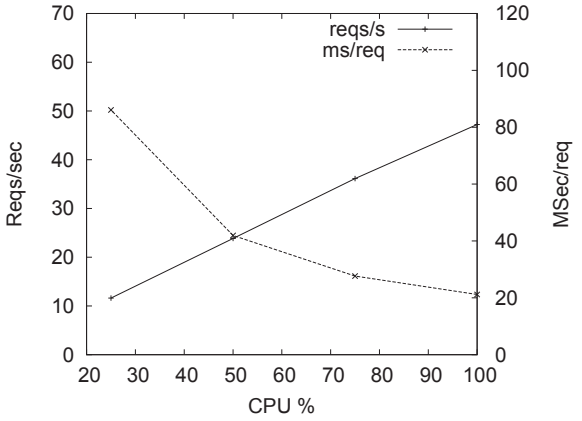

Fig. 4. Application model according to Web Appliance CPU allocation

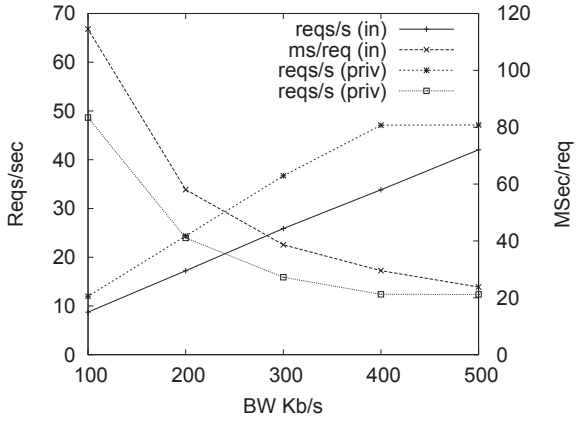

Fig. 5. Application model according to Incoming and Private bandwidth allocation

and 400 Kb/s for the private link. Lower bandwidth results in reduced requests per second and higher response time.

C. Integrating the model with the DEVA manager

The final step consists of integrating the experimental performance model into the DEVA manager and making the appropriate changes so that user requests can specify high-level requirements as parameters. We add the logic to translate such submission into low level parameters by employing the models and specifying an additional global parameter, *applicationType='Chirper'* so that the DEVA Manager knows which model to apply.

After that, we test the system by sending a request to the DEVA Manager specifying the two described Virtual Appliances and the desired non-functional requirements of 40 requests per second and 500 ms of maximum response time. The manager identifies this request to instantiate the *Chirper* application, and translates the requirements to 75% of CPU for the Web appliance and 25% of CPU for the Database appliance, 64 Mb or RAM for each VM, 500 Kb/s for incoming bandwidth and 400 Kb/s for private bandwidth. Finally, it decides that both VMs can be assigned to a single physical machine and provisions them accordingly.

VI. Conclusions and Future Work

As the cloud becomes more mainstream as a method to host applications, developers will need to consider how different providers —or in-house solutions— will be able to fulfill the final users' needs. Similarly, providers need to be able to give reliable guarantees for the Quality of Service of software deployed on their infrastruture. In this paper, we addressed this problem from both the developer's and cloud provider's perspectives. We showed how an example application with concrete requirements can be developed and deployed in a cloud manager that takes high-level non-functional requirements into consideration.

However, there are still many issues to address in order to determine how software can be successfully deployed in clouds: additional non-functional requirements such as fault-tolerance, execution cost or security need to be considered, and improved models that are able to predict applications' performance considering different parameters such as processor, memory, network and disk usage have to be developed.

***Abstract*—The development of service robots has gained more and more attention over the last years. Advanced robots have to cope with many different emerging at runtime situations, while executing complex tasks. They should be programmed as context-aware systems, capable of adapting themselves to the execution environment, including the computing, user and physical environment. Since computational reflection is a programming language technique that offers a high level of runtime adaptability, we have analyzed the suitability of this language feature to fulfill the dynamism requirements of context-aware robotic systems. In order to evaluate their appropriateness, we have implemented an example scenario in a dynamic reflective language and compared it with Java.**

***Index Terms*—Computational reflection, context-awareness, robotics framework, dynamic languages.**

I. Introduction

Robotic systems which should be able to interact in everyday life have to manage the high dynamism and complexity of real-world environments. An important element to be considered is the environment context, commonly referred to as location, the identification of nearby people and objects, plus changes to those objects [1]. Contexts are defined to be the constantly changing execution environment, including the computing, the user and the physical environment [2]. Therefore, context-aware software is software that must adapt itself according to its location of use, the collection of nearby people and objects, and changes to those objects over time [1]. An advanced robotic platform should take into account the context-awareness requirements of future robotic applications.

Dynamic languages have recently turned out to be suitable for specific scenarios such as Web development, application frameworks, game scripting, interactive programming, rapid prototyping, dynamic aspect-oriented programming and any kind of runtime adaptable or adaptive software. The main benefit of these languages is the simplicity they offer to model the dynamism that is sometimes required to build high context-dependent software. Common features of dynamic languages are meta-programming, reflection, mobility and dynamic reconfiguration and distribution. Computational reflection is one of the most distinguishing features of these languages, defined as the capability of a computational system to reason about and act upon itself, adjusting itself to changing conditions [3]. Due to the strong connection between context-awareness and computational reflection, we present in this paper how computational reflection can be used to facilitate the programming of context-aware services in a robotic platform. In fact, it has been previously stated that in order "to support context-awareness in an open and much larger setting, a reflective, or self-describing, context model is required" [4].

Dynamic languages have been previously used in different robotics scenarios. An example is the SmartTCL language, an extension of Lisp that was used to implement the sequencing layer in a three layer robotic architecture [5]. The sequencing layer is the place to store procedural knowledge on how to configure skills to behaviors. Due to the dynamic features of SmartTCL, the plans stored inside the task coordination module can be modified easily at runtime.

The dynamic language Lua has also been used to implement the behavior engine of the humanoid robot Nao [6]. The formalism of hybrid state machines (HSM) was used to bridge the gap between high-level strategic decision making and low-level actuator control. The model of HSMs was extended with dependencies and sub-skills to call the behaviors or skills hierarchically. Lua turned out to be an expressive language to implement these HSM-skills.

Other examples of existing robotics products that use dynamic languages to obtain a high level of adaptability are UrbiScript, an orchestration language for robotics systems; ROS (Robot Operating System), a set of libraries and tools to help software developers create robot applications in Python; and Pyro (Python Robotics) a programming environment for exploring advanced topics in artificial intelligence and robotics, facilitating the creation of interfaces for accessing and controlling a wide variety of real and simulated robots.

II. The TIC4BOT Project

The work presented in this paper is part of the TIC4BOT Project developed by the Treelogic Company, the Cartif Foundation, and the University of Oviedo. The aim of the project is to provide the necessary infrastructure to develop complex services in the social robotics field, by raising the abstraction level. The implementation was tested over a real robotic platform (SCITOS-G5), though the system was designed with total independence of the hardware. In order to get this independence, the Player/Stage [7] system was used during the development process. The SCITOS-G5 robot is controlled by an embedded PC with an Intel Core 2 Duo processor, and multiple small hardware units that monitor several functions of the robot. The PC operating system is Fedora Core 8.

Figure 1 shows the system architecture, consisting of three layers: primary modules, robotics framework and service modules.

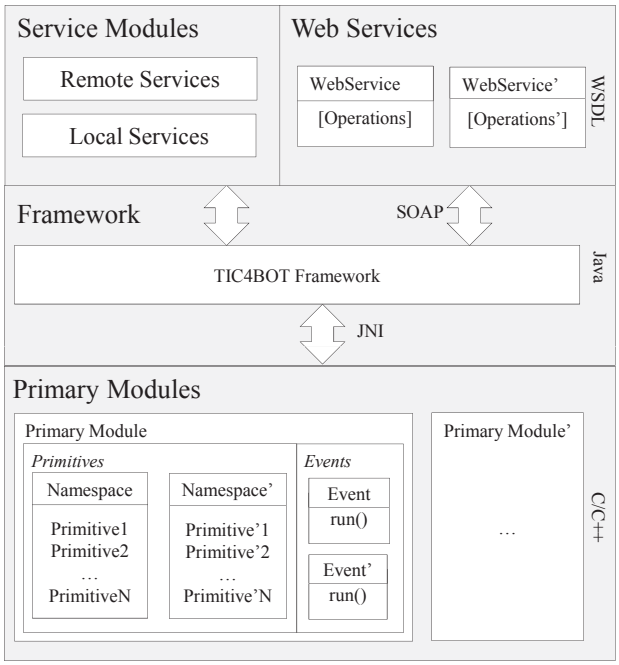

Figure 1. Architecture of the TIC4BOT system.

A. Primary Modules

Primary modules are developed accessing the hardware libraries in C and C++ and they implement primitives and events. A primitive is defined as a low-level function that can perform a simple task or a query over any sensor or actuator of the robotic platform. An event is a notification that something has happened.

In the framework, primitives are classified into *namespaces*. Each *namespace* contains a set of primitives, with a one-to-one correspondence with the primary functions.

B. The Framework

The framework provides a middle layer for the integration of primary modules and service modules [8]. In order to obtain platform independence and a higher level of abstraction, we chose the Java programming language. Java raises the abstraction level, providing automatic memory allocation, garbage collection and multi-threading. However, these benefits come at the expense of lower runtime performance. This implies that the robot hardware should have enough processing capabilities to perform the required tasks. In the case of our project, the SCITOS-G5 processor greatly suffices this requirement. The main functionalities provided by the framework are:

- *Dynamic runtime detection of primary modules*, allowing the addition of new primary modules at runtime. We allow the implementation of these modules in both C and C++, generating a Java proxy class at runtime for each C/C++ module. Proxies are classes providing the access to primary module functions. These Java proxies were developed using the JNI (Java Native Interface) standard through SWIG (Simplified Wrapper and Interface Generator) [9], that provides an automated connection of programs written in C and C++ with a variety of high-level programming languages.

```
// Autentication
Subject subject = null;
subject = Authorization.login("admin", "defaultPassword");
// Retrieve Namespace and Primitive
ApiManager api = FactoryManager.getApiManager(FactoryManagerType.Default);
Namespace namespace = api.getNamespaceByName("Navigation");
Primitive primitive = namespace.getPrimitiveByName("goTo");
// Parameters creation
Object[] parameters = new Object[2];
parameters[0] = x;
parameters[1] = y;
// Invocable element for the framework
InvocationElement invocationElement =
new InvocationElement(subject, namespace, primitive, parameters);
// Create a list of invocation elements
List<InvocationElement> list = new ArrayList<InvocationElement>();
list.add(invocationElement);
// Create the task (Execution Mode)
Task task = new DefaultTask("Sample Task");
task.setInvocationElements(list);
// Create the Runnable (Priority)
ExecutionManager executionManager = FactoryManager.
            getExecutionManager(FactoryManagerType.Default, subject);
Runnable runnable = executionManager.insertTask(task,
            RunnablePriority.MAX, RunnableSyncronism.SYNCHRONOUS);
// Retrieve the result
Object result;
while (true){
    try {
        result = runnable.getResult(0);
        break;
    } catch (NullValueException e) {
        Thread.currentThread().sleep(100);
    }
}
```

Figure 2. Sample code of framework programming.

Figure 2 shows a sample code of the invocation of a primitive. First, authentication over the framework is performed and credentials for executing tasks are obtained. Then, the `Navigation` *namespace* and its `goTo` primitive are obtained. An `Object` array is created containing the values of parameters for the invocation. A list of `InvocationElement` is also created. The `InvocationElement` type is provided by the framework and it could contain a set of primitive elements that will make up a complete task.

- *Transparent publication of all the elements offered by the primary modules*. The framework provides the necessary mechanisms to discover and invoke primitives at runtime. It also provides event subscription management.

  The next step of our sample code in Figure 2 is to create a task with the `InvocationElement` list previously mentioned. In this sample code, the type of the created task is `DefaultTask`. The task type indicates the execution mode of the primitives within the task (a `DefaultTask` indicates non-transactional behavior, while a `TransactionalTask` indicates that the task cannot be interrupted by any other task until it finalizes its execution). Finally, a `Runnable` object is created as the result of introducing the previously created task into the framework execution engine. In this stage, the execution mode is established to `SYNCHRONOUS`. Synchronous tasks cannot be executed in parallel with other synchronous ones, whereas asynchronous tasks can. The task is assigned the maximum priority execution level (`MAX`). The `Runnable` object is then used to retrieve the result of the primitives executed. The loop in the code waits until the result of the primitive is ready.
- *Execution engine for service modules*, providing a prioritization mechanism of tasks and different execution modes (transactional or non-transactional, and syn-

chronous or asynchronous), which can be combined in each specific case.

- *Remote hot reprogramming at runtime*. This service enables remote applications to send their Java source code to the framework at runtime. This was developed through Web Services, using standard technologies. We used the W3C recommended WSDL (Web Services Description Language) for describing Web Services, and the SOAP (Simple Object Access Protocol) protocol to specify the interchange of data with Web Services by means of XML messages.

C. Service Modules

Service modules are complex modules that provide end-user services by means of the composition of primary modules functionalities. The access to primary modules is always performed through the framework. Service modules insert sets of tasks in the framework with a concrete priority and execution mode. These modules can be added at runtime through the hot reprogramming service.

III. Computational Reflection

Reflection is "the capability of a computational system to reason about and act upon itself, adjusting itself to changing conditions" [3]. The computational domain of reflective languages includes their self-representation. Therefore, they can offer their structure and semantics as computable data.

Since context-aware systems should dynamically adapt to runtime changing environments, computational reflection seems to be a suitable technique to face this kind of scenarios. We previously used computational reflection as a suitable technique for adaptive systems such as persistence management [10], dynamic aspect-oriented programming [11] or heterogeneous device support [12].

One classification of reflection considers the observation and modification issues of the system self-representation:

- **Introspection**: Self-representation of programs can be dynamically consulted but not modified. The applications can obtain information about runtime classes, objects, methods, etc. This level of reflection is offered by languages such as Java or C#.
- **Intercession**: The ability of a program to modify its own execution state, interpretation or meaning. Most dynamic languages offer this feature.

Another classification can be established according to *what* can be reflected:

- **Structural Reflection**: System structure can be accessed. In case the system structure is modified, changes will be reflected at runtime. An example of this kind of reflection is the Python feature of adding fields and methods to both objects and classes.
- **Behavioral Reflection**: This level of reflection implies access to system semantics. In case the semantics is modified, it involves a customization of the runtime behavior of programs. As an example, Python offers overriding the semantics of member lookup; if a class has a `__getattr__` method, it will be called whenever a non-existing member is accessed.

Another feature that is commonly used together with computational reflection is runtime generative programming [13]. It consists of the capability of programs to generate new (parts of) programs. This feature is usually offered in conjunction with reflection, because those new parts of generated programs modify the structure or semantics of running applications.

IV. Adaptive Dynamic Programming Layer

The adaptive dynamic programming layer is a new tier over the framework that supports adaptive context-awareness capabilities. This layer is designed to offer runtime adaptation to dynamic environments. Context-aware scenarios often involve the addition of new requirements at runtime, making use of services offered by the framework that are consulted at runtime.

Since dynamic languages offer a high degree of runtime adaptability, we propose their use to provide a runtime adaptive system that additionally provides a simplified way of context-aware tasks. This enhances the framework services with dynamic languages features, obtaining an additional layer with a higher degree of flexibility and adaptability.

Since the framework is developed in Java, an intercommunication mechanism between Java and Python is required. The standard Java Scripting API (JSR 223) [14] allows the use of script engines from Java code. By using it, all the functionality provided by the framework in Java will be accessible at the adaptive dynamic layer using a dynamic language.

We selected the Python programming language to implement the adaptive dynamic programming layer because it is a mature dynamic language that provides runtime structural and behavioral reflection, dynamic generative programming, a simple syntax, a substantial number of powerful libraries and functions.

A. Framework Services

Although the framework provides useful features for many use cases, the code for one single operation over the framework may become verbose (as shown in Figure 2) due to the lack of metaprogramming features in Java. It implies the codification of several lines of code that performs non-functional actions, entailing a less agile development of new services. One of the main goals of the dynamic adaptive layer is to simplify the programming over the framework.

In the adaptive dynamic programming layer, authorization and synchronization data is stored along the entire programmer session, and it is used in all the operations in a transparent way. Furthermore, this data could be changed at any moment by the programmer. Figure 3 shows how the authentication and task priority assignments (and synchronization specification) are performed in the adaptive layer. In addition to this, credentials and synchronization data are stored in the adaptive layer module. When an operation is executed over the framework, this data is retrieved and used.

B. Primitive Management

In the case of primitives, the dynamic adaptive layer allows the final programmers to write their code in a more natural and compact way, facilitating its maintainability and legibility, and without losing any functionality. This layer provides primary module discovery at runtime, making it possible to act over new services discovered at runtime, even if they were not present at design time.

As it was explained in Section 2, primitives in the framework are organized in *namespaces*. At runtime, when a primary module is discovered, its primitives and *namespaces* objects are created. In the adaptive dynamic programming layer, generative programming and structural reflection are used to transparently create classes that wrap the framework services. The resulting code is a Python class that has a one-to-one equivalence for each *namespace* object in the framework. For every object instance representing a `Namespace` with sets of `Primitive` objects in Java, a class with the corresponding methods is transparently created in Python. The purpose of this generation is to provide a simple and natural way to invoke those primitives discovered at runtime. Figure 3 shows the Python source code that invokes the `goTo` primitive at the adaptive programming layer. This code is equivalent to the Java program in Figure 2, being much more compact and legible.

```
from FrameworkLoader import *
# Authorization request
authenticate(USER, PASSWORD)
# Priority, execution mode and name of the task
setTaskType(RunnablePriority.ONE, TRANSACTIONAL_TASK, "HOT-REPROGRAMMING")
# Object corresponding to Namespace Navigation
navigation = Navigation()
# Primitive execution and retrieve of result
res = navigation.goTo(X, Y)
```

Figure 3. Programming over the adaptive layer.

Code generation is implemented using the `exec` Python function. This function receives a character string and evaluates it at runtime. We evaluate strings that generate new classes at runtime. The strings are parameterized with the name of a *namespace* class using the % operator. Figure 4 shows the skeleton string used to generate `namespaces` classes (we do not show the code in the methods for the sake of brevity; it can be consulted in [15]). Generated classes do not contain primitive methods; they provide a mechanism to alter the message passing mechanism through behavioral reflection. Generated classes implement a dynamic lazy search for the invoked method (primitive) using introspection. This search is performed over the framework and it is completely transparent to the final user.

As Figure 3 and its sequence diagram in Figure 5 show, these generated classes make use of the two `__call__` and `__getattr__` built in methods that offer behavioral reflection. The `goTo` message is passed to the `navigation` object. Since this member is not offered by the object, the `__getattr__` method is called. This method stores the name of the requested member (i.e., `goTo`) so it can be later used for searching and invoking the corresponding primitive. Since the returned object

```
classCode = """
# Import sentences
class %(className):
    def __init__(self):
        # Constructor code
    def __getattr__(self, item):
        # Saves the name of the member
    def __call__(self, *args, **kwargs):
        # Invokes the corresponding primitive
"""
```

Figure 4. Sample code to be dynamically evaluated.

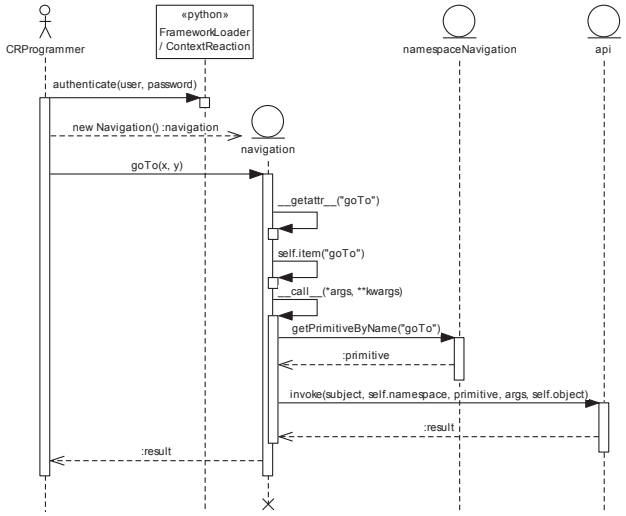

Figure 5. Access to primitive services.

(`navigation`) implements the `__call__` method, it can be called as it was a function. The `__call__` method receives as many parameters as the actual arguments of the call, in a variable-length argument list. This method receives the `x` and `y` parameters, and performs the search of the primitive that fits this signature. Once found, the appropriate primitive of the framework is invoked and the `__call__` method returns the result of calling the primitive.

Computational reflection and generative programming allowed us to fulfill the adaptability requirements without needing to specify all the classes and their methods at design time. This also allows the development of context-aware emerging at runtime scenarios. Furthermore, we can introduce complete service modules on the framework at runtime, using its reprogramming feature. These service modules could introduce new behavior patterns to undertake a specific goal.

We implemented a simple navigation prototype based on fuzzy rules to show the simplicity and adaptiveness provided by the dynamic programming layer. The main `move` function is shown in Figure 6. This function provides the functionality to make the robot advance a step, making use of fuzzy rules.

The rules have the following meaning, expressed with an antecedent and a list of consequents: 1) if there is no obstacle close, go to the target; 2) if the front-left side is freer than the front-right side, turn left and continue until right sonar sensors are free of obstacles; 3) if the front-right side is freer, turn right and continue until left sonar sensors are free of obstacles. An `evaluateFuzzyRules` function evaluates every rule premise and executes the consequents of that rule whose antecedent value is greater.

These three rules provide the logic of decision making for

```
def move(xPos, yPos):
    global x, y
    x = xPos
    y = yPos
    rules = [
        ( fuzzyNot( obstacleClose ),
            [goToTarget] ) ,
        ( fuzzyAnd( obstacleClose, isFrontLeftMoreFree ),
            [turnLeft, moveUntilRightIsFree] ),
        ( fuzzyAnd( obstacleClose, isFrontRightMoreFree ),
          [turnRight, moveUntilLeftIsFree] )
    ]
    evaluateFuzzyRules(rules)
```

Figure 6. Sample fuzzy rules.

the navigation algorithm to avoid obstacles while going toward a specific point. Although this sample logic is very simple, it can be improved by just adding more fuzzy rules describing an optimized behavior of the robot.

Since Python supports first-class functions, fuzzy rules were defined using functions that represent fuzzy operators, predicates and actions. Fuzzy operators (e.g., `fuzzyAnd` and `fuzzyNot`) can be implemented in Python as higher-order functions, i.e., functions that take functions as parameters. The source code is freely available at [15].

C. Event Management

The adaptive dynamic layer enables any single function to subscribe to a concrete event, complementing the framework services and primitive management provided by this layer. In addition, new events can be discovered at runtime, so that programmers can dynamically access new events published dynamically.

Following with our example, let's suppose that we have an artificial vision primary module capable of detecting a person's face. At the moment the face is recognized, the artificial vision primary module triggers an event with the data of the face (e.g., the name of the recognized person). Figure 7 shows an example subscription to a concrete event in the adaptive dynamic programming layer:

- Authentication is performed in the first place. Afterwards, prioritization is established to the maximum, and the asynchronous execution mode is chosen. With these settings, the *Greet* task is executed in parallel with the navigation task that is running in the framework. If the robot is performing any other task at the moment the event is triggered, like for example moving toward any point, it will be able to look to the face detected and greet at the same time, without having to stop its navigation.
- After this, the function that handles the event is defined. This function instantiates a *namespace* of primitives called `Speech`. This *namespace* performs tasks of voice speech synthesis through the `say` primitive, which receives a text and reproduces it by simulating human voice, greeting the recognized person.
- The last statement subscribes the previous function to the face detection event. Therefore, when the event is thrown, the `handlerOfFaceDetectionEvent` function will be automatically called.

By applying generative programming and structural reflection, each event in the framework corresponds to a generated

```
# Authentication and Priorization
authenticate("admin", "defaultPassword")
setTaskType(RunnablePriority.MAX, ASYNCHRONOUS_TASK, "Greet")
# Event Handler
def handlerOfFaceDetectionEvent(data):
    speech = Speech()
    speech.say("How are you " + data.name + "?")
# Event Subscription
event = FaceDetectionEvent(handlerOfFaceDetectionEvent)
```

Figure 7. Face detection event.

Python class. These classes implement the `Observer` interface (from the *Observer* design pattern) provided by the framework. When an instance of any of these event classes is created, a subscriber for that event is also registered. The constructor of this class receives a Python function as parameter. When the framework notifies the occurrence of an event, the subscriber delegates its management to that function.

Because of the dynamic discovery and event generation code, it is possible to add new event types at runtime without having to specify at design time all the events offered by the framework. Furthermore, it allows performing simultaneous tasks, making the most of the prioritization and synchronization features provided by the framework.

D. Remote Reprogramming

The framework execution engine can be remotely reprogrammed at runtime. This remote hot reprogramming allows the introduction of new behavior guidelines at runtime, without having to foresee them at design time, even parallelizing them with other tasks that might be running.

We are interested in allowing the robot to react to the environment context. As an example, we have included in our example the scenario proposed by Pineau *et al.* [16], where the robotic platform has the capability of assisting elderly individuals with an automated reminder system. This system can, for instance, remind to the patient that it is time to have her medicine.

The framework exposes one Web Service for the addition of new service modules from a remote system, which, after authorization, can send the source code to the framework execution engine. The code received is added to the tasks queue, being executed according to its priority and synchronization settings. Making use of the remote reprogramming feature offered by the framework, the *Reminder* module can be added at runtime.

Figure 8 shows the source code we used to develop the reminder scenario. The `Navigation` module shown in Section IV-B is imported, authentication is performed, and the task is set as transactional. This execution mode (transactional) allows obtaining the execution control and avoids other tasks to interrupt it, notwithstanding the parallel execution of other asynchronous tasks (e.g., when the *Reminder* module is running, other asynchronous modules like the *Greeting* one could be executed in parallel). The `patientLocatorWS` reference points to a Web Service that provides the coordinates of patients. Then, a `getPosition` function that retrieves the coordinates of a patient passing her identification it is defined. The main program contains a loop that iterates while the

```
from Navigation import *
# Framework Initialization
authenticate("admin", "defaultPassword")
setTaskType(RunnablePriority.ONE, TRANSACTIONAL_TASK,
            "HOT-REPROGRAMMING")
# Global variables
speech = Speech()
patientLocatorWS = WebService(WSDL_URL)
PATIENT_ID = "1"
navigation = Navigation()
def getPosition(id):
    position = patientLocatorWS.getPosition(PatientId = id)
    return position.getX(), position.getY()
# Main program
x, y = getPosition(PATIENT_ID)
while (not isTargetReached(x, y)):
    navigation.move(x, y)
    x, y = getPosition(PATIENT_ID)
speech.say("It is time to have your medicine, Sir")
end()
```

Figure 8. Reminder module.

target is not reached, performing one more step through the `Navigation` module.

The reprogramming process is initialized by the remote system, which requests the framework for an authorization credential. Then, the remote system would include its own source code like the one in Figure 8. Once this code is included in the execution engine, the *Greet* asynchronous module shown in Section IV-C will be executed in parallel (asynchronously). Thus, the robot would head the patient and, if in its path it detects another person, it would say hello to her, without having to interrupt its navigation—the *Greet* module is asynchronous.

This hot reprogramming system capable of managing runtime emerging primitives and events allows fulfilling the dynamic adaptability requirements of context-aware systems, not only discovering services at runtime, but also adding new programs dynamically. Both computational reflection and generative programming made it possible.

V. Conclusions

Computational reflection seems to be a suitable technique to facilitate the implementation of context-aware scenarios in a robotics framework. The use of a dynamic reflective language allowed us to develop an adaptive dynamic programming layer, which is aware of context environment changes at runtime. This layer offers dynamic runtime discovery of new services and provides transparent programmatic access.

The use of different levels of computational reflection allowed us to achieve the desired degree of runtime flexibility. First, introspection offered the dynamic discovery of services published by the framework and even external devices. We applied generative programming to generate code that wraps these services in Python classes. Generated Python classes were modified by means of structural reflection, adding new attributes to classes and objects when needed. We modified the semantics of the message passing mechanism (by means of behavioral reflection) in order to implement a lazy method search in the generated classes. This allowed us to implement a dynamic adaptive layer, offering the existing services in the current context without the need of specifying them at design time. Additionally, the use of dynamic languages and computational reflection involved a significant simplification of the code to program the dynamic adaptive layer.

The source code of the whole example presented in this paper is freely available at http://www.reflection.uniovi.es/tic4bot. Although the robotics framework is not freely downloadable because it belongs to the TreeLogic Company, the URL above provides a demonstrating video showing the example presented in this paper running on the robotics framework.

***Abstract*—Self-organization systems are rapidly emerging as a powerful paradigm for tacking complexity, improving reliability and optimizing performance in several literatures and are widely applied in a number of domains. Obviously, to develop such complex systems need specified technologies as well as systematic approaches, and they should be developed in an engineering way. We argue software engineering for self-organization systems should consider the specific complexity properties of self-organization and should seek effective approaches to model, design, and deploy such systems. This paper aims to survey the state-of-the-art of the researches on software engineering for self-organization systems from theory, technology and tool viewpoints, investigate the potential issues and challenges in current researches, and suggest future research directions.**

Keywords- Self-Organization systems, Software Engineering

I. INTRODUCTION

As self-organization is a powerful approach to dealing with complexity, it is widely used in several domains to improve the reliability and performance of systems. However, developing self-organization systems in a repeated and effective way is still a great challenge in the literature of software engineering and knowledge engineering. Recently, many researchers have paid attentions to the software engineering for self-organization systems and a lot of relevant research works have been conducted. This paper aims to survey the state-of-the-art of the researches on software engineering for self-organization systems, investigate the potential issues and challenges in current researches, and suggest future research directions. Section 2 gives a survey of the researches on self-organization software engineering. Section 3 discusses the potential issues and challenges in existing researches and suggests some future directions. Finally, conclusions are made in section 4.

II. SURVEYS OF THE STATE-OF-THE-ART OF SOFTWARE ENGINEERING FOR SELF-ORGANIZATION SYSTEMS

We catalogue current works as three dimensions: theory, technology and tool.

A. Theory Aspect

In theory aspect, researchers concern the questions like how to abstract and represent the system in accurate? What mechanisms can be identified and should be utilized to implement self-organization systems?

1) Abstraction and Model

There are three kinds of self-organization abstraction methods for investigating self-organization: differential equations, cellular automata, and agent. These methods are typical based on different metaphors and abstractions.

Differential equation depicts self-organization from dynamic property aspect. Some researchers make use of systems of differential equations to model the self-organized emergence of synchronization with coupled oscillators ranging from fireflies to neurons [1][2]. Although differential equation has range of applicability, it is limited to describe pattern formation, oscillations and other simple collective phenomena. It does not allow enough flexibility for diversity of components and assumes a uniform spatial interaction, neglecting more realistic types of connectivity in real-world systems.

Cellular automata abstraction is a simulation method and has been successfully used for model many real physical self-organization systems from predator-prey systems to chemical spiral waves, to hydrodynamics [3][4]. Such abstraction assumes the world is a discrete grid and each site in the grid can be found in one of a set of possible discrete states. Cellular automata allows for locality, i.e. sites in the grid interact directly only with neighboring sites, thus there is no action at a distance and all signals must propagate along path of connected neighbors. On the other hand, cellular automata is readily exhibit interesting behaviors such as forming a range of patterns similar to differential equations and also far more complex dynamics such as moving patterns[29]. A fundamental requirement for cellular automata to exhibit interesting behaviors is synchronous updating. There are simple algorithms which do allow collections of objects to synchronize, so it may be possible to engineer a system to fit the cellular automata.

Agent-based abstraction is a natural metaphor if components in a self-organization system can vary dramatic from one another and display a range of behaviors and strategies like decision making. In contrast with Cellular Automata, agents do not need to assume an underlying topology, specifying or restricting which components can interact with, and they can come together and interact with each other in complex and dynamic ways. These characteristics are important if we want to model interactions among humans with complex decision making abilities. Many researchers use Multi-Agent Systems (MAS) as a basic abstraction to model

self-organization systems. [5]-[11]show different models based on MAS. Agent-based approaches are extremely flexible to model the interactions among collection of autonomous agents. They can model phenomena in social systems as well as bio-systems. However, a major drawback of agent based modeling is the lack of rigorousness. Because of the complexity of the model specifications, it is difficult to assess the robustness of observed phenomena to change in the specifications and the accuracy by which the model describes the real systems.

2) Self-Organization Mechanism

Self-organization mechanism guides the behaviors of individuals, it determines how the individuals in the system act and interact, as well as restrict the emergent result of the self-organization system. As bio-systems and human societies exhibit self-organization properties, current mechanisms are almost inspired by bio-system or human society. [30] discusses mechanisms which are inspired from bio-systems and gives some application examples.[12]surveys mechanisms from human societies. Besides, some researchers discuss the engineering principles for special mechanisms, for example [31] discusses the engineering principles from stigmergy. These mechanisms provide good inspirations for implementing of self-organization.

B. Technology Aspect

In most of researches on self-organization systems, agents often as the individual metaphor are represented and designed. However, as argued in [13], most current approaches disregard the macro-scale issues and focus on development of micro-scale MAS. Researchers need to find new technologies and methodologies for engineering self-organization systems.

1) Methodology

The methodologies for self-organization systems often take agent as the entity of system. These methodologies care about how to construct a self-organization system? What principles and processes are needed in the development process? From life cycle aspect, these researches concern about different phases of software life cycle, e.g. [17][19][15]concern all of the phases in life cycle from requirement analyzing phase to testing phase. [19]proposes a domain-independent methodology for designing and controlling self-organization systems. The iterative and incremental methodology includes five steps: Representation, Modeling, Simulation, Application and Evaluation, which are interrelated, and in each step, corresponding development actions are also proposed. [18] And [20]are engaged in design phased and [20]also considers implementation phase. At the design phase, [18] proposes a design guide for swarming systems engineering consisting of ten design principles, in [20] the requirements related to the properties of components as well as the rules that guide their behavior and how the development process has to be carried out are identified. During the implementation phase, the run-time infrastructure, components, policies, and metadata are developed.

In modeling languages aspect, there are still no effective modeling languages to support the modeling of self-organization systems. The reason is that the macro properties of self-organization systems are often novel for the individuals, so representing of the relationship between macro properties and individual behaviors is difficult. Some researchers try to solve this problem, for example [14] [16], however the results are limited.

2) Implementation Technology

Autonomy of entities and emergence also bring challenges to the implementation of self-organization systems. How to realize this kind of agents is an important problem.

- Middleware

Middleware in self-organization systems is used for supporting implementation of the agent which is adaptive and uncoupled interaction mechanisms as well as context awareness. Many self-organization mechanisms are such mechanism e.g. stigmergy, schooling. The representative work is TOTA [26]. It is a spatially distributed tuples. Agents can inject these tuples in the network, to make available some kind of contextual information and to interact with other agents. Tuples are propagated by the middleware, on the basis of application specific patterns. Agents can locally sense these fields and rely on them for both acquiring contextual information and carrying on distributed self-organization coordination activities. The similar works include Anthill [25]and MMASS [33].

- Architecture

In agent architecture aspect, researchers referred to some theories that make agents easy to realize self-organization. For example [34] refers to AMAS theory (Adaptive Multi-Agent Systems) proposes a three level architecture. When agent aware the changes of its environment, higher level can choose the best state from self-organization of lower level. [35] proposes an observer/controller architecture which refers to Cybernetics. In system architecture aspect, researchers provide conceptual framework which can guides the interplay of application dependent component functionalities and their coordination and therefore prepares a constructive approach to the utilization of self-organization, for example SodekoVS project [22]. [36] considers either agent architecture or system architecture.

- Design pattern

Software reuse in self-organization applications is also attracted the interest of some researchers, who want to design some general self-organization design patterns from some self-organization mechanisms and expect to apply them in different applications. For example [28] distinguishes five patterns from a lot of self-organization applications. These patterns are described in a format description and a catalogue of these patterns by the name of "Problem/Solution" is proposed with the aim of helping engineers find the applicable patterns or mechanisms for their developing systems. Such researches offer some design patterns for self-organization applications, but they lack a strict representation, all of these patterns were represented by nature language.

3) Testing technology

Self-organization systems will only be acceptable in large scale applications if they can guarantee that they will accomplish exactly what they were designed for. Therefore, we need a practical and efficient method to anticipate and verify this emergent behavior. However, because of the autonomy of entities and macroscopic emergence, self-organization-based testing technology is still very few. [37]presents a method to verify self-organizing multi-agent systems using an autonomic computing approach and based on online planners and self-configuration.

C. Tool Aspect

There are only a few works in tools aspect. They can be classified in three aspects: 1) Self-organization MAS development tools. The tools have a database which stores the behaviors of agents, and these behaviors are refined from self-organization mechanisms. Behaviors are chosen by policy and are loaded into the behaviors of agents when the system is running. 2) Self-organization MAS simulation platform. Designers can model their designed mechanism by such tools to simulate the real running of systems and observe the running result.3) Self-organization system running environment. These environments are distributed implementation of self-organization systems that provide low-level functions such as communication, security, resource management and mechanism scheduling. Table 1 illustrates these tools.

III. CHALLENGES AND DIRECTIONS

C1: Effective and enabling mechanism of self-organization

An important challenge in engineering is to research how we can translate the insights of self-organization we have got into decentralized software mechanisms that allow controlling distributed complex system efficiently. The development of such mechanisms, for example reusable frameworks can be a huge support for software engineers to construct self-organization systems. Designers can select the mechanisms which can achieve the expected global coherent behavior, and realize these mechanisms into design of systems easily. We need to propose a framework of self-organization mechanisms which needs to meet two requirements. Firstly, the framework needs to have a standardized format and sufficient capability to express different mechanisms. Secondly, the mechanisms represented by this framework are easy to be translated to the decentralized algorithm for different applications.

C2: Breakthrough of modeling technology

A great challenge for modeling this kind of system during the development process is how to model the macro properties of system as well as the behaviors of individuals in the system. Current modeling technologies just care about the microscope individuals. We first need a general modeling language with formal or semi-formal semantics to either represent the behaviors of individual or the system macro properties. The modeling language should have a multi-level expressional capability to represent the self-organization system from different aspects, and effectively support represent the characteristics of this kind of systems like dynamic, autonomous, and local interactions etc. In addition, a challenge consists in current research works is that models of the self-organization systems are always from different abstract levels and different viewpoints, as a result, these models are inter-correlative. Some technical methods like strategy, tools which can support the consistency checking for these multi levels models are needed.

C3: Change in the development process

Current methodologies for engineering of self-organization systems often adopt the traditional development process like RUP [17]. However, Self-organization system is a kind of complex systems, the autonomy of entities and emergence of system make the traditional process models can not effectively support the development of such system, traditional top-down approach is hard to analyze the emergence of system macro properties which can not be refined to the behaviors of individuals. We need to find some innovative and effective process models to construct self-organization systems, for example bottom-up process. In this process, emergence of system macro properties is not acquired from refining of requirements, but from the designing of individual agents and their interactions. This approach is an Ad hoc manner which always needs a lot of experiments and experience of designers.

C4: Software quality assurance technology

Software quality is very important for software engineering. An effective means of achieving quality assurance is a major pre-condition for large-scale application of self-organization systems. However, software quality assurance technologies for self-organization are still lacking. We need some methods to assure the software quality of self-organization systems. For example, testing technologies for individual of self-organization system, it is need to study the agent software testing technologies in different phrase of life cycle and overcome the challenges of complexity of self-organization.

C5: Effective Tools and Platforms support

Although some tools for self-organization systems have been proposed [32], they still have some drawbacks. E.g., some important development processes like software testing are also short of supported by tools. Effective tools can great improve the development efficiency and quality. In self-organization system field, future work should encourage the development and refinement of development tools from two aspects. 1) With respect to the software life cycle, development technologies for different phrases of life cycle need to be implemented, which is the foundations of effective tools. The appearance of tools depends on the maturity of corresponding technologies. 2) Current tools need to be improved from many aspects: reliability, friendly, simplicity, and integration.

IV. CONCLUSION

In this paper, we analyzed the complexities of self-organization systems and the challenges that the complexities bring to software engineering. We also have surveyed the state-of-the-art in software engineering for self-organization systems, focusing on three core areas of theory, technology and tool. Based on this we have identified some key areas where we feel the state-of-the-art is lacking, and could be improved. For each of these key topics we have discussed ways for meeting the challenges, and suggested some possible directions for the future research.

Abstract

Embedded software systems interact with several external devices that may come across faults or failures. Most of the approaches have focused on software and hardware systems, but relatively less attention has been given to self-management of faults or failures of external devices in embedded software systems. It is necessary to develop an approach such that faults or failures of external devices in embedded software systems are detected and self-managed.

This paper describes an approach to establishing a framework for detecting and self-managing the failures of external devices for embedded software systems. Failed external devices are identified based on external device types, being self-managed in different ways. The proposed approach in this paper is applied to the use case modeling of an elevator system case study.

1. Introduction

Embedded software systems need to be more reliable against faults or unanticipated events so that the systems become more resilient to the system failures. Embedded software systems may still contain software faults in terms of specifications, semantics, logics, resources, and synchronizations even though the systems are verified and validated during development. Embedded software systems are running on hardware, which may fail due to hardware failures like aging, on-board circuit issues, peripheral or accessory maintenance. Previous approaches [Cheng06, IBM06, Roy07] have focused on failures in software and computer hardware [Coyle04, Pinheiro07, Wikipedia10].

However, not much attention has been given to faults or failures of external devices in embedded software systems, such as elevator systems and robotic systems. An elevator system should control several external devices such as direction lamps, elevator buttons, door, and motor. These external devices can run into some faults or malfunctions, which may lead the systems to failures. The software for embedded systems may not work correctly even though these external devices have minor faults or malfunctions.

This paper describes an approach to establishing a framework for detecting failures in the external devices of embedded software systems and for self-managing the detected failures. This paper develops the detection framework based on the external device types in embedded systems. There are unique communication patterns between embedded software systems and their external devices. These patterns are used to devise failure or fault detection mechanisms. Further, the self-managing framework is developed for handling external device failures from the software perspectives. The self-management is carried out by means of self-healing, self-configuration or adaptation, and self-reporting. The proposed approach in this paper has been applied to the use case modeling of an elevator system.

This paper is organized as follows. Section 2 describes classification of external devices. Section 3 describes the devised framework for fault detection, followed by self-management of external device failures in section 4. Section 5 describes the use case modeling for detecting and self-managing failed external devices. This paper is concluded in section 6.

2. Classification of External Devices

There are different external devices in software systems, which can be classified into several types [Gomaa00]. A type of external devices has the unique communication pattern between the devices and the system. This uniqueness of communication styles is used to develop a framework for detecting faults or failures in external devices. Each device type is categorized by means of device characteristics, such as input/output, periodic/non-periodic, asynchronous, or active/passive.

- Input/output devices: An input or output device can provide input to or receive output from the system respectively. Some devices have only one role of either input or output, or both input and output. For example, an elevator button is an input device and an elevator lamp is an output device in an elevator system.
- Periodic/non-periodic devices: A periodic device interacts with the system periodically, whereas a non-periodic device interacts with the system as needed. For example, a brake is a non-periodic device, and an engine is a periodic device in a cruise control system.
- Asynchronous devices: An asynchronous device generates an interrupt to send a message to the system, which then reads a message from the device. Examples of this type are elevator buttons in an elevator system and cruise control buttons in an cruise control system.
- Active/Passive devices: An active device cannot generate an interrupt to be sent to the system, but it may send directly a message to the system. A passive device cannot generate an interrupt for communication with the system and cannot send a message to the system. The motor and the elevator door in an elevator system are passive.

3. Detection for External Device Failures

3.1 Failure Detection of Asynchronous Input Devices

An asynchronous input device generates an interrupt and delivers it to the device interface whenever it meets some event interesting to the interface. When the interface receives an interrupt from an asynchronous input device, it may need to read a message from the device. An asynchronous input device is characterized as input, asynchronous, and non-periodic. An asynchronous device may not generate any interrupt if it fails. In that case, the interface cannot detect the failures of the asynchronous input device. Examples of this type of asynchronous external devices are floor buttons and elevator buttons in the elevator system.

However, there are some exceptional asynchronous input devices whose failures may be detected under some conditions. An arrival sensor in the elevator system is an example of the asynchronous input device whose failures are detected using other devices in the system. Figure 1 shows the communication between the arrival sensor and the elevator control. An arrival sensor is installed at each floor, sensing the arrival of the elevator at the floor. As an elevator reaches a specific floor, the arrival sensor sends an interrupt to the arrival sensor interface, which notifies the elevator controller of the message arrival. The elevator controller checks if the elevator should stop at the floor or not. When an elevator is going up, the i-th floor arrival sensor may be presumed that it fails if the elevator controller receives an arrival message from the (i+1)th arrival sensor without a message from i-th arrival sensor. Similarly, this can be applied when the elevator is going down.

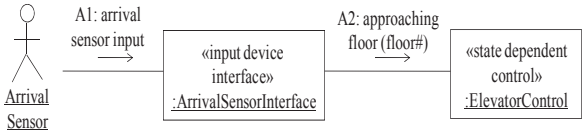

Fig. 1 Communication Diagram for Arrival sensor and Elevator Control Objects

3.2 Failure Detection of Periodic Input Device

A periodic input device delivers inputs to the system periodically, but it is not an active object. A periodic input device is characterized as input, periodic, and passive. A system polls a periodic input device to get an input from the device on a regular basis. When the system polls the device, the device is presumed that it fails if the system cannot read an input from the device upon each poll.

The engine in a cruise control system is the example of this type of device. The engine is polled by the engine interface to read an input at periodic intervals. When the engine does not return its input to the interface, it may meet a failure. Figure 2 shows the engine failure detection in the cruise control system. Also failures of an engine can be detected in another way. If the system does not receive the normal heat temperature values from the heat sensor for a certain period of time, the system detects the failure of engine.

3.3 Failure Detection of Periodic Output Device

A periodic output device receives output from the system periodically and handles the output. A periodic output device is passive, thus it just waits for an output from the system. Failures of a periodic output device may not be detected by the system. This is because the device may not respond to the system when an output is arrived. But failures of periodic output devices may be detected by users. Examples of such devices are a mileage display, a trip average display and a maintenance display in a cruise control system, and a microwave display in a microwave system (Fig. 3). These displays show some information to users in which the information is changing. Users can detect the failures of these displays when the information is not changing.

Some periodic output devices can be monitored by polling the devices. Such an example is the throttle in the cruise control system. The throttle is classified as a periodic output device whose failures may not be detected. But a throttle is a polled device whose failure is detected when the throttle position sensor does not return any value to the system within a defined period of time.

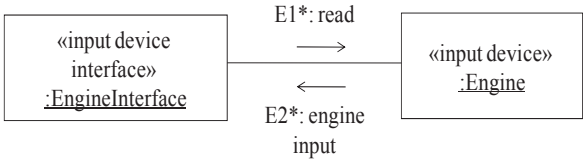

Fig. 2 Engine sensor failure detection

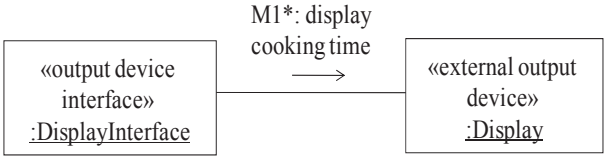

Fig. 3 Microwave display failure detection

3.4 Failure Detection of Passive Output Device

The system sends an output to a passive output device as needed, which handles the output. A passive output device is checked for the status by the system after an output is sent to the device. A passive output device is characterized as output, passive, and non-periodic. The motor, elevator lamp, and elevator door in the elevator system are examples of passive output devices.

The status of the motor (Fig. 4) in the elevator system is determined by checking the rotation/motion sensor after an output, such as motor start or stop, is being delivered to the motor. When the rotation/motion sensor does not return a valid response to the elevator system within a defined period of time, it leads to a conclusion that the motor has failed. Similarly, the elevator direction lamp is monitored by the voltage sensor, and the elevator door's failures are detected by the rotation sensor status.

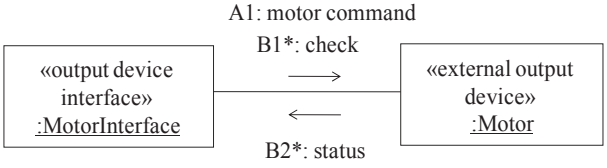

Fig. 4 Elevator motor failure detection

4. Self-management of External Device Failures

4.1 Self-healing

Failures detected in external devices may be resolved by retrying the communication with the devices. Similar to software, an external device may meet a failure attributed to some minor mechanical error or instant error. For failures of a periodic input device, the system reads an input from the devices again. For instance, an engine interface retries to read an input from an engine if there is no response from the engine. A passive output device interface retries to send an output to the device, and polls the status of the device again. For example, the motor in the elevator system may be retried if it meets some failures.

Failed external devices can be reinitialized by calling the initialize() operation, which initializes the devices and its related variables. A device interface object has the initialize() operation that is called at initialization time. However, the system calls the initialize() operation if it meets failures in the devices, and the system retries to communicate with the failed devices.

The system controller switches failed external device to another device if a secondary device is available. The secondary device has the same functionality as the primary device. The switch between a primary device and a secondary device is carried by the device interface, but the system does not require reconfiguration of software components constituting the system. An external device may not have its secondary device if the device is not critical to the system or if the secondary device is not cost-effective.

The self-healing approach can be applied to the external devices that are non-time critical. A failure of external devices can be categorized with response time, such as time critical or non-time critical. A time critical device's failure is intolerant if the device does not work on time. A time critical device does not have enough time to self-repair the failures. A failure of time critical device may shut down the entire system. The brake or engine in a cruise control system is an example of the time critical device. A non-time critical device is not a time bound device whose failure may be fixed by self-repair. A floor button in an elevator system is an example of non-time critical device.

The self-healing approach for external devices has some limitations that may not fix failures attributed to real mechanical problems. An external device with a mechanical problem needs to be replaced physically by hardware engineers if the secondary device is not installed with the primary device. For example, an elevator direction lamp may be burn out due to the life time, and the motor of an elevator may meet a mechanical problem that cannot be fixed by retrying or initializing it.

4.2 Self-configuration or adaptation

Failure analysis enables us to analyze the impact and the consequences of the failed device in the embedded system. The failures can be classified as tolerable, serious and catastrophic. A failure of external devices that does not disrupt the normal functioning of the system is termed as a tolerable failure. An example is a failure of a direction lamp of an elevator. Even though a direction lamp fails, the elevator works fully without degrading its services to passengers. A serious failure in the external devices degrades the functions of a running system, but it may not necessarily bring the system to a total failure. For example, an elevator button's failure makes some passengers not reach to a specific floor, but the elevator still works. Another example is a failure of arrival sensor at a specific floor in an elevator. A catastrophic failure is irrecoverable, and it brings the entire system to a sudden halt. The examples are failures of the motor in an elevator system, and failures of the brake in a cruise control system.

The embedded software may need to be reconfigured or adapted against tolerable or serious failures of external devices so that the system prevents from the ripple effect in terms of the failures – worse performance or additional failures. When a device meets either a tolerable or serious failure that cannot be self-repaired, the system should not communicate with the device in order to send an output to or read some input from the device. This communication can make the device interface meet the same failure, and try to self-repair it using retry or re-initialization. Even the same failure may be notified to the system controller, which already knows the device status. For example, an elevator system should not send an "on or off" message to an elevator direction lamp if this lamp is already detected to be failed. Otherwise, the elevator direction lamp will try to self-repair the same failure again and the system's performance will be getting worse.

A failure of external device may bring another failure to the system if the system is not adapted against the failed device. Suppose that multiple elevators are operating in a building and an arrival sensor for a specific floor of an elevator fails. The scheduler of the elevator system should not patch the elevator to the floor with a failed arrival sensor. The elevator cannot stop at the floor due to the failure of arrival sensor. If the elevator is patched to the floor, the elevator may continue to go up or down repeatedly to reach the floor.

4.3 Self-reporting

The embedded software systems can be divided as unmanned control or manned control systems. The elevator system is an example of unmanned control system, whereas the microwave and the cruise control systems are manned control systems. This criteria is made based on to whom the non-self managed failures should be reported. In the case of the unmanned control systems, the maintenance centers are notified while the users are notified in the manned control systems. When a device failure is detected, the failure can be either detected by the device interfaces, or users. If a catastrophic device in the unmanned control system fails and there is no way to self-manage, the system should stop and report to appropriate person or maintenance center.

5. Detection and Self-management in Use case Modeling

The proposed approach for detection and self-management of failed external devices is applied to the use case modeling for the elevator system, cruise control system and microwave system [Mane10]. The following is the Stop Elevator at Floor use case [Gomaa00] in the elevator system, which is extended to

detect and self-manage failed external devices – arrival sensor, motor, floor direction lamp, and elevator door.

Name: Stop Elevator at Floor Use Case
Actors: Arrival sensor
Precondition: Elevator is moving.
Description:
As the elevator moves between floors, the *arrival sensor* detects that the elevator is approaching a floor and notifies the system. The system checks whether the elevator should stop at this floor. If so, the system commands the *motor* to stop and turns on the *floor direction lamp*. When the elevator has stopped, the system commands the *elevator door* to open.
Alternative for Application:

- The elevator is not required to stop at this floor and so continues past the floor.

Postcondition: Elevator has stopped at floor with door open.
Detection and Self-management of External Device Failures:

- Arrival sensor (asynchronous input device). **Detection -** the system may not detect the failure, but it may detect it using neighbor sensor input.
  Self-management - if an arrival sensor fails and the elevator needs to stop at the floor, the system stops the elevator at the next (up or down) floor to drop passengers. The system self-reports this failure to the maintenance center if the arrival sensor does not send the signal to the system continuously.
- Motor (passive output device). **Detection** - if the motor does not return the status within a defined time or return an abnormal door sensor value, the system detects the failure of motor. **Self-management** – the system reinitializes the motor and commands it to start moving the elevator. If the motor is still not moving the elevator and the elevator is located at a floor, the system commands the elevator door to open so that passengers can go out of the elevator. The motor is a critical device, so the system self-reports this failure to the maintenance center. The system does not allocate this failed elevator to user requests.
- Floor direction lamp and Elevator door (passive output devices). **Detection** - if the floor direction lamp (elevator door) does not return the normal value, the system detects the failure of the floor direction lamp. **Self-management** – the system reinitializes the floor direction lamp (elevator door) and goes to the next use case description step because it is not critical device. Since it is a non-critical, tolerable failure, the system reconfigures the failed floor direction (elevator door) lamp interface so that the system does not send messages to the failed device. The system self-reports this failure to the maintenance center.

The use cases for the elevator system with detection and self-management of failed external devices are implemented to validate the proposed detection and self-managing framework. This implementation is to develop a simulator for the elevator system in which the external devices are implemented as software objects rather real devices. The software architecture for self-managing external devices of the elevator system is designed as a layered architecture structured with the service layer and self-management layers [Mane10]. The service layer has application objects for the elevator system, whereas the self-management layer has objects – detection, planning, and execution modules - related to detection and self-management of device failures.

6. Conclusions

This paper has described an approach to establishing a framework for detection and self-management of failed external devices in embedded software systems. This paper has developed the detection framework based on the external device types in embedded software systems. The communication patterns between external devices and the system are used to detect failure or fault of external devices. The self-managing framework handles external device failures from the software perspectives. The proposed approach in this paper has been applied to the use case modeling of the elevator system.

This paper can have further research. This research has been applied to three embedded software systems - elevator system, cruise control system and microwave system. This research may need to other embedded software systems so that we enable to identify more device types. Also this paper does not include the relationship between an external device and its sensor. An external device may have its sensor that is used to monitor the device. When an external device fails, the failure may be in the device or its sensor. This relationship needs to be addressed in our future research.

***Abstract*— With the complexity and the dynamic analysis requirements during software adaptation for software in the open and dynamic environment, the software analysis requires integrating multiple analysis methods and controlling the execution of analysis methods in specific sequence. As a result, the analysis process is hard to be communicated to its designers, implementers and users without an explicit model. In addition, if dependent methods are not included or encounter runtime failure, the data dependency and control dependency between analysis methods may cause correctness problem. In this paper, we proposed a domain-specific language for modeling the analysis process using subset of notations from BPMN. In order to cope with the dependency problem in model and implementation level, the dependency relationships are divided into static dependency and dynamic dependency. Dependency identification and matching algorithm is provided to assure the static dependency in the analysis process model. For the dynamic dependency, we provide a service to detect the analysis failure caused by dynamic dependency. We model and validate two analysis processes supporting software adaptation with performance and reliability concerns, and apply the analysis processes in analyzing a running system ECPerf.**

Keywords- software analysis; analysis process, process validation, analysis process modeling

I. INTRODUCTION

Analysis is the process of breaking a complex topic or substance into smaller parts to gain a better understanding of it. Software analysis technology is widely used during software lifecycle, and generates descriptive, predictive or prescriptive analysis results regarding to the system consistency, correctness, quality attributes and so on.

More and more software systems are running in the internet which is open and dynamic. In order to provide continues and high quality services in the internet, software may change the structure or behavior according to the changing user requirements and environment [1]. The increasing complexity of the software system brings challenges to the software analysis.

Software analyses play an important role during software adaptation. A general adaptation process contains four stages: monitoring, analysis, planning and execution. In the monitoring stage, the system model generated by monitoring system is usually low-level model containing raw data of different system aspects. These models are hard to be used without a transformation to high-level model or domain-specific model. In the analysis and planning stages, the system designer usually employs analysis methods to acquire status of the system, possible adaptation strategies and change impact, so as to gain a better understanding for decision making. For the information of different kinds: descriptive, predictive or prescriptive, usually more than one method are needed. Even in the execution stage, analyses of platform specific features and execution strategies are usually required for assurance of adaptation correctness.

During the software adaptation, multiple analysis methods are used and carried out in specific sequence. For example, an analysis method for adaptation planning may be used after the analysis methods for system quality attributes. In addition, the analysis results may affect the choice of analysis methods afterward. For example, the quality attributes acquired in the analysis stage may affect the choice of adaptation planning methods. If there is security problem, the designer may choose to analyze the possibility of adding fault-tolerant ability. If the system's performance is too low to fulfill stakeholders' requirement, the designer may choose to see possible reconfiguration with higher performance.

The analysis requirements for software adaptation bring new challenges. First, the analysis process is complex that it contains several related analysis methods. The set of analysis methods is chosen according to the system status and these methods should be carried out in specific sequence. The analysis process is repeatedly executed by hand. As a result, the execution process is error prone and hard for reuse. Second, the assurance of the analysis process correctness is hard because of complex relationships between analysis methods. There are two kinds of dependency relationship: the data dependency and control dependency. Data dependency means that an analysis method's input relies on the output of another analysis method. Control dependency happens when an analysis method's output decides whether another analysis method is executed. Thus, if an analysis method relies on the analysis result produced by an analysis method which is not included in the process, or the relied analysis method encounters runtime failure and can not

provide proper result for other analysis methods, the analysis process could not generate correct results or even could not finish execution.

Recent works on the integration of analysis methods have proposed methods and framework to ease the integration of analysis methods. These works focus on extracting proper model for analysis, controlling external analysis tool to carry out analysis task, and synthesizing analysis results back to the core model. Among these works, ADD [7] provides guidelines and standard interface for integration of analysis input, execution and output; XTEAM [5] and KAMI [3] focus on providing facilities for input adaptation and tool execution; our ongoing work focus on the integration on the synthesis of analysis results. However, these works assume that the analysis methods can be integrated independently and used together to finish an analysis process. The relationships between analysis methods during an analysis process are not considered.

In this paper, we propose a process based method to model and validate analysis process. We propose a domain-specific language for modeling the analysis process based on notations from BPMN. The modeling language considers the sequence relationship and dependency relationship between analysis methods in the process. In order to cope with the dependency problem in model and implementation level, the dependency relationships are divided into static dependency and dynamic dependency. Based on the analysis process model, dependency identification and matching are provided to assure the correctness of analysis execution. To ensure the static dependency could be guaranteed, the require input of each analysis method is evaluated. For the dynamic dependency, we provide a service to detect the analysis failure caused by dynamic dependency which is expressed by the elements with runtime data dependency definition, and this detection service is added to the process.

The remainder of the paper is organized as follows: Section 2 illustrates the modeling and validation requirement of analysis process. Section 3 and 4 introduce the modeling and validation method for analysis process. Going back to our example, Section 5 presents the use of our method to model and validate analysis process for software adaptation. Finally Section 6 discusses some related works before Section 7 concludes our work.

II. ILLUSTRATIVE EXAMPLE

In this section, we will introduce an analysis process including three analysis methods to show the modeling and validation requirement.

This example is a software adaptation analysis process, which first appeared in the work on performance adaptation [9]. The process includes three analysis methods for monitoring, analyzing and planning respectively: behavior model generation method COMPAS (Component Performance Assurance Solutions) [2], performance related pattern detection method [9], pattern-based reconfiguration method [9]. The user first uses the COMPAS analysis method to generate the behavior model based on runtime information contained in a software model from the monitoring stage. Then, the user uses an analysis method to detect Fine-grained Remote Calls structure in the software model. If instance of the bad structure pattern is found, the user will execute pattern based reconfiguration method to generate an adaptation plan. If bad structure does not exist in the software model, the analysis process is finished without planning.

In the example, the pattern detection method relies on the behavior model generated from the COMPAS method. Whether the planning method will be executed is decided by the result of pattern based detection method. The data dependency and control dependency may cause problem in design time and runtime. At design time, if the user first chooses the pattern based detection method instead of the COMPAS method, the detection method could not be executed without behavior model. We add the COMPAS method in the analysis process to solve the static dependency problem. However, dynamic dependencies may happen. For example, the COMPAS analyzer will not generate any result when it encounters runtime error. In this situation, all the analysis methods and control switchers rely on it will be affected. The analysis process will stop executing, or generates fault results or useless results.

Besides modeling the analysis process, we need to validate the process in order to correctly analyze the system.

III. MODELING ANALYSIS PROCESS

Our approach starts from the modeling of analysis process. The activities in the process are all of the type analysis method. An analysis process can be viewed as a group of analysis methods.

In order to simplify the analysis process modeling, we build our modeling method based on existing works on the integration of analysis methods. The integration of the analysis methods can be divided into three aspects: the integration of the input, the integration of the execution and the integration of the output. We assume that the analysis methods are already integrated that its input is provided by the software model through input adaptation; its tool is integrated and can be invocated; the analysis results are synthesized back into the software model.

Data proceeding and control logic are two important consideration in the molding of analysis process.

From the data level, all the analysis methods in an analysis process have the same analysis object: the software system. The analyzed system is usually abstracted and saved as model. The analysis results are the features of software system and can be modeled as elements or attributes of elements in the software model. As a result, the data flow in the analysis process includes the core software model and the analysis results. The analysis methods are organized as a star configuration.

In order to simplify the data processing modeling, we use our former work [11] on the integration of analysis results to update the core software model. Based on the framework, the software model is updating during the analysis execution. After an analysis method is executed, the software model will be extended with its results. For each analysis method, its required input can be provided by the software model and the analysis results produced of the analysis method executed

before. As a result, the analysis result integration framework maintains the models and manages the data processing in the analysis process. Based on the integration framework, modelers do not need to model the data processing in the analysis process; they can concentrate on modeling the control logic of analysis process.

The complex control logic of a process can be described using three kinds of structure: sequence structure, decision structure and repetition structure. However, an analysis method is seldom repeatedly executed during an analysis process. Because analysis is a way to generate software features from the software model, the analysis behavior does not affect the model. For a specific analysis method and a software model, the analysis result is the same if the analysis method is executed repeatedly. Thus, repetition structure is not needed in analysis process. It should be noted that an analysis method may be carried out more than once during an analysis process. This is because an analysis method can be applied to analyze different part of software model especially analysis results generated by other analysis methods.

Besides the sequence structure and decision structure, parallel structure is supported in the analysis process modeling for performance consideration. Because analysis methods are usually provided and implemented by different vendors, their analyzers may be running in different nodes. If some of the analysis tasks are time consuming and can be carried out by the analyzers in different node, the designer can model these analysis methods in a parallel structure.

We use a subset of notation of BPMN to model the analysis process. The modeling element types are listed in table 1. The start event and end event are used in the beginning and ending of the analysis process. Inter Event is only used to show possible exception in the process. A Task is mapped to an integrated analysis method which is the only kind of atomic activity in the analysis process. AND Gateway is used to describe the set of analysis methods which should be carried out in parallel. XOR Gateway and Sequence Flow are used to describe the sequence structure and decision structure.

Table 1 modeling elements

Element	Description
Start Event	The Start Event indicates where a particular process will start.
Inter Event	Intermediate Events occur between a Start Event and an End Event and will affect the flow of the process.
End Event	The End Event indicates where a process will end.
Task	A task is an atomic activity within the process. It represents work to be performed. A task will be activated when one of its incoming sequence flows is triggered and will trigger all its outgoing sequence flows when it is finished.
AND Gateway	An AND Gateway will trigger all outgoing flows, when all incoming flows are triggered.
XOR Gateway	An XOR Gateway will trigger one of its outgoing flows when one of its incoming flows is triggered.
Sub-process	Sub-processes are used to support hierarchy. A Sub-process contains its own Start and End Event.
Sequence Flow	The Sequence Flow shows the order in which activities will be performed in a Process.

Our analysis process modeling language uses the notation of BPMN. Designer can use the BPMN visualization modeling tool and implementation generation tool to model the analysis process and get the executable process described using BPEL regarding semantic mapping between BPMN and BPEL.

IV. VALIDATING ANALYSIS PROCESS

There are two kinds of dependency: data dependency and control dependency. To ensure the static dependency could be guaranteed, the dependency occurs during the analysis process is detected and the depended analysis method is automatically added to the process. For the dynamic dependency, we provide a service to detect the analysis failure caused by dynamic dependency which is expressed by the elements with runtime data dependency definition, and this detection service is added to the process afterwards

A. Dependency Definition

In order to validate the dependency relationship, we extend the integration definition in the analysis result integration framework. Fig 1 shows the extended meta-model, the integration model is extended with the element Relied Element. Analysis method integrator can specify the relied elements and their validation rules. The default validation rule for a relied element is that it should not be null. For the Gateway element in the analysis process, the switcher usually relies on some elements for decision making. The process modeler can define an integration model for a Gateway element. The integration model only includes a list of relied elements. We detect static dependency problem and validate the required input model at runtime based on the integration models of analysis methods and Gateway elements in the process.

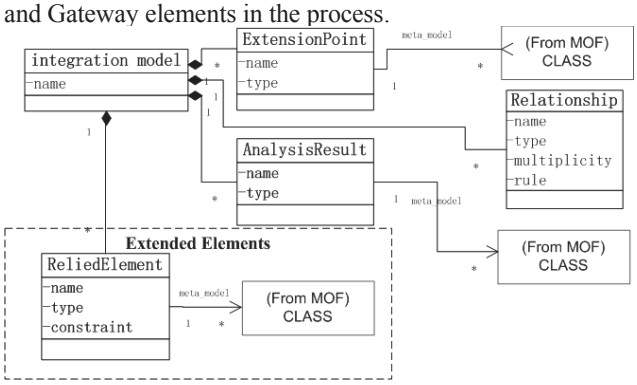

Fig 1. Extended Meta-model of Integration Definition

B. Static Dependency Detection

There are two kinds of dependency relationship between analysis methods: data dependency and control dependency. An analysis process is incorrect if there is any analysis method or control switcher who relies on one or more analysis methods which could not generate needed analysis

result for this method or control switcher. The dependency problem may occur when (1) the relied analysis method is not included in the analysis process; (2) the relied analysis method is included in the analysis process, but could be executed after the analysis method or control switcher in some situation; (3) the relied analysis method is included in the analysis process and could be executed before the analysis method or control switcher in any situation, but the analysis method has dependency problem.

For an analysis method am_0 in the process model, it does not have dependency problem if

(1) All the analysis methods which am_0 relies on are included in the process model.

(2) All the process instances will carry out am_0 's dependent analysis methods before am_0 。

Because analysis methods do not affect each other directly even if they are in the same analysis process. Their dependency relationships are built based on the relationship between their input and output. $\mathrm{AR}_{\mathrm{am0\_dependent}}$ is the set of analysis results which analysis method am_0 relies on; $\mathrm{AM}_{\mathrm{am0\_dependable}}$ is the set of analysis methods whose results can be used by analysis method am_0 ; $\mathrm{AR}_{\mathrm{am0\_dependable}}$ is the set of analysis results produced by all the analysis methods in $\mathrm{AM}_{\mathrm{am0\_depedable}}$. An analysis process do not have static dependency problem when all the analysis methods in the process rely on the analysis results which can be generated before its execution in any process instances. The constraint can be expressed in OCL as below:

$$P.task \rightarrow forall\{\mathrm{am}_0 \mid (\mathrm{AR}_{\mathrm{am0\_depend\ able}} \cup CoreModel) \supseteq \mathrm{AR}_{\mathrm{am0\_depend\ ent}}\} = P.task$$

For an analysis method am_0 in the analysis process, its dependent analysis results are defined by the integrator. We developed an algorithm to find out the dependable analysis methods, the union of all the results produced by the dependable analysis methods is $\mathrm{AR}_{\mathrm{am0\_dependable}}$.

Input: process model P, analysis method am_0 , the starting point and ending point in the process model P $point_{start}$ and $point_{end}$;

Variables: $\mathrm{AM}_{\mathrm{dependable}}$, $\mathrm{AM}_{\mathrm{dep\_temp}}$ and $\mathrm{AM}_{\mathrm{temp}}$ are sets of analysis methods, SF_{temp} is a set of sequence flow, and $checkpoint$ is a reference to an element in the process, e_{start} and e_{end} are the start event and the end event of process P;

FindAMDepedent (P, am_0 , $point_{start}$, $point_{end}$)

Initialization: $\mathrm{AM}_{\mathrm{dependable}} = \phi$, $checkpoint = po\mathrm{int}_{start}$, $\mathrm{SF}_{\mathrm{temp}} = checkpoint.outgoing$;

1. if $checkpoint = po\mathrm{int}_{start}$ and $AM_{temp}.size = 1$, then $checkpoint = AM_{temp} \rightarrow first()$
   $\mathrm{AM}_{\mathrm{temp}} = checkpoint.outgoing$
2. if $checkpoint = po\mathrm{int}_{end}$, goto (9)
3. if $checkpoint = am_0$, goto (8)
4. if $checkpoint$ is of the type Task and $AM_{temp}.size = 1$, then
   $\mathrm{AM}_{\mathrm{dependable}} = \mathrm{AM}_{\mathrm{dependable}} \cup \{checkpoint\}$,
   $checkpoint = AM_{temp} \rightarrow first()$,
   $\mathrm{SF}_{\mathrm{temp}} = checkpo\ \mathrm{int}.outgoing$;
5. if $checkpoint$ is of the type Gateway, then
   for *am* in AM_{temp}
   $\mathrm{AM}_{\mathrm{dep\_temp}}$ = FindAMDepedent(P, am_0 , *am*, $checkpoint.jointpoint$)
   If $\mathrm{AM}_{\mathrm{dep\_temp}} \neq \phi$, then
   $\mathrm{AM}_{\mathrm{dependable}} = \mathrm{AM}_{\mathrm{dependable}} \cup \mathrm{AM}_{\mathrm{dep\_temp}}$
   Goto (9);
   endfor
   $checkpo\mathrm{int} = checkpoint.jointpoint$
   if $checkpoint$ is of the type AND Gateway and $\mathrm{AM}_{\mathrm{temp}} = \phi$, then
   goto(6)
6. $\mathrm{AM}_{\mathrm{dep\_temp}} = \phi$
   for *am* in AM_{temp}
   if *am* is of the type XOR Gateway, then
   $\mathrm{AM}_{\mathrm{dep\_temp}} = \mathrm{AM}_{\mathrm{dep\_temp}} \cup am.jointpoint$
   if $am \neq checkpoint.jointpoint$ and am is of the type Task
   $\mathrm{AM}_{\mathrm{dep\_temp}} = \mathrm{AM}_{\mathrm{dep\_temp}} \cup am.outgoing$
   $\mathrm{AM}_{\mathrm{dependable}} = \mathrm{AM}_{\mathrm{dependable}} \cup \{am\}$
   endfor
   if $\mathrm{AM}_{\mathrm{dep\_temp}} \neq \phi$, then
   $AM_{temp} = \mathrm{AM}_{\mathrm{dep\_temp}}$
   goto (6)
7. goto (1)
8. return $\mathrm{AM}_{\mathrm{dependable}}$
9. return ϕ

Using this algorithm, a process can be validated. If for each analysis method in the process, its relied input can be provided by the core model and the analysis results of its dependable analysis methods, this analysis process do not have static dependency problem.

C. Runtime Validation of Required Input Model

During the execution of an analysis process, runtime exception may affect the analysis execution and produce meaningless analysis results. The runtime exception may be caused by missing input from the core software model, exceptions from analysis tool execution, and so on. The fault or meaningless analysis results may affect other analysis methods which rely on these results. Thus, if this kind of fault can be detected at runtime, the process can be stopped so as to save time and avoid the misleading analysis results.

The runtime validation is the process to make sure that the input constraints are not violated. The validation is based on the dependency definition. The validation objects are the elements specified as relied elements in the integration model. There is a default rule that the required input element should not be null. This rule can be described using OCL:

$$integrationmodel.reliedElement \rightarrow oclIsUndefined() = \text{false}$$

Besides this rule, analysis method integrator can define rules as constraints for the *reliedElement*.

The runtime validation of required input model can be abstracted as a special analysis method in the analysis process. Its analysis result is used to decide whether the process will continue or not. For each analysis methods or switchers with relied elements, we add a runtime validation method before it. We develop and integrate the validate tool in the integration framework. Then, the analysis process can detect validation of constraints at runtime.

V. Case Study

In this chapter, we use our approach to model and validate the analysis process for the adaptation of a component-based system, the ECPerf system [6]. The ECPerf system is provided by Sun Microsystems, which has been adopted as a standard benchmark application for JEE systems. It is an online "Just-in-Time" manufacturing system. We used the SM@RT [10] monitoring platform to extract data from the running ECPerf system and to visualize the corresponding software model. We used the analysis method integration framework [11] to integrate the related analysis methods. For space limit, we focus on the modeling and validation of analysis process, detail of analysis methods integration is not included in this paper.

A. Peformance Adaption

In section2, we introduce an analysis process for performance adaptation. For a maintainer who is not familiar with the analysis methods, he does not know that the pattern detection method relies on the behavior model which is not provided by the monitoring system. He my model an analysis process containing two steps: detect performance related bad pattern, and reconfigure the software if bad structure exists, as shown in Fig 2.

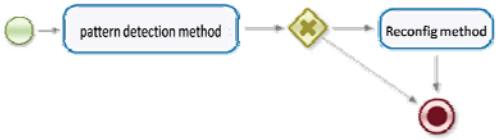

Fig 2 Analysis Process for Performance Adaptation

We use our static dependency detection algorithm to validate this analysis process. Because pattern detection method is the first method in the process, it can only rely on the core software model. In the integration definition of pattern detection method, two relied elements are defined: software configuration element *Config* and the behavior model element *SequenceDialog*. The configuration model is included in the software model. However, the software model only contains a list of invocation records. The software model does not contain any element of the type *SequenceDialog*. There is static dependency problem in the process. If an analysis method COMPAS is added before the pattern detection method, as shown in Fig 3, it can generate behavior model based on the invocation record in the core model. This analysis process does not have dependency problem and can be used for performance adaptation.

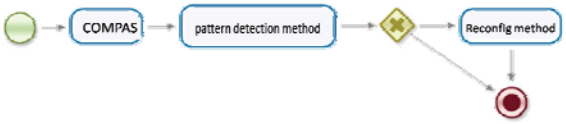

Fig 3 Analysis Process for Performance Adaptation

B. Fault-torelant Style based Software Reconfiguration

Reliability is one of the most important quality attributes for online services. Because reliability is important, the maintainer chooses two reliability analysis methods SBAR [12] and ABRAM [14] to analyze the runtime software model. If the value of any reliability result is less than 90%, the maintainer will choose a planning method ASPIRE [13] to generate adaptation plan, and then use the SBAR and ABRAM method again to analyze the planning result to make sure that the reliability will be improved. During the analysis process, the maintainer may stop analyzing if the system reliability is acceptable. We use our modeling language to describe this analysis process, as shown in Fig 4.

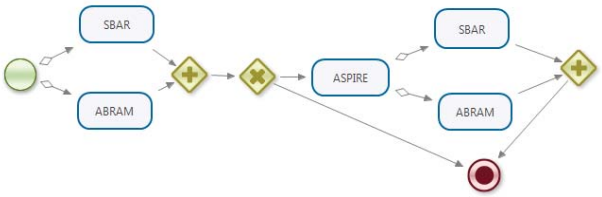

Fig 4 Analysis Process of Style-based Software Adaptation

In this example, the SBAR method and ABRAM method is used twice with different input. The XOR Gateway before

ASPIRE method relies on the reliability analysis results: *SBARresult* and *ABRAMresult*. The constraints for these two elements are the same that the value of the element should be in the range of 0 to 1. A validation analyzer is added before the gateway in the analysis process. This analyzer will check both the *SBARresult* and *ABRAMresult* when the SBAR and ABRAM method finishes execution.

When we apply this analysis process in analyzing the software model of ECPerf system, the process always stopped and through an exception before the XOR gateway. Because we re-implement ABRAM analyzer using the model transformation language ATL with too many nested statements, the analyzer will be short of memory when analyzing software models with more than 10 components. When analyzing the ECPerf software model, the ABRAM analyzer cannot return the result *ABRAMresult* until timeout. As a result, the runtime validation carried out before the XOR gateway will find that the required input *ABRAMresult* violates its constraint. The runtime validation is also helpful for us to detect improper usage of analysis method.

VI. Related Work

The works on the Enterprise Application Integration (EAI) can be applied to integrate analysis tools. However, EAI most focuses on the translation the outputs of some application into inputs for other application, and the invocation of application interfaces [15]. The relationships between integrated analysis methods are not considered.

Many approaches and frameworks have been developed for complex analysis of software models. Some approaches are proposed to facilitate the use of multiple analysis methods during software design. ADD [7] and FADF [6] provide standard interfaces for integration of analysis methods. These works notice the requirement for the analysis process, but do not provide support for process modeling. In addition, these works simplify the relationship between analysis methods as data exchanging and leave the user to guarantee the process correctness.

Several research projects propose frameworks [3, 4, 5, 6] to simplify the integration of existing model-based analysis methods. XTEAM [5] is a framework focusing on solving the mismatch between SA model and required input of analysis methods. KAMI [3] is a framework for run-time model adaptation. These frameworks provide facilities to simplify the development of model interpreters and model updaters, respectively. DUALLY [4] is an automated framework that allows architectural languages and tools interoperability. It provides the infrastructure for (semi) automatic generation of the weaving model to integrate analysis abilities provided by ADLs. However, these frameworks assume that analysis methods are independent and do not consider dependencies of the analysis methods. Our framework focuses on the modeling and validation of analysis process, and is build based on some of these works.

VII. Conclusion

This paper introduces an approach to model and validate the analysis process for software adaptation. We believe that an explicit model for analysis process can enhance the reuse of analysis process and save effect for analysis execution. Considering the dependency relationship in analysis methods, our method provide an algorithm to detect static dependency problem in the analysis process model and an analysis method to validate required input model at runtime, so as to avoid correctness problem caused by dependency .

***Abstract*—Autonomic Computing aims at realizing computing systems that are able to adapt themselves, but the engineering of such systems in the large is rather a challenging task. It is hard to find an appropriate model that controls the adaptation itself and several loops are likely to be coordinated to avoid unexpected and harmful behaviors. This paper presents an approach and a runtime support to architecture self-adaptive systems, in which each part of the feedback control loop is uniformly and explicitly designed as a first-class adaptive element. Making these elements explicit allows the architect to reason about system modeling and to reuse them. Code generation from the architecture model avoids painful details of low-level system implementation.**

***Keywords*-Autonomic Computing, Model-Driven Engineering, Software Architecture**

I. Introduction

The 24/7 deployment of distributed systems is dramatically increasing the complexity and maintenance costs of software systems. The ability to adapt then becomes crucial for such systems. Autonomic computing is a promising way to organize self-adaptive systems. This approach aims at realizing computing applications that can dynamically adjust themselves to accommodate changing environments and user needs with minimal or no human intervention [1]. The engineering of such systems in the large is rather a challenging task. It is hard to find an appropriate model that controls the adaptation itself [2]. Its implementation being generally integrated in a feedback control loop, developing several adaptive behaviors necessitates to reason on them, at least to obtain an appropriate coordination between them. Moreover, engineering in the large obviously needs some reuse capabilities on loops or more likely, on elements composing the loops [3].

Following the general principle that control loops should be made explicit [4], [5], we present in this paper an approach for engineering self-adaptive systems with an explicit architectural model and its runtime support. In the proposed architecture each part of the feedback control loop is uniformly and explicitly designed as a first-class adaptive element. Making these elements explicit allows the architect to reason about system modeling, while capturing different patterns of interactions and controls (coordination of loops, adaptive monitoring, etc.). By applying a model-driven approach with a framework based on standardized interfaces, loops and loop elements are then likely to be more easily reused. Moreover code generation from the architecture avoids painful details of low-level system implementation.

The remainder of this paper is organized as follows. Section II introduces some background on autonomic control loops and discusses requirements. Our approach is described in Section III, giving details of its principles and architectural model. Section IV illustrates our proposal on an overload scenario of an extensively used distributed batch computing system. The runtime support is also presented, and first experimental results are evaluated. Some related work are discussed in Section V. Finally, we conclude and briefly present future work in Section VI.

II. Engineering Self-Adaptive Systems

Self-adaptive systems are characterized by runtime decisions to control their structure or their behavior and making these decisions autonomously (i.e. without or with minimal interference) while reasoning about their contexts and environments [5]. Self-adaptive software is generally organized around closed feedback loops aiming at adjusting itself during its operation. The Autonomic Computing refers to self-managing characteristics of computing resources that manage themselves given some high-level objectives by adjusting their operation in the face of changing environment and user needs [1].

Making autonomic computing a reality necessitates to put together and evolve results from several research disciplines, from Artificial Intelligence (planning, decision theory, machine learning, agents, etc) to Control Theory and engineering [6], [3]. Moreover numerous challenges are directly related to the software engineering of feedback control loops, to ease the application of other disciplines. Loops have been originally designed following the *sense-plan-act* control decomposition, or refined to make four steps appear, i.e. collect, analyze, decide, act. When engineering such loops, it has been first shown that it is hard to find an appropriate model that controls it [2]. Besides, building the software artifacts around this control model is far from being trivial, as monitoring data must be consistently collected and actions on the adapted systems well coordinated. Finally, overlapping in all concerns of a loop may appear when

several feedback loops need to be deployed, leading to unexpected and potentially harmful behaviors.

Previous work tackle these challenges. IBM proposed a form of standardized approach for the feedback loops with the *Monitor-Analyze-Plan-Execute-Knowledge* (MAPE-K) architecture [1], [7]. This makes explicit the behavior of autonomic managers which activity follows the *M-A-P-E* decomposition using some shared *Knowledge* (indicators, policies, plans...). Several systems and frameworks have been developed according to this principle [8], [9], [10][1], generally aiming at providing an architecture to organize the self-adaptive part. For example, Garlan et al. [9] proposed two-layers framework with an external fixed control loop that can be customized. The controlled and control system are clearly separated and a mapping allows data to be transmitted between them. The control loop is then made explicit but several feedback behaviors cannot be separately designed.

Recently, it has been advocated that control loops and their elements must be explicit to facilitate reasoning about them as well as their reuse [4], [5]. Even if recent work made some advances, with hierarchical MAPE-K coordination [11] or component-based analysis architecture [12], there is, to the best of our knowledge, still the need for an architecture that would provide the right abstractions for rapid prototyping, but yet remain flexible enough to cope with the diversity and dynamic aspects found in current systems. In our vision, such architecture should support i) several kinds of loop element grouping and loop architectures, so that different forms of coordination between loops can be designed together with some sharing between monitoring elements or effectors on the controlled system; ii) adaptive capabilities over the controlled system but also on the control system, so that the architecture would capture adaptations over the monitoring, parameterizations on the models used by the controllers, etc. Moreover, the architecture should be versatile enough to capture the relevant parts of the feedback systems while being as abstracted from technological details as possible. In reusing some generative approach, this would foster reuse while avoiding painful details of low-level system implementation for most parts.

III. Approach

In this section we present the main principles of the proposed approach, together with the model for the architecture.

A. Principles

In our approach, we focus on an externalized self-adaptation that is based on a closed loop feedback control. We express an architecture of such a self-adaptive system in a technologically agnostic model that is centered around the notion of a feedback loop and where each of the loop's

[1]See [5] and [6] for surveys.

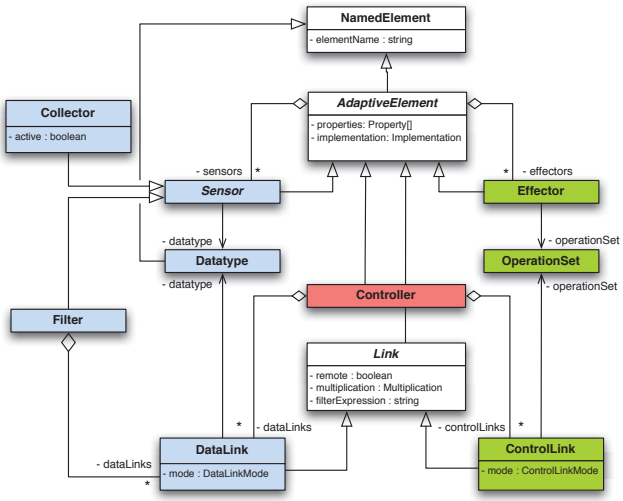

Figure 1: Architectural model.

elements is made explicit [4]. Four main elements represent the main responsibilities in the feedback control. The target system and its context observability is captured in *sensor* elements, the decision making process is represented by *controller* elements and the actual system adaptation is carried out by the *effector*. We also explicitly model the data and control flow in the architecture via *links* that represent the dependencies between the components. Figure 1 presents the resulting architectural model. In the following paragraphs, we detail the different modelling capabilities of our proposal to design the different elements of a loop.

One of the main originality of the model is that it supports reflective self-adaptation. In the model, each element inherits from *adaptive element*, which itself can provide its own sensors and effectors. This feature allows elements to be introspected (meta-data, state) and modified in the very same way as the target controlled system is. One can hierarchically compose not only control on the top of controllers, but also on the top of sensors, effectors and links. The added adaptation then becomes self-adaptable as well, and in an uniform way. This notably distinguishes the model from other model-driven proposals [15]. In this paper, we do not deal with the distribution of loops and loop elements, but in that case, as links can be themselves adaptive, remoting issues like the inevitable delays and network failures could be addressed with our architectural model.

Besides, by using a model to express the adaptation concerns it allows us to support different degrees of separation in respect to the target system. From being completely external, running aside the target system in its own runtime platform, to be completely integrated inside the system using aspect-oriented techniques or direct source code generation. The model is technologically agnostic thus it only captures

the semantic of the adaptation: the definition of the components and with relevant inputs and outputs for data and control flow respectively.

B. System Observation

The monitoring part of the model (left part in fig. 1) is responsible for supplying information about the system into controllers so they can reason about the state of the system and its environment in order to take the appropriate decisions. This information is provided by hierarchically organized sensors elements in a form of a directed acyclic graphs with *data links* connecting them together. There are different types of sensors: collectors and filters.

Collector: The leaf nodes in the hierarchy are called collectors. A collector provides data of a defined *datatype* that are directly gathered from an external entity like various operating system resources, services calls, user preferences, etc. Essentially, it can operate in two modes: active or passive. An *active collector* is responsible for updating itself. This is used in cases where the update is based on some external notifications like a file change, new socket connection, etc. A *passive collector*, on the other hand, waits until it is explicitly requested by an associated link to provide data.

Filter: The other nodes in the graph, which are not leaves, are filters. These sensors are used to aggregate or in some other way process data that are coming from one or more connected sensors. They can be real data filters, stabilization mechanisms, converters, rules inference engines, etc. A typical example of a filter is a noise filter that is used to stabilize the context information that comes from other sensors. Since each filter is therewith an adaptive element, its parameters can be advertised using specific sensors and effectors, thus providing a uniform means to adjust them at runtime.

Each of the data links connects a producing node (a sensor) with consuming node (a filter or a controller) and can be configured *before and at runtime* to be operating in different modes. With *periodic notification or observation* (▶, ◀) a link requests, at a fixed rate, the producer to get data and forwards it to the consumer. With *reactive notification* (▷) a link is explicitly requested by a producer to forward given data to the connected consumer. *Reactive observation* (◁) is the opposite of the notification, a link is explicitly requested by a consumer to get data from the connected producer.

When all elements of the monitoring part are connected, the model can easily be checked against the well-formedness of the resulting data flow (non-interrupting, correct typing). As the model relies on strong typing, the controller (through its data link) and its sensors must have compatible data types in order to be connected. The resulting data flow itself logically originates in collectors and terminates in controllers, however, the actual data transfer that triggers the adaptation is driven by either active collectors or the periodic links. These are the only entities in the system that are actively running, the rest of the system is event based.

The links themselves supports adaptation so that their transmission properties, such as the notification or observing periods, are advertised and can be used by other loops. For example it can be used to model some adaptive monitoring or to handle timeouts on remote links.

C. Decision Making

The decision making part is in the model represented by the controller element. Essentially, the idea behind the decision making is to choose an appropriate action among the set of all permissible actions based on the observed state of the subjected system. There are many different kinds of controllers that can be used for the decision making process. A good overview of the some strategies is given in [13], but different kinds of controllers can be designed, for example supporting a decomposition between the analysis and planning phases, like in the MAPE-K decomposition [1]. In this paper we are not concerned by the actual design of the adaptation behavior itself, but rather we focus on supporting the architecture of the system as a whole.

D. System Alteration

The actual system modification is carried out by effectors that are orchestrated by controllers based on the actual decisions. An effector encapsulates a set of operations and provides them to the controlling elements via *control links*. An operation is a named action that can take an arbitrary number of arguments. Similarly to the data links, control links also use strong typing.

IV. Illustration

In this section we illustrate our approach with a simplified feedback based overload control system in the high-throughput computing domain.

A. Scenario Overview

We consider an environment made for executing compute-intensive scientific workflows [14] with the Condor infrastructure [16]. Condor is a well established distributed batch computing system that has been used extensively in both academia and industry. We use a typical Condor deployment with one scheduler, a *schedd* agent, that is responsible for managing user submitted jobs and mapping them onto a set of resources where the actual execution is performed. Condor default support for executing workflow is provided by DAGMan (Directed Acyclic Graph Manager) execution engine, which acts as job meta-scheduler on the top of Condor batch system. Each workflow execution starts a new instance of the *DAGMan* that carries out the actual submission of the tasks into the schedd agent.

Since especially scientific workflows tend to be rather large, containing many computer-intensive tasks, the scheduler can easily become overloaded, as the more tasks it has to handle the more resources it uses. The default behavior of the schedd is to accept all valid submission requests regardless the current state of the system. There are configuration options for both schedd and DAGMan, but they are static and do not take into account the current state of the system nor the number and nature of workflow executions varying over time.

B. Overload Control

In order to maintain a certain utilization of the system and prevent its overload, we design a basic controller that will be integrated in our illustrative self-adaptive architecture. The control maintains a certain number N^* of jobs in the queue. There is a configuration option in DAGMan that controls the number of seconds it waits before submitting a task. By making this option reread at before each submission we can impose an adjustable delay d for each client. We denote m the number of clients representing the DAGMan instances at some sample time t. Each client is submitting at rate $\lambda_i = \frac{1}{d}$ therefore the total arrival rate at t is $\lambda = \sum_{i=1}^{m} \frac{1}{d} = \frac{m}{d}$. The control optimizes the utilization of the queue $\rho = \frac{\lambda}{\mu}$ depending on the number of jobs N in the queue where μ is service rate. We use three cases for the state of N: if $N = N^*$ then the buffer is ideally filled so we only maintain the $\lambda = \mu$; if it is less, we linearly increase the arrival rate and when it is more we vigorously decrease it all the way to 0 shall $N = N_c$. The $N_c > N^*$ denotes some critical number of jobs in the queue that must not be reached.

$$\rho(N) = \begin{cases} \rho_0 + \frac{N(1-\rho_0)}{N^*} & \text{for } 0 < N < N^*, \rho_0 > 1 \\ 1 & \text{for } N = N^* \\ \alpha(N - N_c)^p & \text{for } N > N^*, \text{ where } \alpha = \frac{1}{(N^* - N_c)^p} \end{cases}$$

From the utilization and total arrival rate we can derive the target delay d:

$$\rho(N) = \frac{\lambda}{\mu} = \frac{\frac{m}{d}}{\mu} \qquad d = \frac{m}{\rho(N)\mu}$$

The ρ_0 denotes the maximum growth rate allowed in the system.

C. Architecture

In figure 2 we present the resulting architecture using a graphical domain specific language. To increase readability, the names of the implementation classes have been added to the model while removing the names of links.

The first controller (1) is responsible for the submission rate control elaborated above. It thus requires three inputs: the current number of jobs N provided by the `queueStats` collector and further stabilized by a moving average filter, an information about the current service rate μ that is coming from the `serviceRate` collector also stabilized, and the number of clients m is obtained from the `dagmanCounter` collector. The control output is linked to the `dagmanDelayFile` effector which simply writes the given delay to the appropriate file to make it available to the running DAGMans. The `queueStats` collector internally executes the `condor_q` command and parses its output. However, the more jobs are queued the longer it takes to execute and the more system resources it uses. In order to control it, we make this monitoring part self-adaptive as well by adding the controller (2) that adapts the trigger period of the link towards the controller (1) based on the average time that it takes to execute. Using again the self-adaptive capabilities of each adaptive element, we make the properties of the model in controller (1) i.e. the target number of jobs in the queue N^* and the critical number of jobs N_c, changeable over time. In our simplified case, it is only dependent on the system memory. The controller (3), running at a slower pace, is responsible for controlling these properties.

Finally, in Condor there is a `condor_master` daemon responsible for keeping all the rest of the Condor daemons running. If it crashes, the pool looses its managing authority and has to be restarted. In our model, this can be done easily by adding a controller that gets its input from a process heartbeat sensor and start the process if it is not running anymore. Similarly to the master daemon, it uses an exponential back off delay before each attempt. While not being coordinated with other loops in this simplified version, several behaviors are currently added and coordinated with our approach. They can then be used to provide high-level indicators or notifications to system administrators. The overall system shows some relevant capabilities of our model to explicitly design various feedback control loops and self-adaptive behaviors on loop elements themselves. Some potentially reusable parts are also shown, with monitoring filters or loop patterns (adaptive monitoring, parameterization of the controller).

D. Implementation

Our current runtime support is based on the Equinox OSGi framework[2]. In this runtime each instance of an element from the model, including links, is registered as an OSGi service. For each dependency a proxy is generated. Upon request, it consults the OSGi service registry to locate the concrete instances. This allows us to employ the whiteboard pattern [17] for handling the data and control flow in the system. For example, instead of registering a listener for each reactive link to the respective elements, the link itself is registered as an OSGi service with appropriate service properties, so that the proxy can discover it and call when a notification or observation is needed.

[2]http://www.eclipse.org/equinox/

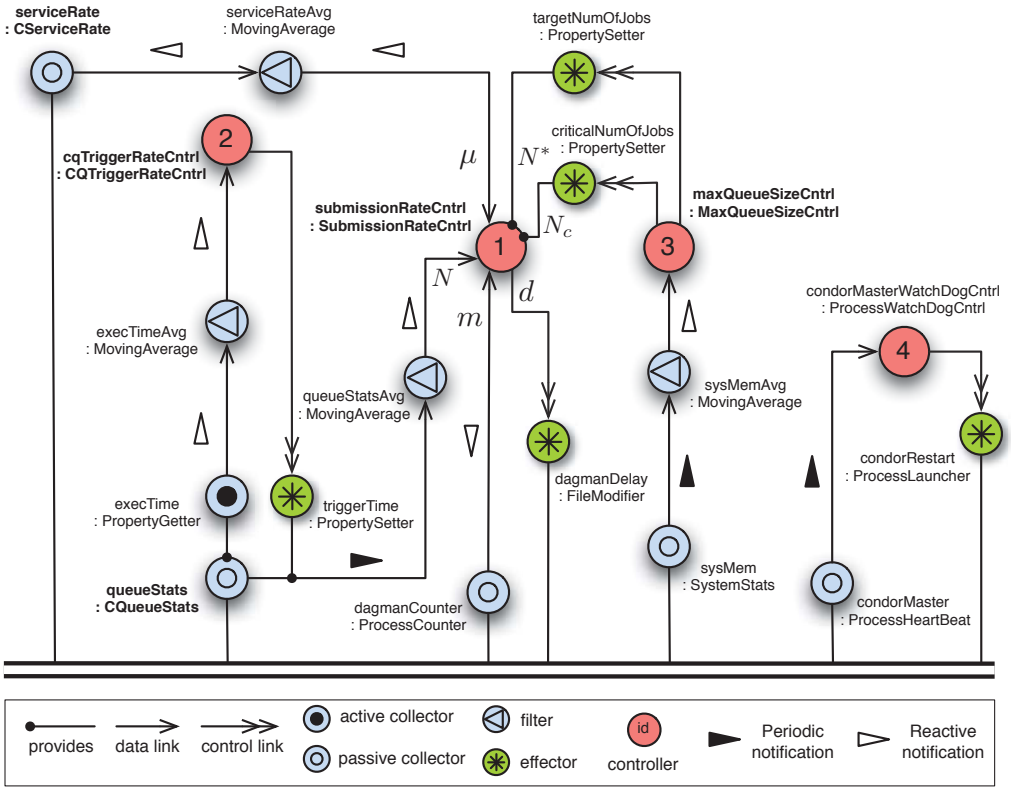

Figure 2: Architecture of the WMS overload scenario. The names of the links are omitted. Each element also contains its corresponding implementation type. In case of controller (1) also the individual inputs and outputs are marked.

In order to turning the architecture into a running system, we first need to formally describe the model of the architecture from the fig. 2. We use a Domain Specific Language (*not shown in this paper*) that defines both the type model and the concrete instances together with values for all required properties and parameters needed at runtime. Additionally we need to provide an implementation for all the custom sensors, controllers and effectors (see elements marked bold in the figure 2). The rest are general reusable elements provided by our framework for the runtime support.

Listing 1 shows an excerpt of a custom controller. This generated Java class skeleton is used as a delegate for the `DelegatingController` provided by the framework. This controller is responsible for handling the observation and notification of the data and control links and providing all the necessary inputs for the annotated control method of the delegate.

```
public class SubmissionRateController {
...
  @ControlMethod
  public void control(
      @DataInput("queueStats") int queueStats,
      @DataInput("serviceRate") float serviceRate,
      @DataInput("dagmanCounter") int dagmanCounter,
      @ControlOutput("writer") FileManipulation writer) {
    ...
  }

  @ProvidedEffector ("targetNumOfJobs")
  public void setTargetNumOfJobs(int targetNumOfJobs) {
    ...
  }

  @ProvidedEffector ("criticalNumOfJobs")
  public void setCriticalNumOfJobs(int criticalNumOfJobs) {
  ...
  }
  ...
}
```

Listing 1: Excerpt of controller (1) implementation

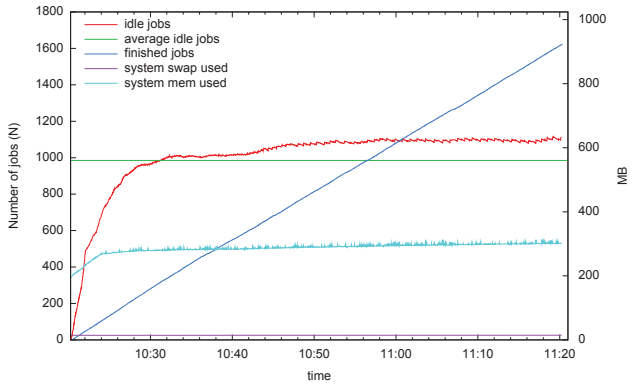
Once we have the model in the DSL and an implementation of all the elements, we transform it into an OSGi bundle. The generated resulting bundle contains the implementation classes with their resources and an activator that is responsible for instantiating and registering the individual elements as OSGi services as well as resolving their dependencies by creating necessary proxies and managing their life-cycles.

This bundle together with the other bundles from the framework can be installed and started by the Equinox container.

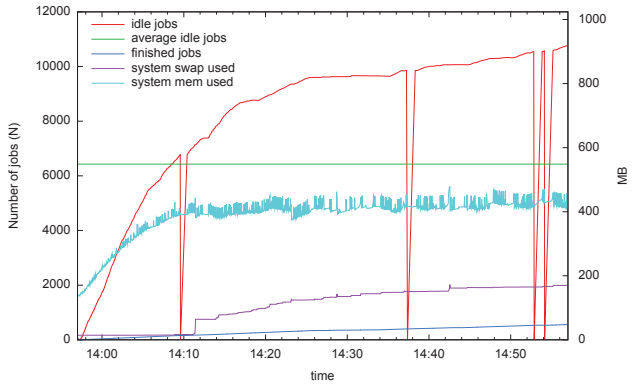
Since Condor DAGMan only evaluates its configuration options when it starts, we made a small modification that refreshed the delay time before every submission.

E. Experimental Results

To evaluate the capacity of the resulting architecture, we set up two Condor deployments, with and without the main feedback control loops. For both runs we used 20 clients



(a) controlled



(b) uncontrolled

Figure 3: System behavior with and without control

together submitting a wide workflow of 1000 tasks each with different running time. We initialized the overload control model with $N^* = 1000, N_c = 1500, p = 5, \rho_0 = 10$. Results are show in figure 3a and figure 3b presenting the system behavior with and without control respectively.

In the feedback controlled system, the amount of idle jobs were for most of the run slightly (6.9%) above the N^*, on average by 69 jobs (116 max). The average load on the host with control was 0.6 in comparison to 3.37 in the system without any control. As shown in figure 3b, major problems arose when the system started running out of memory and started swapping. After that, it spent most of the time waiting for I/O (on average 51.29% of CPU time were *iowait* comparing to 15.6% in case of the managed system). The gaps in figure 3b were caused by timeouts when `condor_q` tried to get the queue information from the schedd agent during the period the system was too stressed (corresponding to load > 9).

Finally, one of the important differences is in the amount of work done during the observed period. Because of the resource waste caused by the overload, the unmanaged system executed only 560 tasks while the controlled version did 1620 tasks. This demonstrates the basic capability of the feedback system generated from our architectural model to regulate the load on this example.

V. Related Work

In addition to the previous work on architecting loops evoked in Section II, some recent works attempt to propose an explicit fine-grain modelling of feedback control loops. In FORMS [18], the focus is more in characterizing the kinds of autonomic architecture with appropriate metamodels so that they can be compared. Similarly, in [12] Hebig et al. provides an UML profile to explicitly architect several coordinated control loops with component diagrams. Nevertheless the loop elements are not adaptive and there is no link to any runtime support.

Regarding control, in [13] Litoiu et al. describe a hierarchical framework that accommodates scopes and timescales of control actions, and different control algorithms. Their architecture considers three main types of controller reflecting the three different stages that they focus on: tuning, load balancing and provisioning. While being similar, our architecture is more general but provides less fine-tuned building blocks to control the behavioral models used inside controllers. A lot of research efforts [2], [20], [21] has been put into tackling the problem of overload control of dynamic distributed systems. The major focus has been in designing a scalable and robust adaptive algorithm. In contrast, our main focus is complementary, dealing with the surrounding architecture in order to provide an appropriate supporting environment for the researchers to focus on the adaptation design.

VI. Conclusion

In this paper, we have presented an approach to support the architectural design of control loop elements and their connection links. The approach relies on an architectural model that makes control loops and their elements explicit. Moreover each element (sensor, controller, effector, links between them) is uniformly designed as a first-class adaptive element. The proposed model does not help in designing the behavior inside the controllers, but rather in architecting all the surrounding elements. Software architects can thus capture different patterns of interactions and controls (coordination of loops, adaptive monitoring, etc.) while reasoning about complex self-adaptive systems. The presented model is also technology agnostic and we provided a default implementation using an OSGi runtime support and a DSL to define architectures from which main parts of the final code are generated.

We also illustrated the architectural model on a overload problem arising in the Condor distributed batch computing system, showing both the capabilities of the model and the efficiency of the resulting code at runtime. The results are obviously only partial and we plan to conduct larger experiments on different and more complex scenarios, both

on Condor and on the gLite grid middleware [3]. This should enable us to identify some bottlenecks on both the architecture and the runtime platform.

Regarding the architectural model, ongoing work consists in turning it into a fully recursive model, so that composition of adaptive elements is supported and larger models can be more easily expressed and managed. Another way to simplify resulting architectures and to improve scalability of the approach is to support inlining of the elements in case there is no direct interaction. Besides, we are currently developing the parts of the runtime support to deal with distribution of the loop elements and making remote links between them self-adaptive.

ACKNOWLEDGMENTS

The authors would like to thank the Condor team from the University of Wisconsin-Madison for all their support, as well as Mireille Blay-Fornarino and the reviewers for valuable comments on the model.

The work reported in this paper is partly funded by the ANR SALTY project[4] under contract ANR-09-SEGI-012.

***Abstract*—We present our work on modeling distributed ensembles of virtual appliances (DEVAs) on Infrastructure as a Service (IaaS) clouds. Designing solutions on IaaS providers require a good understanding of the underlying details such as the software installation or the network configuration. We propose the use of DEVAs, a modeling approach built on top of the notion of virtual appliances, that allows easy-to-compose and ready-to-use cloud application architectures that are IaaS-agnostic, and that abstract away unnecessary details for web application developers. In this paper, we extend the definition of a DEVA from previous work by presenting an underlying metamodel and how that metamodel can be transformed to an actual deployment. We also present a case study where we model a web application architecture and we discuss how we can instantiate it in an IaaS cloud. We argue that the DEVA modeling approach is suitable for typical cloud use cases.**

***Index Terms*—virtual appliance, non-functional requirements, cloud computing architectures.**

I. Introduction

In this paper, we extend our work on modeling groups of interdependent virtual machines in the cloud. Designing these compositions require a good understanding of the underlying details such as the software installation or the network configuration. They are typically deployed in a cloud layer called Infrastructure as a Service (IaaS). Each IaaS provider has its own API to configure the virtual machines and its connections, requiring users to learn the details of yet another API. Similarly, manually installing software stacks in these virtual machines is a tedious task. In [1], we presented a visual modeling approach to make these architectures easy-to-compose and ready-to-use. We call these models *distributed ensembles of virtual appliances* (DEVAs)[1]. We now extend our work by presenting an underlying meta-model for DEVAs.

Sapuntzakis et al. presented in 2003 the idea of a virtual appliance, effectively treating full stacks of software applications and OS as updatable image files [2]. These virtual appliance files could then be cloned in bare metal computers, or instantiated in virtual machines. Still, when the time comes to compose multi appliance systems with interdependencies, Sapuntzaki's implementation relied on defaults from software vendors for most of the configurations. This may not be the case for web applications (e.g., when trying to configure interdependencies between a database server and its clients). Similarly, the configuration of the network connection between appliances had to be done by hand. Various recent attempts at automatically configuring virtual appliances and their network dependencies have been presented [3], [4], [5], but they all rely on having experts on appliance configurations, or on specific IaaS providers.

In [1], we proposed that with proper modeling of these kind of scenarios, the configuration problems could be abstracted away. By designing DEVAs, non-expert users can easily architect interdependent virtual appliances. DEVA models include quality of service (QoS) constraints, which can account for the non-functional requirements of the modeled architecture. In this paper, we extend our modeling approach by 1) presenting an underlying meta-model, and 2) how a model generated from the meta-model can be instantiated to an actual deployment.

The main technical challenge for this work was to come up with a meta-model with sufficient details to be able to instantiate DEVAs on the spectrum of current IaaS providers. To demonstrate our modeling approach, we present a case study where we model a web application architecture and discuss how we can instantiate it in a current IaaS provider.

We argue that the DEVA modeling approach is suitable for typical cloud use cases, and that having a model of a cloud architecture can simplify co-allocations and migrations across-different IaaS providers. In Section II, we present background information on the methodology used and on our previous work. In Section III, we present our metamodeling framework. In Section IV-A, we discuss a system that can transform DEVA models into instances, and in Section IV-B, we present a simple case study. In Section V, we discuss related work, and finally, in Section VI, we enumerate some concluding remarks.

II. Background

In this section, we present background information on model-driven engineering, the methodology used for this work, and present details on previous work including the definition of DEVAs.

[1]Note that in [1] we called our models *virtual environments* instead of DEVAs. We have desisted of the previous name as it is already used in other CS areas.

A. Model-Driven Engineering

MDE is a methodology that aims to effectively apply models to software development. Instead of looking at models as simple diagrams, MDE captures the problem domain in a modeling language. This language can later be used to generate solutions that can be automatically generated. MDE has many goals, including accelerated development, automated transformations, and platform independence [6].

In this work, we utilize the MDE methodology to present a modeling approach that simplifies cloud architecture design, as well as to achieve platform independence from IaaS providers. In addition, we use MDE's metamodeling approach as presented in [6] to realize an abstract syntax definition for our models. Static semantics are presented in Object Constraint Language (OCL) notation [7].

B. Distributed Ensembles of Virtual Appliances

A *distributed ensemble of virtual appliances* is a model of a logical architecture of interdependent virtual appliances. From the point of view of users of DEVAs, these models should present the following properties:

1) **Easy to understand**: Views for the design, deployment, change management, and monitoring of these architectures should only present what is strictly necessary to realize them. Advanced options should be available but normally hidden.
2) **Self-configurable**: Once the user has specified a description of the architecture needed, our solution should be able to instantiate the model and configure all the details automatically by following the constraints and policies specified.
3) **Present deployment choices**: Modeling should be abstract enough to allow for an implementation to present deployment choices. Given the heterogeneity of current IaaS APIs, this is one of the main challenges of our approach.

C. Visual Concrete Syntax for DEVAs

Research has shown the benefits of visual aids when designing system architectures, claiming a gain of over 60% in comprehension [8]. Since our target users are web developers, which may not be experts on architectures for the cloud, a graphical representation is desirable. We model virtual appliances with boxes with *service endpoints*. The boxes represent all the necessary software, the OS and the configuration necessary to support the services provided or consumed. Figure 1 presents an example of a DEVA composed of two virtual appliances. The box entitled 'RoR Node' is a representation of an appliance provisioned with the Ruby on Rails web framework (and all other needed software). Similarly, the box entitled 'MySQL DB' is an appliance provisioned with a MySQL database. These appliances have been interconnected with a 'db' link by joining the corresponding endpoints. This connection assumes that any interdependent configuration will be resolved by our solution. For example, to be able to provide the db service, a username and password must be agreed by the db provider and db consumers. In our approach, there is no need to configure IP addresses, ports or configuration files.

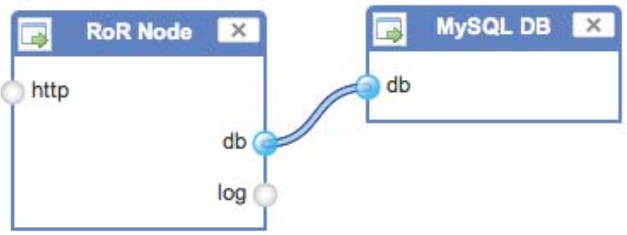

Fig. 1. An example of a simple DEVA as presented in [1].

III. A Metamodeling Framework for DEVAs

In [1], we investigated the first property of our model by presenting an uncomplicated visual concrete syntax to design DEVAs. In this paper, we investigate the second property. We realized that for our solution to be able to model arbitrarily complex cloud architectures, we needed a formal definition of our modeling approach. The third property, to be able to present deployment choices, remains as future work.

Having an underlying metamodeling framework for DEVAs facilitates the steps necessary to go from a model to an instance in a similar way that the Meta-Object Facility (MOF) defines the UML language. Figure 2 presents an overview of the framework. Note that to keep our modeling as simple as possible, we do not currently use the MOF, or UML Profiles to define our framework.

At the top of the figure, we have the DEVA Meta-metamodel. This level defines what the valid constructs are for our modeling approach. Based on this constructs, we propose two different DEVA metamodels with the main difference being that one allows the instantiation of resource-independent (RI-DEVA) models, and the other allows resource-dependent (RD-DEVA) models. Resources in this paper mean computational resources as we would typically obtain from a IaaS provider, such as CPU allocations, RAM memory, and network connection speed and IP addresses.

We make this resource dependency distinction for two main reasons. First, to present the user with a simple designing tool that separates the concern of modeling a DEVA, and the concern of modeling the resources needed to run such DEVA. By having a RI-DEVA, a user can let our framework allocate the required resources based on the specified high-level policies and constraints. We can achieve this by transforming an RI-DEVA to a RD-DEVA using model to model (M2M) transformations [6].

Second, the resource performance from IaaS providers has been shown to have high variability [9]. Similarly, different IaaS providers have different metrics for specifying available resources. Thus, we believe it is desirable to model application architectures by quantifiable SLA constraints (*i.e.,* "able to do 100 transactions per second"), rather than subjective resource

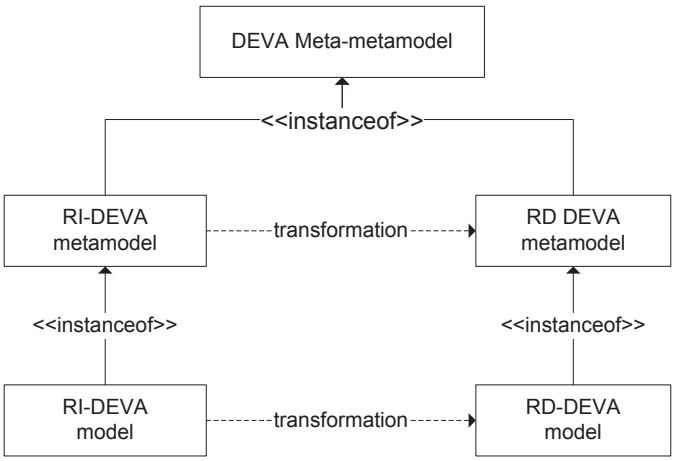

Fig. 2. Metamodeling Framework for DEVAs.

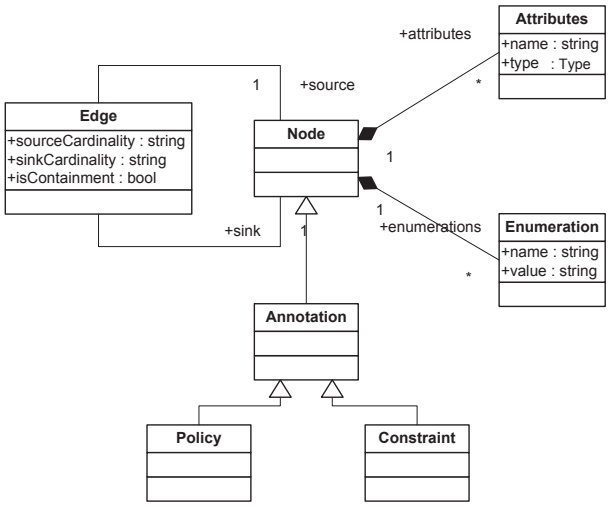

(a) Abstract syntax for DEVA meta-metamodel.

Fig. 3. Meta-metamodel for DEVAs.

metrics (*i.e.,* "having an equivalent of a 1GHz CPU with 256MB RAM") as IaaS providers currently offer [10]. Our main concern is to allow developers to specify RI-DEVAs that are transformed to RD-DEVAs by our system.

A. DEVA Meta-metamodel

Our proposed DEVA meta-metamodel abstract syntax is presented on Figure 3(a), and the static semantics on Figure 3(b). At this level, we can construct simple graphs, with Nodes and Edges. This metamodel is a simple extension of a graph which allows Annotations against Nodes. These Annotations can be either Policies or Constraints. Each of the Nodes can have a list of Attributes, or a list of Enumerations, but not both. Edges have a source Node and a sink Node, which cannot be the same Node. An attribute is composed by a name and a type. Enumerations have names and literal values. With these basic constructs, we can generate the metamodels for both RI-DEVAs and RD-DEVAs, which we describe below.

B. RI-DEVA Metamodel

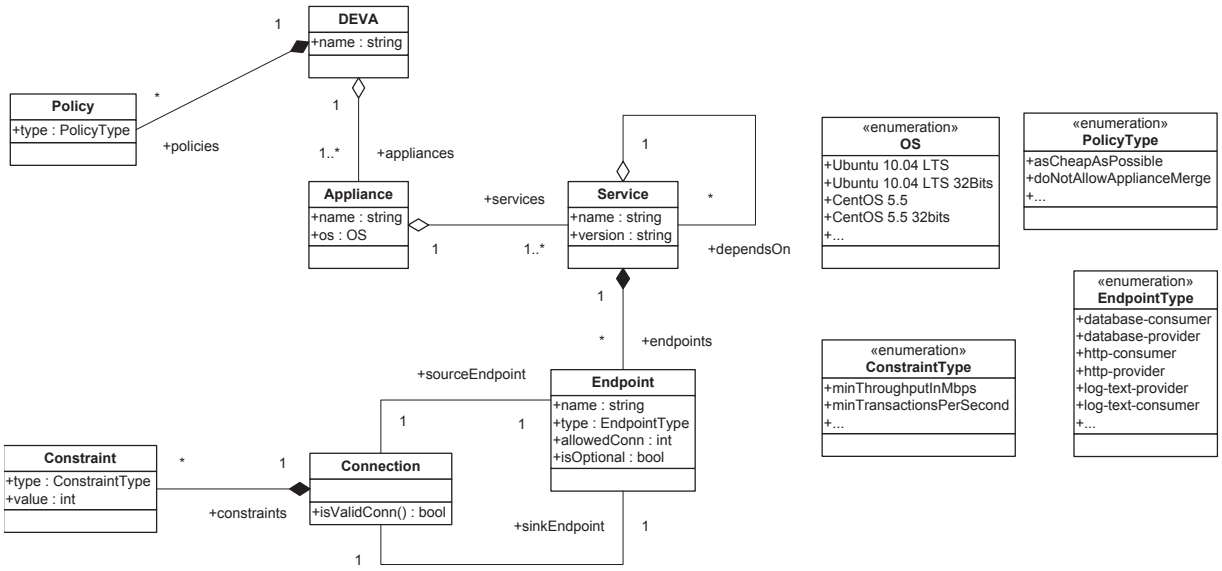
Our proposed RI-DEVA meta-model abstract syntax is presented in Figure 4(a), and the static semantics in Figure 4(b). An RI-DEVA is a named composition of zero or more global Policies and one or more virtual Appliances. In this context, Policies refer to high-level guidelines that a DEVA instance will try to meet. An example of a policy is to be able to instantiate a RI-DEVA with the least amount of resources possible (*i.e.* 'asCheapAsPossible' in our PolicyType enumeration). This means that economy will have a bigger weight whenever we try to realize this RI-DEVA. A RI-DEVA could include policies that are contradicting. In such cases, they would be accommodated in an arbitrary order.

At least one virtual appliance is necessary to convey a RI-DEVA. Note again that our Appliance definition is isolated completely from resource usage. These Appliances are represented by a name, a specific operating system, and a list of one or more services.

Each service is identified by a name, a version number, a list of the services it depends on (if any), and a set of zero or more endpoints. These endpoints are key to our approach, as can be seen in Figure 1. They allow to specify service production or consumption at the service level, rather than specifying network level details. This approach implicitly generates meta-data about the architecture that allows for easier appliance provisioning, as all the connection and service-to-service dependencies are known *a priori*.

Endpoints are represented by a name, a type, and an integer that specifies how many connections are allowed. A connection is composed of a source endpoint linked to a sink endpoint; sink and source cannot be the same endpoint. Connections should have valid type matches at each endpoint. Going back to Figure 1, a database-consumer can only be connected to a database-provider, and the provider endpoint can specify a maximum number of consumer connections. For this, we include a function $isValidConn : EndpointType \times EndpointType \rightarrow bool$ which determines Connection validity based on Endpoint type and their allowedConn property. Endpoints also specify if they can be left unused, or if a connection is necessary.

Each connection can have zero or more Constraints. These Constraints specify QoS non-functional requirements for the service-to-service connections. For example, in the case of a database connection, a constraint "at least 50 transactions per second" could be applied. Again, this meta-data could be used in the model transformation to try to guarantee the constrained connection performance.



(a) Abstract syntax for RI-DEVAs.

```
context Connection
inv: sourceEndpoint != sinkEndpoint and isValidConn()

context Service
inv: self.dependsOn->forAll(dep: Service | dep != self)

context Constraint
inv: self.value >= 0

context Endpoint
inv: self.allowedConn > 0
```

(b) Static semantics for RI-DEVAs.

Fig. 4. Meta-metamodel for RI-DEVAs.

C. RD-DEVA Metamodel

Figure 5(a) presents a partial abstract syntax for RD-DEVAs, and Figure 5(b) the static semantics. These models have a similar metamodel as RI-DEVAs. The main difference is that we do not have policies nor constraints; rather, we have IaaS resources mapped to each Appliance. These Appliances must be mapped to 3 or more resources, and there should be at least one resource of CPU, RAM, and NIC, respectively.

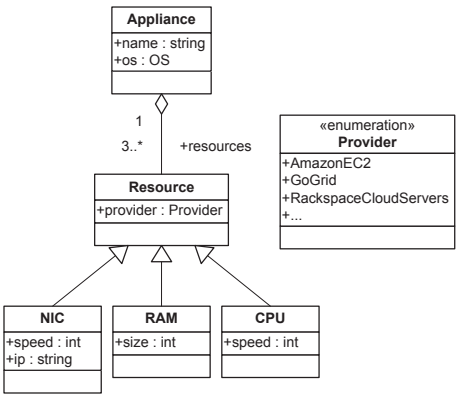
In this paper, we focus on how to construct RI-DEVAs and how to transform them to RD-DEVAs. Work on directly modeling RD-DEVAs is presented elsewhere [11].

IV. Transforming DEVAs

A. A model to instance reference system

Figure 6 presents an overview of a system that can transform DEVA models into instances. As input, the system would have a RI-DEVA model. This model would be received by a Model to Model (M2M) transformation engine aware of the metamodels for RI- and RD-DEVAs. The transformation between these models can be done in various ways. The task is to translate quantifiable constraints and policies to available resources in an IaaS cloud. This could be realized by having a mapping $Instantiate : ConstraintType \times Constraint.value \longrightarrow < R_{CPU}, R_{RAM}, R_{NIC} >$ applied to all of the services in a specific virtual appliance, where $< R_{CPU}, R_{RAM}, R_{NIC} >$ is a tuple representing the allocated resources in a specific IaaS cloud. This mapping could be implemented by using resource usage predictions based on empirical data in a black box manner, as in previous work where we model resources used by specific software [12], or in a white box approach as presented in [13]. The results of the mapping can then be aggregated to have the total needed resources for an Appliance.

Once we have a RD-DEVA, we need to have a DEVA model to instance (M2I) transformation engine that is aware of the IaaS resources. Again, we have various choices. Either the engine could be an IaaS provider which is aware of DEVAs, as in [11], or the engine could be a middleware which translates RD-DEVA models to IaaS API calls. To resolve interdependencies and to provision the appliances with the necessary software, this middleware would generate configuration scripts



(a) Partial abstract syntax for RD-DEVAs.

```
context Appliance
inv: self.resources->
          exists(c | c.oclIsKindOf(CPU))
inv: self.resources->
          exists(r | r.oclIsKindOf(RAM))
inv: self.resources->
          exists(n | n.oclIsKindOf(NIC))
```

(b) Partial static semantics for RD-DEVAs.

Fig. 5. Partial metamodel for RD-DEVAs. All other entities are as in RI-DEVAs if we eliminate the Policies and Constraints.

which would then be run on the instantiated Virtual Machines (VM) on top of the IaaS provider. Note that in our approach, a different M2I engine would be needed for each target IaaS provider. Nonetheless, some work from this engine can be modularized. For example, to make the software provisioning process repeatable, a software installation utility like Chef could be used [14].

B. A Simple Case Study

Because of space constraints, we present a simple case study of our approach based on Figure 1. A small composition like this can be instantiated as follows. First the user would define this RI-DEVA by using our prototype DEVA designer. We chose to have a web-based designer for DEVAs to provide a cross-platform solution. The model would then be sent to the M2M engine. Note that we can always compare the DEVA being designed against the metamodel to find discrepancies, and acknowledge the designer accordingly.

Since the model in Figure 1 does not present any specific Constraints, our system would choose the simplest transformation, which could be a direct mapping to, say, two Virtual Machines in Amazon EC2 of the type "small instance". A small instance in Amazon EC2 provides one CPU allocation, with 1.7GB of RAM, and a basic network connection with two IPs, one public and one private [10]. This would be the transformation to an RD-DEVA.

Now that we have an RD-DEVA, we can send the model to the M2I engine. On this engine, we can instantiate the architecture by making the IaaS-specific API calls necessary to launch 2 VMs, and then provisioning the software of each virtual appliance. After this, we would need to resolve the interdependencies (such as username and password for the database) by running configuration scripts on the instantiated VMs. Note that the meta-data of the Connections could be used in this step. For example, on Amazon EC2, the private IP could be used to make the DB connection, instead of using the public one. Similarly, we also know that there is only one connection possible to the database server. Therefore, the instance could be configured to reject any connection other than to the DB port.

V. Related Work

We have identified the need for better abstractions from the current IaaS implementations provided by vendors such as Amazon [10] or GoGrid [15]. Thus, we propose a modeling approach that is abstract enough to allow these interdependent systems to be easy-to-design, fast-to-deploy, and that limits the effects of IaaS vendor lock-in. We do not currently use a standardized IT information model, such as DMTF's Common Information Model [16], as current IaaS providers do not support them.

Commercial applications implementing a similar modeling approach are available [17], [18]. They only offer closed-source implementations and only work on their proprietary cloud platforms. IBM has worked on a similar project, but their implementation assumes that users are experts in the domains of virtual image provisioning, image composition, and composition deployment [3]. While they target enterprise customers, we target non-expert cloud users.

Platform as a Service (PaaS) providers, such as Google AppEngine [19], abstract away the underpinnings of a fully working web application. Of course, this means that the user has to learn the vendor's API, and that migrating the application to other PaaS provider implies changing most of the implementation. Our work envisions models that once specified do not need to be changed because of a vendor switch.

Recently, Amazon started to offer a service called CloudFormation. Customers can now specify groups of virtual machines with provisioning scripts that provide repeatable architecture instantiation. Compared to our solution, Amazon's offering only work on their IaaS service and of course the details of their API need to be well known. Nonetheless, this is a welcomed addition to their cloud offering, and validates the current and future importance of easier-to-compose solutions for the cloud.

VI. Concluding Remarks

In this paper, we presented a modeling approach for DEVAs. First, we defined a metamodeling framework to be able to formulate two metamodels, one for RI-DEVAs, and the other for RD-DEVAs. We argued that RI-DEVAs are more desirable for describing cloud architectures, and that an automatic transformation between these two metamodels allows developers to specify DEVAs with quantifiable QoS constraints rather than

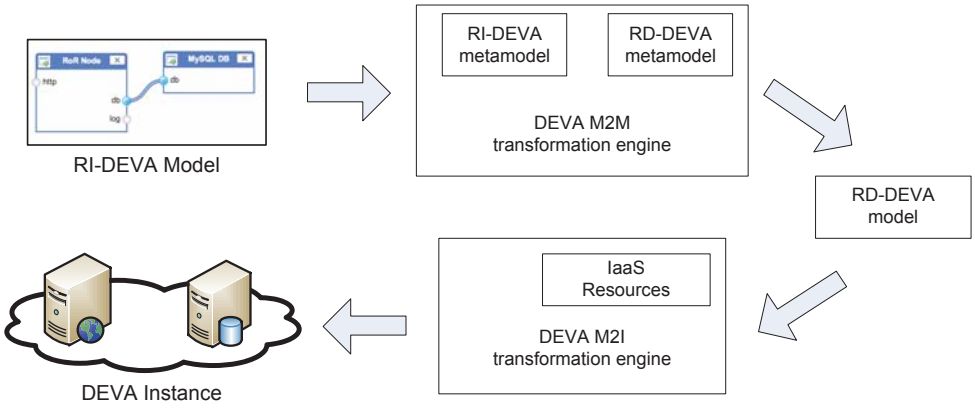


Fig. 6. Transforming DEVA models to DEVA instances.

by subjective performance metrics provided by current IaaS providers.

We then presented the details of our framework, by describing RI-DEVAs and RD-DEVAs with their abstract syntax and static semantics. We also described our key modeling abstraction, which consist of making service-to-service connections between Appliances, so that the architecture developer does not have to specify network level details. This abstraction aids in two ways: network level details may not be the developer's expertise area, and also its configuration can vary between different IaaS APIs.

We also presented how a system could implement our modeling approach, by describing the various stages needed to transform a RI-DEVA modeled by a developer to an actual instance in an IaaS Provider. Finally, a simple case study of how a typical web architecture could be modeled with our approach was discussed.

Designing solutions on top of IaaS providers is a growing problem domain in the cloud. A modeling approach such as the one presented can potentially make these architectures easy-to-compose and ready-to-use. We are in the process of prototyping a system that follows the details presented in Section IV. We are also investigating how to expand our approach to monitor and autonomically enforce Constraints and Policies of instantiated DEVAs.

ACKNOWLEDGMENT

We appreciate the discussions held with David Villegas. This work was supported in part by a GAANN Fellowship from the US Department of Education under P200A090061 and in part by the National Science Foundation under Grant No. OISE-0730065.

Towards Automated Conformance Checking of ebBP-ST Choreographies and Corresponding WS-BPEL Based Orchestrations

Matthias Geiger, Andreas Schönberger and Guido Wirtz

Abstract

Web Services technologies are a natural candidate for Business-to-Business integration (B2Bi). For cross-organizational processes, the concepts of "choreography" and "orchestration" are important. The term choreography denotes a model of a global view over message exchange scenarios, whereas the term orchestration focuses on models of the local implementation. While WS-BPEL is already kind of a de-facto standard in the field of orchestration languages, there does not exist a standard choreography language. We propose the usage of ebXML BPSS (ebBP) in order to provide choreography modeling at the business level. A frequent problem is to ensure and enforce the consistency and conformance of choreography and orchestration models which is often referred to as "conformance checking". In this paper we examine a way to check the conformance between ebBP-ST (a subset of ebBP) choreographies and corresponding WS-BPEL based implementations. To achieve this check well-known and approved model checking methods and tools are used: First ebBP-ST choreographies are directly transformed into the process algebra CCS. Second, the low level WS-BPEL processes are analyzed for code blocks that implement choreography elements and the sequence of these code blocks is then mapped to CCS, too. Afterwards these formalized representations will be checked for bisimulation equivalence in order to reveal inconsistencies between the choreography and their implementations.

Keywords: SOA, choreography, orchestration, conformance checking

1. Introduction

In the domain of Business-2-Business integration (B2Bi) Web Services technologies provide a suitable solution for integrating the cross-organizational business processes. As in B2Bi scenarios a global coordinator cannot be assumed, the distinction between choreographies and orchestrations is important: Choreographies define a process from a global perspective which may be seen as a communication contract between the integration partners involved. Orchestrations describe the local, executable implementation for each of the partners. In the B2Bi domain the *ebXML Business Process Specification Schema* (ebXML BPSS or ebBP; [8]) is a suitable choice for choreography modeling as it provides several features that are well-suited for the business domain. One core concept of ebBP is the usage of so-called *Business Transactions* (BTs) to model the exchange of a single business document from a sending to a receiving role - optionally followed by a response document and so-called *Business Signals* which notify the senders about the processing status of the exchanged documents. More complex scenarios composed of more document exchanges may be modeled as *Business Collaborations* (BCs). Within BCs, Business Transaction Activities (BTAs) are used to require the execution of BTs and to map BC roles to the roles of the previously defined BTs. The control flow and the ordering between BTAs is modeled in BCs using basic control flow constructs like *Transitions*, *Decisions*, *Forks* and *Joins*.

In [9], an ebBP dialect called ebBP-ST is presented to introduce explicitly modeled *Shared States* (STs) into ebBP choreographies which leads to clearer models in complex scenarios by providing control flow synchronization points.

In order to execute the choreography models defined in ebBP-ST, they have to be transformed into executable orchestrations. In the area of Web Services technologies the *Web Services Business Process Execution Language* (WS-BPEL; [7]) is the de-facto standard for realizing orchestrations which is also used in [9] to implement ebBP-ST choreographies.

For enabling executable orchestrations the integration architecture depicted in figure 1 is assumed between two partners A and B. These partners use backend components to

encapsulate business logic and control processes to enforce the correct sequence of message exchanges as defined in ebBP-ST choreographies. In this paper, we investigate automated conformance checking of WS-BPEL based control process implementations and ebBP-ST choreography definitions.

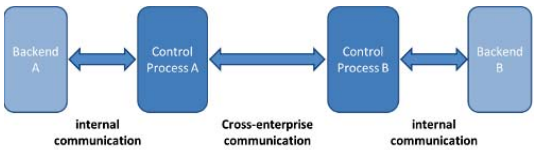

Figure 1. Integration Architecture (adapted from [9])

The paper proceeds as follows: First, in Sec. 2 a use case which serves as a running example is introduced. In section 3, the approach of checking ebBT-ST choreographies and WS-BPEL orchestrations is presented by clarifying which process models are supported, choosing a suitable conformance notion, introducing algorithms to transform ebBP-ST resp. WS-BPEL to the process algebra CCS [5], and describing the actual conformance check. The paper concludes with a discussion of related work and an outlook on ongoing research.

2. Use Case

Throughout the paper an excerpt of a purchasing use case between two partners shall be used to clarify the proposed approach. A visual representation of this ebBP-ST choreography is given in Fig. 2. The use case consists of three different STs and BTAs: The process starts with the ST "*initPurchase*" in which the BTA "*requestQuote*" has to be performed. This BTA defines the exchange of a business document containing a quote request. In the subsequent decision it is checked whether the request could be successfully transfered to the receiver ("*BusinessSuccess*") or not ("*TechnicalFailure*"). In case of a "*TechnicalFailure*", the current ST "*initPurchase*" is not left and the BTA has to be repeated. Otherwise, if the result is "*BusinessSuccess*" the process enters the new ST "*receivedQuote*".

When a quote has been received successfully it may be accepted by a corresponding BTA "*acceptQuote*" which leads to another ST "*concludedContract*" in case this BTA finished with a "*BusinessSuccess*", otherwise the BTA shall be repeated. The other option in ST "*receivedQuote*" is to request another quote by performing the BTA "*requestQuote*" again. The decision afterwards evaluates whether the BTA has been executed successfully or not. Here in both cases the process will be resumed in ST "*receivedQuote*". The difference between both paths is that the ST shall not be left in case the BTA finished with a "*TechnicalFailure*", i.e., the timer defined for the BTA shall not be reset, but shall be reentered with resetting the timer in case of a "*BusinessSuccess*". Note that this fact is not respected in the visualization of the use case in Fig. 2. The last aspect to consider is that a ST may be left by a timeout event. Here, a timeout occuring in ST "*initPurchase*" and "*receivedQuote*" will terminate the process in the end state "*TechnicalFailure*". The further progress of the purchase scenario, e.g., shipment and billing is left out here.

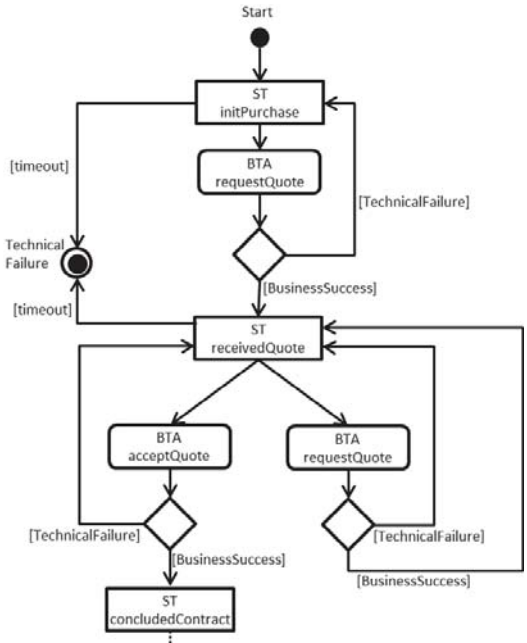

Figure 2. ebBP Structure of the Use Case

3. Conformance Checking ebBP and WS-BPEL

Figure 3 gives a brief overview of the proposed conformance checking approach: First, the given ebBP-ST choreography model and the corresponding WS-BPEL orchestrations which should be checked have to be transformed into a common formal representation. The process algebra CCS is appropriate for the scope of our analysis. After transforming ebBP resp. WS-BPEL into CCS models, the orchestration CCS models can be checked for conformance to the choreography model successively. As conformance is seen as a binary decision in our work, the conformance check returns whether the checked orchestration model conforms to the choreography specification or not.

3.1. Supported Process Definitions

Before describing the approach of checking the conformance between ebBP and WS-BPEL it has to be clarified which kind of processes are supported. As mentioned in the previous section, ebBP-ST models are used to model ebBP

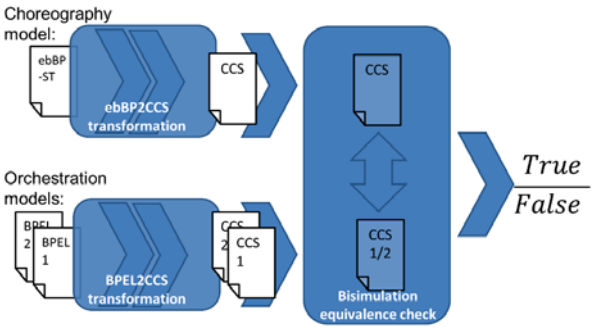

Figure 3. Proposed Approach (Overview)

choreographies. Our approach supports arbitrary ebBP-ST models which are valid regarding the formal definitions and rules for well-formedness in [9]: ebBP-ST models may be formalized as a 5-tuple (R, N, G, ϕ, θ) where R is a set of participants, N is a set of allowed ebBP nodes, G is a set of guards, ϕ is a function that assigns timeouts to each ST and θ is a transition relation which defines all allowed transitions. The set of nodes $N = \{s_0\} \cup ST \cup SBTA \cup DEC \cup T$ contains the ebBP concepts of a starting node, shared states, business transaction activities, decisions and end states which are used to model choreographies. Some important restrictions of ebBP-ST models are that only binary collaborations are supported, ebBP Forks and Joins are not allowed and STs may not overlap. The introduced use case is an example of a rather simple, well-formed model which uses all main aspects of ebBP-ST.

While a formal model of ebBP-ST and its semantics, is given in [9], such a formalization is not provided for the corresponding WS-BPEL implementations. There exist various formalisms for WS-BPEL (see [10]) but all of them are intended to directly formalize low level WS-BPEL language constructs, which would create much too detailed models for our use cases as we are only interested in a formal representation of the control flow between WS-BPEL patterns that realize ebBP choreography concepts. For this purpose the ebBP formalization is adapted to the WS-BPEL realizations: With respect to the set of nodes N it is obvious that all of these aspects have to be represented in WS-BPEL. Concepts such as BTAs may not be directly mapped to WS-BPEL but need to be expressed by more complex combinations of various elements. Possible WS-BPEL patterns to implement a given ebBP-ST choreography are also introduced in [9].

3.2. Conformance Notion - Why Bisimulation?

Conformance checking is not a new problem in the field of Web Services technologies, in fact, conformance checking techniques have been proposed for various combinations of choreography and orchestration languages. But as the notion of conformance is highly dependent on the context there does not exist a commonly accepted definition of the term conformance. A straightforward informal definition is: *An orchestration should be declared as conform to a choreography if all orchestration executions do not violate the predefined protocol.* As conformance checking problems are a specialization of the widely researched process equivalence problem, solutions from this domain can be used in order to specify the conformance notion more precisely. When looking at the message level, it is widely accepted that so-called *trace equivalence* which only analyzes the flow of exchanged messages is too weak to check conformance (e.g., [4]). *Bisimulation equivalence* [6], as another classical process equivalence notion, frequently is regarded as too strict for conformance checks. In most of the related work, the conformance notion distinguishes between incoming and outgoing message flows. An orchestration has to respect all incoming messages in order to be conform to the choreography. In case of outgoing communication, at least one (of possibly more) alternatives has to be implemented in the orchestration. An example is the ST "*receivedQuote*" in our use case, as two different BTAs ("*acceptQuote*" and "*requestQuote*") may be initiated by the potential customer here. The customer does not have to implement the possibility of performing the BTA "*requestQuote*" which means that he always performs "*acceptQuote*" and therefore all quotes have to be accepted (or the process is left by a timeout). Conversely the seller has to implement both execution possibilities as from his viewpoint it is not clear which BTA may be performed next.

However, for our conformance checking scenarios this conformance notion is not suitable as it cannot be applied to our integration architecture: We differentiate between the actual orchestration implementations in the so-called control processes and the existing backend systems that encapsulate business logic. Regarding the incoming information the already proposed conformance condition is not critical: The control processes must be able to react to all possible incoming events as they do not know how the partner will react. But the less strict requirements for outgoing information are only possible if the orchestration is directly deciding which steps should be performed next. In our architecture (cf. Fig. 1), the control processes delegate this decision to the backend systems which trigger the subsequent process flow. So, the control processes must be able to react to all possible backend decisions and must also be able to produce all allowed outgoing communication specified in the choreography. Therefore the conformance requires the rather strict notion of *weak bisimulation equivalence*.

The formal model used to perform conformance checks is the process algebra *Calculus of Communicating Systems* (CCS) developed by Milner [5]. For our purposes, the main aspects of CCS are sufficient to express our integration models: Processes (starting with a capital letter) are defined by an assignment. Linking to processes is done by

using the name of a predefined process in a process body. Sequences are built using the "." operator and choices may be created with the operator "+". Therefore, e.g., "`P1 = action1.((action2.P2)+(action3.P3))`" defines the process `P1` in which after performing action "`action1`" either "`action2`" is performed followed by the execution of the process "`P2`" or "`P3`" is performed after "`action3`".

3.3. ebBP-ST to CCS Transformation

The basic principle of transforming an ebBP-ST choreography model into a CCS representation is to define a CCS process for each ST and each end state used in the choreography whereas timeout events, the execution of BTAs and their evaluation in decisions will be represented by CCS actions. Algorithm 1 shows the concrete steps needed in order to transform ebBP-ST choreographies to CCS.

As shown in line 1-3, for each end state $t \in T$ a process is defined using the prefix "`END_`" followed by the name of the state. The process body simply contains a single action named by the corresponding end state in order to distinguish different end states and the CCS *empty* element "`0`". The actual creation of the process is performed by the method `CreateProcess(`*`processName`*`,` *`processBody`*`)` which creates a CCS process with the name *`processName`* containing the *`processBody`*.

In comparison to this, the transformation rules for STs are much more complex: As described before and in [9] a timer should be started when entering a ST. But it also should be possible to reenter an already visited ST without resetting this timer. In order to describe this behavioral difference, two different CCS processes for each shared state are created. An outer process definition "`ST_`*`STname`*" simply performs a `start_timer` action and then links to an inner process definition (named "`INNER_ST_`*`STname`*") which contains the actual control flow logic (stored in variable `processBody`) of a shared state (ll. 28/29, Alg. 1).

BTAs, Decisions and Timeouts are realized in CCS using actions. Therefore each possible BTA in each ST followed by the decision evaluation is added to the ST process body (Alg. 1, line 20) using the method `AddBTA(`*`processBody`*`,` *`btaToAdd`*`)` which combines the allowed BTAs with the "+" operator. BTAs are simply mapped by a single CCS action named like the BTA sequentially followed by the decision. The different decision branches are realized using the CCS choice operator ("+"): First, each guard is translated to a CCS action followed by a link to the CCS process of the subsequent ST and afterwards all of these constructs are combined using the `AddDec` method. A flag f indicates whether a timeout should be reset or not: If $f == \{tt\}$ (l.10) the outer process definition will be used, otherwise it will be linked to the inner process definition of the subsequent ST.

Applying the algorithm to our use case will clarify the output of the algorithm which is presented in listing 1: Line 1 shows the outer process definition "`ST_receivedQuote`", the following lines 2-11 describe the actual control flow logic: The two BTAs allowed and the timeout event are combined as a CCS choice. The execution of a BTA is represented by a CCS action (e.g., "`bta_requestQuote`" in line 7). The decision after this BTA evaluates whether the BTA has been a "*BusinessSuccess*" (BS) or a "*TechnicalFailure*". If the BTA was successful the ST "*receivedQuote*" should be reentered and the timer should be reset. Therefore the referenced CCS process is "`ST_receivedQuote`" (line 9 in List. 1). As the timer should not be reset in case of a "*TechnicalFailure*", the internal process definition "`INNER_ST_receivedQuote`" is referenced in line 8.

The other STs in the use case are transformed in the same way.

Listing 1. CCS Representation of the Use Case (Excerpt)

```
1  ST_receivedQuote = start_timer.INNER_ST_receivedQuote
2  INNER_ST_receivedQuote =
3  (bta_acceptQuote.(
4    (dec_acceptQuote_TF.INNER_ST_receivedQuote)+
5    (dec_acceptQuote_BS.ST_concludedContract)
6    )
7  )+(bta_requestQuote.(
8    (dec_requestQuote_TF.INNER_ST_receivedQuote)+
9    (dec_requestQuote_BS.ST_receivedQuote)
10   )
11 )+(timeout.END_TechnicalFailure)
```

3.4. WS-BPEL to CCS Transformation

The aim of transforming WS-BPEL to CCS is to check whether the WS-BPEL implementations conform to the predefined ebBP-ST choreography models. As mentioned before, we are not interested in low-level formal models but in a representation which allows for this check. For example, there is no need to model the concrete implementation of a BTA including all WS-BPEL *sequences*, *scopes*, *invokes*, etc. in CCS because for our purposes it is only relevant whether a BTA may be performed in a ST or not. So, the most important task for transforming WS-BPEL to CCS is to detect the used patterns which express the different concepts of ebBP and afterwards transforming the sequence of patterns into CCS. When looking at an ebBP *decision*, a possible WS-BPEL implementation pattern may send the previously exchanged *Business Document* to the backend systems (*invoke* statement) which analyze the outcome and the result is stored in a variable (*assign*). Afterwards in a

Algorithm 1: ebBP to CCS Transformation

Input: A valid ebBP-ST choreography $(R, (\{s_0\} \cup ST \cup SBTA \cup DEC \cup T), G, \phi, \theta)$ to be transformed
Output: A CCS representation of this choreography
Algorithm:

```
1  foreach t in T do
2  |  CreateProcess("END_" + t.name, "end_"+t.name+".0")
3  end
4  foreach st in ST do
5  |  processBody = " ";
6  |  foreach (st, {tt}, bta) in θ do
7  |  |  decisions = " ";
8  |  |  foreach (bta, {tt}, dec) in θ do
9  |  |  |  foreach (dec, g, f, nextST) in θ do
10 |  |  |  |  if (f == {tt}) then
11 |  |  |  |  |  AddDec(decisions, "(dec_"+dec.name+"_"+g.name+".ST_"+nextST.name+")")
12 |  |  |  |  else
13 |  |  |  |  |  AddDec(decisions, "(dec_"+dec.name+"_"+g.name+".INNER_ST_"+nextST.name+")")
14 |  |  |  |  end
15 |  |  |  end
16 |  |  |  foreach (dec, g, t) in θ do
17 |  |  |  |  AddDec(decisions, "(dec_"+dec.name+"_"+g.name+".END_"+t.name+")")
18 |  |  |  end
19 |  |  end
20 |  |  AddBTA(processBody, "(bta_"+bta.name+".("+decision+"))")
21 |  end
22 |  if ∃(st, g^to, nextST) in θ then
23 |  |  processBody += "+(timeout.ST_"+nextST.name+")"
24 |  end
25 |  if ∃(st, g^to, t) in θ then
26 |  |  processBody += "+(timeout.END_"+t.name+")"
27 |  end
28 |  CreateProcess("ST_"+st.name, "start_timer.INNER_ST"+st.name)
29 |  CreateProcess("INNER_ST_"+st.name, processBody)
30 end
31 CreateProcess("Start", "ST_"+firstST.name)
```

series of *if* statements it is checked which result has been evaluated and the switch to the next state is initiated.

After all such patterns and their ordering have been identified, the transformation to CCS is similar as for ebBP-ST. In case of the decision example, each decision branch is transformed to a CCS sequence, containing an action indicating the decision, followed by a reference to the CCS process of the next state.

3.5. Checking the Conformance

After transforming the ebBP-ST choreography model and the two corresponding WS-BPEL orchestrations to CCS, the actual conformance checks can be performed. Therefore each CCS orchestration model has to be checked against the choreography representation for bisimulation equivalence. The result of each bisimulation equivalence check is (see Fig. 3) the binary answer whether an orchestration is conform to the choreography definition or not.

An advantage of this checking approach is that the two different implementations may be analyzed independently, i.e., it is not necessary to analyze the implementation of a partner who possibly does not want to publish his internal orchestration models.

Note that CCS is supported by various model checking tools (e.g. the *Edinburgh Concurrency Workbench* (CWB)[1])

[1] available at: `http://homepages.inf.ed.ac.uk/perdita/cwb/`

and therefore the check can be automatically executed using such a tool. Using the proposed CWB model checker we are able to prove the conformance of the WS-BPEL implementations as well as to detect various intentionally produced faults in orchestrations.

4. Related Work

Conformance checking problems have been investigated for various choreography and orchestration languages:

For example the work of Baldoni et al. (i.a.,[1]) is rather generic and uses automata representations to model choreographies and orchestrations. Martens ([4]) discusses rather extensively suitable conformance notions for conformance checking problems and proposes a formalization of abstract and executable WS-BPEL processes using Petri Nets. A proposal for the *Web Services Choreography Description Language* (WS-CDL) has been developed by Foster et al. ([3]) who use *Finite State Processes* (FSP) to represent WS-CDL and WS-BPEL. The actual check is based on *trace equivalence*. The only work that we are aware of which is dealing with conformance checking ebBP and WS-BPEL is [12] which uses the process algebra *Communicating Sequential Processes* (CSP) to perform so-called traces refinement to check the conformance. The common problem of all these approaches is that they do not use the strict conformance notion we propose in this work. As we have shown above the proposed weaker notions are suitable for the contexts considered in the various papers, but it is not appropriate for the integration scenario we assume.

Another approach which uses a stricter conformance notion when checking WS-CDL choreographies is presented in [11]: The authors derive a new formalism called piX-Model to formally represent WS-CDL choreographies. The piX-Model is based on the well-known π-calculus and open bisimulation is used as conformance notion.

Apart from conformance checking there exist various approaches to formalize WS-BPEL (see [10] for an overview). A WS-BPEL formalization using CCS is presented in [2]. Generally these formalizations are not perfectly suitable for our approach because they provide direct mappings for basic WS-BPEL constructs while we concentrate on those patterns that realize ebBP concepts.

5. Conclusion and Future Work

In this paper, we have introduced an approach for checking the conformance between ebBT-ST choreographies and corresponding WS-BPEL based orchestrations. The key elements of this approach are the proposed transformation algorithms to CCS which allow for a common representation of ebBP-ST and WS-BPEL in order to perform the actual conformance check by a bisimulation equivalence check. Preliminary results show the general applicability and correctness of our approach.

Ongoing research now concentrates on relaxing the requirements concerning the structure of the WS-BPEL processes by using existing WS-BPEL semantics. Furthermore we are working on better usability, such as integrating the proposed tool chain to improve the work flow and direct highlighting of detected conformance issues in the original ebBP-ST and WS-BPEL definitions.

Abstract

In the service business, event correlation systems are used to predict and avoid system failures. Strategically, this may contribute to higher system availability and better service activity planning. Companies that want to benefit from this competitive advantage often meet two fundamental problems: the complexity of service monitoring increases with the number of correlation patterns. At the same time, the cost transparency for the whole process is lost. This paper shows on a business process level why these problems arise and how they can be avoided.

Keywords: *Service Management, Event Management, Event Correlation, Predictive Maintenance*

I. INTRODUCTION

Manufacturers of hardware systems are often faced with enormous cost pressure. In some industrial sectors, the profit achieved by selling the hardware device itself becomes very limited. In this case, a value-adding service organization may help to differentiate from others. An important efficiency criterion of a service organization is the degree of automation in the case of a system failure. In this context, a change is happening in many industrial domains: *reactive* service or "waiting for the failure" is no longer seen as an adequate support by customers. By using event correlation systems, it is possible to make *predictive* statements about imminent system failures. By predictability, failures can be prevented (*predictive/preventive maintenance*). This may contribute to higher customer satisfaction. At the same time, additional customer-specific contract options may be set up, such as an agreement of a guaranteed system availability level. The possibility to plan service activities may increase, which implies a positive impact on personnel costs and material costs. At best, predictable system failures can be handled within the standard planning processes. However, the use of complex failure patterns/correlations may cause high development costs. This challenge can be faced on a technical level by automization for example by using data mining systems and machine learning methods [1]. In the long run the uncontrolled creation of a huge set of failure patterns may cause problems by increasing complexity of configuration, deployment and execution. With increasing handling, the pattern efficiency control gets harder. Thus, many companies are faced with the question: how do we have to structure our operational service processes to handle these problems?

II. SERVICE MANAGEMENT

It is possible to investigate a service management system from two different views. On the one hand, the system consists of business management targets. The "top-down" view which is deduced from the business core tasks and the definition resulting from the value-adding business processes is called *business service management* [2]. On the other hand, there exists a "bottom-up" IT-view on a service management system. From this perspective, the formal goal of a service management system is providing the right services for the business. Those services may be combined in IT Service Level Agreements. On a process level, adequate IT processes have to be defined. To certify an efficient service organization, the regulation ISO/IEC-20000 was created. It is divided in two parts. While part 1 defines service management basics, the second part proposes structures which should be used in service management organizations [2]. The requirements which are derived from ISO 20000 can be implemented using the IT Infrastructure Library (ITIL). Both methods are based on the British standard BS15000 and for this reason, most ISO 20000 definitions may be found in the ITIL framework, too. ITIL was created by the English Office of Governance Commerce (OGC) as a collection of "good practices" to ensure an efficient IT structure. This definition implies that its basics are not derived scientifically. In fact, ITIL proposes one way how to structure service processes. There exist similar approaches like COBIT [3], MOF [4] eTOM [5]. The basic idea is to create an IT organization which acts as a uniform interface between customers and the company sectors IT development and operation. Therefore, ITIL defines a generic process model, which includes the major service processes. ITIL is structured in a lifecycle model in the core sectors service strategy, service design, service transition and service operation [6]. Additionally, the idea of continual service improvement was introduced in the actual ITIL version V3. Service Strategy includes processes for strategic planning of an efficient IT organization. In detail, this sector consists of

the processes financial planning, portfolio planning and demand management. Service design and service transition primarily handle the development and roll-out of new services. On the design level, service managers arrange Service Level Agreements (SLAs) with customers. To keep these agreements, capacity, security and suppliers has to be managed. New IT services are brought into the field by transition processes like application development, change management, release and deployment and testing. Service operation deals with services which are already used. ITIL defines event management, incident management, problem management, request management and access management. In the following, this paper takes a closer look of what events, incidents and problems may look like and how they fit together.

A. Event Management

An *event* is a change of state of an object which has significance for the service. Event management is the activity of observing objects, identifying such events and categorizing them [10]. Usually, an event management process is used to implement a remote monitoring service, which could be reactive and/or proactive. The architecture of event management platforms is usually based on the manager-agent-model [7]. A manager takes the role of a central distributor/collector's node. On each connected device ("managed node"), a software agent is installed. The agents receive tasks and send information on the device status and the workflow to the manager. Historically, the idea of event management can be tracked to the first approaches of remote monitoring of network devices [8]. Over time, the networks sector became bigger and more complex. Also, the remote monitoring service was expanded. To structure the growing complexity, literature differentiates between the management levels component management, system management, application and enterprise management [9]. *Component management* refers mainly to the handling of network components, i.e. routers or switches. *System management* focuses on more complex nodes with a set of several sub-components. System management organizes single distributed functions. Thus from an outside view the systems behave like one (virtual) system [9]. For service, the component set is considered as an integrated system where a single failure may no longer depend on one single component, but also on a complex connection between several components. If the component set is based on software functions, the level *application management* may be separated [9].

The event management definition assumes that events are created in a continual process. Event management agents have to read these events (event detection) and to filter and categorize in simple groups. For example, ITIL suggest errors, warnings and informational events. In many cases, the total amount of events is rather big; therefore, a manual analysis by humans is usually not possible or (economically) not reasonable because of complexity. For this reason, event correlation systems are used.

Event correlation systems use logical, temporal and statistical functions to model semantic connections between events. By aggregating a set of events, one new event may be created containing a better information quality. This reduces the effort for (human) analysts. The reference process defines a trigger mechanism to escalate critical events. The alarm is handled in the incident management process. Before the event is being discarded, the service organization may start an event review to assure the correctness and the efficiency of correlation patterns. The following figure shows the activities of the ITIL reference process event management.

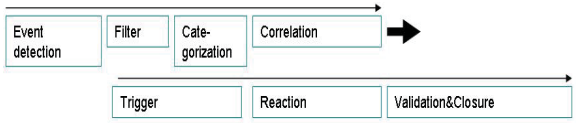

Figure 1. event management activities, according to [6]

B. Incident Management

An *incident* is an unplanned failure or quality reduction of a service. Incidents are handled in a incident management process. They may be identified in several ways, i.e. by customer information, a service engineer's report or via the event management process. According to ITIL, incidents may be handled by a service desk. This function acts as a single point of contact to the customer. Usually, the incident management uses a ticketing system. One important task is the categorization by impact and urgency. Urgent incidents with high impact are marked as "*major incidents*". In this context, the roles first, second and third level support are proposed: if a ticket cannot be solved quickly by a first level diagnosis, it may be escalated to a second level, where better a qualified service team will try to solve the problem. If the second level fails, the problem may be forwarded to a third level expert team. The incident management is usually controlled to ensure that all SLA requirements are kept in time. The following figure shows the activities of the ITIL reference process incident management.

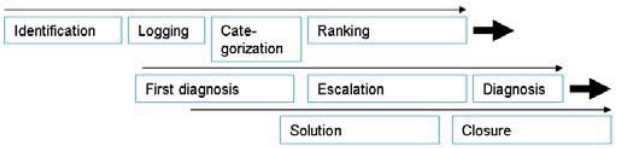

Figure 2. incident management activities, according to [6]

C. Problem Management

A *problem* defines an unwanted situation which is considered as trigger for one or more (active or potential) incidents. A problem causes at least one incident. If the root cause of a problem is known, the problem is called *known error* [11]. The focus of incident management is primarily set on the elimination of actual failure symptoms. Instead, problem management is focussed on finding a final solution which removes the root cause of all problem-related incidents. In comparison to incident management, it does not depend on a rigid, customer-specific time plan. The problem management process structure resembles to incident management. Once a problem was defined, categorized and prioritized, a workaround may be defined which tells the incident management team how to act on upcoming incidents.

Identify applicable sponsor/s here *(sponsors).*

Additionally, the problem is stored in the *known error database*. The problem is closed when a final solution is provided as a result of a *request for change*. Problem management can be handled in a reactive and a proactive way. *Reactive* problem management starts after a set of incidents occurred. A *proactive* problem investigation uses operative service data sources and generates analyses and reports to minimize the impact of potential future problems. Beside the incident records, event management may be an important source and tool for proactive problem management. If a problem is detected early, a *workaround* may be defined. This workaround could i.e. be an event pattern, which indicates an upcoming incident based on that specific problem. By this means, an incident may be prevented or its impact may be minimized. The following figure shows the activities of the ITIL reference process problem management.

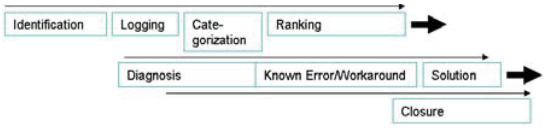

Figure 3. problem management process, according to [6]

The ITIL framework is originally meant to be an IT service approach. However, incident management and problem management are generic processes. Moreover, event management is usually done as a remote service, which is a distinct IT product. Thus, the ITIL framework is also applicable outside of the plain IT business.

III. CASE STUDY - MEDICAL DEVICE SERVICE

To give an idea to how the processes of event management, incident management and problem management can be linked together, we present a case study which focuses on a sample of the actual structure of a service organization which sells medical devices and associated remote services. The case study focuses on the three service operation processes described above.

The service organization is a provider of various products in the field of medical technology. The product range includes imaging systems from different modalities, such as nuclear medicine, computed tomography, magnetic resonance imaging, angiography and ultrasound. In most cases, the systems are complex and service-intensive objects. The healthcare service organization structure implements the service operation processes event management, incident management and problem management.

A. Event Management

The organization uses a management platform (Common Platform Remote Service Platform *cRSP*) to provide a set of IT services, such as *software distribution*, *inventory management* and *event monitoring*. The event monitoring service implements the event management process and includes among other components the software as HP OpenView Operations (HP OVO). HP OVO provides an event agent which reads events from different data sources and filters them by special rules (*policies*). For event correlation, HP OVO provides three mechanisms. On the one hand policies can be used to generate simple event correlations. Additionally, the Event Correlation Services (ECS) Composer and Event Correlation Services (ECS) Designer may be used to perform complex correlations. ECS Designer correlations are known as *circuits*. In comparison to ECS Designer, ECS Composer offers limited functionality for event correlation [12]. The HP OVO Event Agent is able to send alerts/messages to a back-end HP OVO Event Management Server. There, the alerts can be monitored by device experts in a Regional Support Center (*RSC*) using HP OVO Java Console.

B. Incident Management

Incidents may be created based on a customer notification. In this case, the service organization acts reactive, since such measures can be initiated only after the perception of the issue by the customer. Reactive messages are processed by a service desk team called Uptime Service Center (*USC*). To perform a classification, the current situation is pre-clarified by device experts or solved via cRSP remote access. If it is not possible to solve the problem in a given time frame, the Regional Support Center (*RSC*) and Headquarter Support Center (*HSC*) are being involved as second and third level support. If necessary, a service technician is being sent. Incidents are solved and completed by the USC. The service organization acts *proactively* if incidents are reported before they are found by the customer. Proactive tickets can be generated using event correlation patterns. The RSC provides a monitoring team that checks the incoming messages and evaluates them. If onsite actions are necessary, the RSC forwards this information to the USC which dispatches a service engineer. Proactive tickets are closed by the RSC. Alarms, which indicate an upcoming system failure with high confidence, will automatically generate a new incident.

C. Problem Management

The service organization offers a variety of different products. To analyze the associated problems, domain knowledge is necessary. Therefore, the function-oriented organization structure is replaced by an object-oriented modality organization. In order to present a consistent case study, we refer to one of the modalities.

To investigate the root causes of frequently recurring incidents, information from the operative business processes is obtained from a data warehouse system. In addition, workflow data from the devices and from spare part logistics are included. Personnel and material expenses are compared with respect to various temporal, geographic, systems and customer-specific characteristics. There exists a set of criteria to decide whether to open a problem ticket or not, including equipment availability, degree of market introduction, effort and cost criteria. When a new problem ticket is being opened, an activity plan is being developed, resulting in a final problem solution. In many cases, additional organizational units are being involved, such as the product development. The problem management is organizationally separated from the incident management and is therefore not subject to downtime-based time-limits. However, there may exist strict time limits in the problem management, especially when a product when new products are introduced to the market.

IV. A PROPOSOAL FOR INTEGRATING EVENT CORRELATION SYSTEMS INTO PROACTIVE PROBLEM MANAGEMENT

ITIL does not make an explicit statement on how the interaction of event management, incident management and problem management has to be organized, as this depends substantially on internal structure of each service organization and on external conditions. If the organization's processes are not coupled properly, two problems in the event management process may arise.

- *Complexity problem*

The more correlation patterns are generated, the higher is the cost handling, maintaining, improving them. This increases the total costs of the event management process. The more correlation patterns exist, the more messages are generated on the management server. This makes the monitoring task more difficult and therefore, the system may come to a point where an appropriate in-time reaction is no longer possible.

- *Transparency problem - missing business case*

Another problem arises when correlation patterns are created which cannot be associated with a particular issue. Such correlations may support the incident management in a short-term manner. However, it may become hardly possible to set up a cost and efficiency controlling mechanism. Thus, the added value of the monitoring service can hardly be calculated and the event management is in a permanent need for justification.

A. Problem identification and categorization

The goal of the following approach is trying to prevent the emergence of these problems or at least minimize their impact by integrating incident management, problem management and event management. The approach should be perceived as a best-practice-proposal for *one* possible connection of the three processes and does not exclude other solutions or existing approaches. The basic idea is to introduce proactive problem management based on event correlations. In particular, major incidents (system failures) shall be avoided which lead to high service costs. First, a problem ticket has to be opened, based on existing, historical data. As a basis for an analysis, the number of incidents within a specific time frame may be used. The incidents should be grouped by their associated material data. To identify material defects as root causes for this group of incidents it is reasonable to include the spare part consumption data in this analysis. By doing so, a filter mechanism may be created which groups only homogenous material problems. This approach presumes that incidents have been created and categorized properly. Similarly, the spare parts consumption has to be recorded. Defective parts need to be investigated in case of service in order to determine the underlying material defect. Wherever it is possible, new incidents are assigned to previously identified problems. With this connection, patterns may be identified easier; moreover, the information can be used in a problem management controlling.

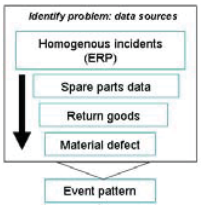

Figure 4. *Pattern identification based on material problem*

B. Problemprioritization

By referring a problem ticket to a material defect, an individual cost analysis can be done for each pattern. Therefore the mean emergency extra charge of service organization has to be identified. Extra costs for device failures include for example additonal personnel costs, emergency spare part logistics costs, the cost of consequential damages or penalties for not reaching a certain service level. By linking the extra charges costs for one failure with historical incident data, the potential savings may be extrapolated (assuming an equal number of service calls in period t and t +1).

- Potential savings = number of incidents (based on the same defect) * mean emergency extra charges

Since the approach relates to imminent device failures, the number of incidents may also be used for the calculation of additional usage time (uptime). By preventing a system failure the customer saves the time for the restoration of service, therefore, the incidents of a period may be set in a relation to the average time to resolve an incident (Mean Time to Restore Service, MTRS), which is basically:

- Potential additional uptime = Number of incidents (based on the same defect) * mean time to restore service

Based on this cost analysis, the problem tickets may be prioritized. Assuming that the number of material defects in t1 is equal to the number of material defects in the incidents of the period t0, the incidents of t0 are analyzed. The ranking may relate to the quality improvement (the increase of potential savings). If product quality is used instead, the potential uptime may be used as decision criterion. If both goals are important to the service management, a pareto-optimized decision may be used. The following table shows an example.

Materialdefekte	Anzahl Incidents Periode t_0	Einsparungspotenzial (EUR)	Uptime-Potenzial (Stunden)
Defekt A	152	325.000	2200
Defekt B	86	254.000	1900
Defekt C	32	175.000	700
Defekt D	32	173.000	750

Figure 5. Problem ranking based on potential cost savings from a previous period.

The transparency provides several advantages. The prevention of failures and the uptime potential may contribute to higher customer satisfaction. The improvement in quality of service enables the organization to create new service level agreements, based on a guaranteed uptime level. Therefore it is necessary to prevent a majority of the defects with high uptime potential through proactive correlations. At the same time, unprofitable correlation patterns are excluded already in the planning phase. The effort for pattern creation can be set into

relation to the potential cost savings, so the event management process may be perceived as a value-adding service.

C. Problem diagnosis and workaround

By referring a problem ticket to a (hardware-based) material defect patterns may be identified and future system failures may be predicted. In this sense, a pattern is part of the proactive service strategy. For problem management, the pattern serves as a workaround to an impending major incident. It is therefore not to be regarded as a solution to the problem because the actual cause of the incident is not affected. By defining a pattern as workaround, its usage is limited in time. The solution of the problem itself- and the replacement of the work-around - is the improvement of the material or the introduction of an improved component version. To use these workarounds, patterns have to be identified first. As we have already shown in [13], the pattern identification process may be standardized and supported by data mining tools. A prerequisite is that a certain material defect shows up in the same manner in the event data. The data analysis bases on the deviation between failure data compared to normal operation data of the device. Besides counting single events, those events that occur exclusively or more frequent in the case of failure are connected to sequences ("*semantic block*s") and used as part of an event correlation. Additionally, sensor data may be used. If an abnormal situation has been detected, the event correlation system raises an alert. Further follow-up actions, such as automatic incident generation can be performed. The activities incident logging, categorization, ranking and initial diagnosis can be automated in many cases, because it the expected failure is already known (by pattern definition). Since the event correlation indicates a specific defect, it is possible to start product-specific actions, such as staff planning spare parts ordering.

D. Problem solution

The actual problem solving addresses the cause of the defect and is not part of the incident and event management process. The problem ticket is closed if the solution was rolled out to all service objects. With the closure of the problem tickets, the event correlation is obsolete as a workaround and can be removed from the event correlation system. The efficiency of event correlations can be controlled. As a prerequisite, the incident tickets have to be linked to the corresponding problems.

- Event correlation efficiency = number of incidents proactively processed / number of total incidents (related to the incidents that have been associated with this problem in context)

By using temporary event correlations and controlling mechanisms it is possible to prevent a steady increase of the total correlation set. Thus, a lack of transparency and complexity can be avoided.

V. CASE STUDY - USING PROBLEM-BASED EVENT CORRELATIONS IN MEDICAL DEVICE SERVICE

In the service organization, event correlation patterns are defined by the serviceability group. The pattern development is mostly based on product specifications that are given by product development. For example, error messages for certain components are defined by external suppliers and integrated into event correlation in the form of simple correlation rules. Other correlations are based on empirical knowledge. For that, single incidents are analyzed. Error messages that may be associated with the incidents are summarized in event correlations. The service organization is using some statistical methods to assess the performance of new event correlations before they are used. In a few cases, event correlations are generated based on problem tickets. On the whole, the organization produces a growing number of event correlation patterns. Without a consistent efficiency controlling mechanism, this leads to growing complexity of the correlation set. From a cost perspective, there may occur the risk that the event management process is questioned, if the overall process costs get to high. By introducing the problem-based event management approach, this risk could be reduced. By reducing the number of patterns, the costs for implementation, distribution and operation may be kept as low as possible. This effect may be intensified by a better efficiency controlling. By bringing the data from actually performed service calls together with the number of associated alert messages, a sensitivity and specificity rate of each individual pattern can be determined. The problem-impact may serve as a basis for the importance of event correlation.

Example: within the period 2008 - 2009 a part of the organization reported 119 incidents. These incidents are caused by one specific device problem. Assuming that a correlation pattern would have detected 70% of these incidents proactively, 83 cases would have been predictable. For this specific problem type, three important cost drivers were identified, that is cost of emergency orders, personnel costs and costs for operations with multiple onsite presence.If the pattern would have been used in the given time period, this would have led to cost savings of approximately 24,500 €. It is possible to extrapolate this potential for worldwide use, assuming a constant or increasing incident frequency in the future. This calculation is the basic motivation for the development of an event correlation. Besides the cost analysis, the device downtime has to be considered. For this purpose, the mean time to restart (mean time to recover) is calculated for this use case and multiplied by the total number of failures. If the solution of a problem requires onsite technical service and / or material usage, the problem is often a medium or long term issue, because the changes have to be rolled out to all devices in the field. Therefore, the product support team may set a workaround (a correlation pattern) which is available faster. The involved incident teams USC, RSC and HSC take advantage of such patterns in several ways. First, proactive alerts may lead to higher device availability, so unplanned service activities may be reduced, which improves the planning and dispatch of service engineers. The organization may provide detailed handling options, because they know which defect is about to occur. Depending on the classification

precision of the pattern, the incident management process activities *identification, logging, categorization, ranking, first diagnosis and escalation may be automated, as the figure below shows*. The diagnosis itself tries to confirm the pattern-based failure expectation and follows the given handling options.

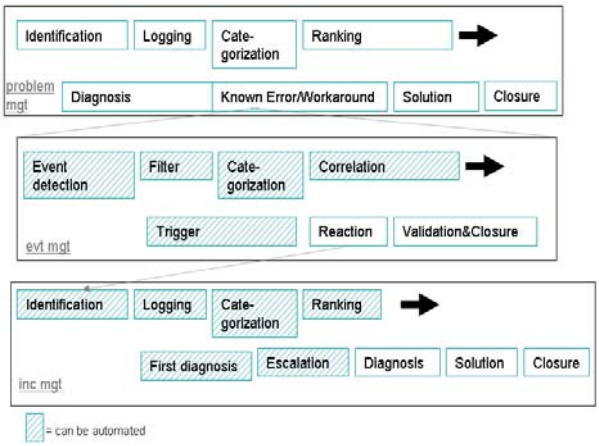

Figure 6. Proposed process structure. Evt. correlation as workaround

The introduction of problem-based event correlations may have a positive impact on a number of service-relevant indicators. By partial automation of incident management, the cost of troubleshooting for proactively detected incidents (Mean Time To Repair, MTTR). By clear description of the fault service calls can be reduced, fixed by the First Visit Rate (FVFR), or the relative number of successful one-off operations can be measured. In the best case, and the index Site Visit Avoidance (SVA) will be positively impacted by an increase of cRSP Remote Access operations. From the perspective of the customer results from the use of proactive correlations increased system availability, which prevented on the basis of the problem based on the downtime incidents (Mean Time to Restore Service MTTRS) can be calculated. The introduction of problem-based event correlation may have a positive impact on a number of service-relevant indicators. By (partial) automization of incident management activities, the cost of troubleshooting my be reduced, which could be measured by the performance indicator Mean Time To Repair, MTTR. A clear description of the failure may help to reduce multiple onsite visits, which can be expressed by the performance indicator First Visit Rate (FVFR). In the best case, the performance indicator Site Visit Avoidance (SVA) will be positively impacted, with a parallel increase of remote access operations. From the perspective of a customer, proactive actions increase the device availability, which may be expressed by the performance indicator (Mean Time to Restore Service MTTRS).

IV. CONCLUSION

Based on the ITIL v3 framework, the service operation processes incident management, problem management and event management were described. The presentation of a medical device service organization was used as an example how these processes may be implemented outside of the "IT world". Based on the reference processes, we presented an integrated process model for problem-based event correlation. The goal of this approach is to avoid the complexity and transparency problem. These problems are a logical consequence when using a "classical" approach, based on single incidents and product development knowledge. However, the problem-based approach implies that historical device data is available. So, it has to be complemented by a correlation strategy for first-time defects/new devices. Also, the approach focuses on hardware defects, where defects can be tracked down to exactly one device failure. This prerequisite may not be given for software failures [14]. By applying the approach to the case study service organization, we showed a possibility how to implement the model and what benefits would arise from its introduction. As a conclusion, we presented key performance indicators which could be used to prove the efficiency of problem-based event correlations.

***Abstract*—Regression testing is a hot research area for Web service composition, which has direct impact on QoS of applications. This paper proposes an aspect-oriented regression test technique for analyzing functionalities of service composition. An extended version of Petri net is proposed as the underlying formalism. Services and components are modeled by Petri nets, service evolution is specified as crosscutting concerns, and in turn woven into the testing model of service composition by following weaving rules. A regression testing algorithm of service composition is designed. Theories of Petri nets help prove the effectiveness of the testing method. A case study shows that the approach simplifies the process of testing, and improves its efficiency as well.**

***Index Terms*—Service composition; regression test; aspect orientation; Petri net; formal method**

I. Introduction

Service oriented computing (SOC) is a paradigm for building applications by selecting and composing software resources or services available on the Internet[1]. Web services are considered an implementation of *SOC* that facilitates the integration of heterogeneous applications. Web service testing is important because it helps evaluate various quality attributes, and prevent late detection of errors. However, some specific requirements need to be carefully considered: (1) The relationship between the service providers and requesters is highly unstable. Therefore, the testing method must be dynamically adjusted to different services and users according to the actual environment; (2) Web service testing is based on its interface, so the system must have sufficient flexibility to dynamically weave the test modules. In addition, service composition involves a variety of standard protocols, which brings new challenges to system testing.

Several techniques have been developed to test Web services, which includes unit testing, integration testing, black box testing and white box testing [2,4]. In [2], the BPEL specification is transformed into an intermediate format model that is based on timed automata. A test generation framework for BPEL composition is proposed in [3], where BPEL semantics was defined by Web service automata. Many works in Web service testing are in code level. However, the source code of a service is usually inaccessible, which limits applicability of those techniques. A large number of coverage-based test case reduction techniques have been proposed by using statement-coverage, branch-coverage, or define-use association criterion[5,6] . Meanwhile, model-based testing is also getting more and more attention both in industry and academia as a test prioritization approach[7−9]. However, these techniques prioritize test cases by means of code coverage achieved, such as the number of statements or branches covered by individual test cases. However, the internal logic and states of a service are encapsulated by the service boundary, which cannot be realized effectively in service-oriented testing.

Aspect-oriented programming (*AOP*)[10] is a software engineering approach to separation of concerns, which is capable of capturing dynamics of system evolution. Moreover, formal methods can be used to enhance *AOP* with a solid foundation. This paper proposes an approach to testing the functionalities of service composition, and proposes a composition Net(*CN*) by extending the formalism of Petri net[11]. Different components of service composition are modeled by *CN*. *AOP* is used to abstract the evolution process of service composition as the crosscutting concerns, and weaves into the testing model of service composition. Based on this, the regression testing algorithm is given, the operation semantics and related theories of Petri nets help prove its effectiveness. A case study shows that the approach can effectively simplify the testing process and improve efficiency of testing.

II. Service Composition Modeling

A. Aspect-oriented service model

An application system is composed of a number of independent components, and each component can be implemented by a bunch of available services. To capture dynamic evolution of service application, we take service composition as the core concern, while its evolution as crosscutting concerns.

Before formally defining the model, we first introduce some notations. C, WS, TC are the sets of finite components, available services, and test suites before the evolution respectively. $RL : C \times C \rightarrow \{>, +, \|, n\}$ is the relation function between components, where $>$, $+$, $\|$, n represent the sequence, choice, parallel and loop relationship. $TW : C \rightarrow WS^*$ is the available service of component. $TW(C_i) = WS_i = \{WS_{i,1}, WS_{i,1}, \ldots, WS_{i,m}\}$ is the available services of component C_i, $WS_{i,j}$

is the *j*th available service of component C_i; $RO = \{It_0, Bi_0\}$ describes the interface and component binding before the evolution; $RN = \{It_n, Bi_n\}$ is the evolution interface and binding; $TR : TC \rightarrow WS \wedge C$ is the action set of test case.

Definition 1 (Base Net): A 7-tuple Σ = (N, IO, D, A_T, A_F, λ, M_0) is called Base Net (*BN*) model if:

(1) $N = (P, T, F)$ is a Petri net, where P, T, F represent the place, transition, arc, and they are disjoint;

(2) $IO \subset P$ is a special place, which is called the interface of Σ and denoted by dotted circle;

(3) D is the non-empty finite individual set, f_D, f_S is the predicate set and symbol set;

(4) $A_T : T \rightarrow f_D$, for $t \in T$, the free variable in $A_T(t)$ must be in the directed arc with one end of the arc is t;

(5) $A_F : F \rightarrow f_S$, if $(p, t) \in F$ or $(t, p) \in F$, then $A_F(p, t)$ or $A_F(t, p)$ is the *n*-symbol set, the default value is empty;

(6) $\lambda : T \rightarrow N^*$ is the priority of transition, the default value is 0, the smaller of λ_i, the greater of transition's priority.

(7) $M_0 : P \rightarrow f_S$ is the initial marking of Σ.

For $\forall x \in (P \cup T)$, we denote the pre-set of x as $^\bullet x = \{y | y \in (P \cap T) \wedge (y, x) \in F\}$ and the post-set of x as $x^\bullet = \{y | y \in (P \cap T) \wedge (x, y) \in F\}$.

Definition 2 (Composition Net): A 6-tuple $\Omega = (\Sigma, \Gamma, TI, TA, PI, PA)$ is called Composition Net (*CN*), where:

(1) Σ is a *BN* model for the basic structure of Ω;

(2) $\Gamma = \{\Gamma_i | i \in N^*\}$ is a finite set of pages, each page is a *BN* or *CN* model, and it is disjoint between pages;

(3) $TI \subset T, PI \subset P$ are sets of substituted node and interface node;

(4) $TA : TI \rightarrow \Gamma$ is the page allocation function, which allocates page to the substituted node;

(5) PA is used to map the interface node of substituted node into the input and output interface of the page.

The individual set D is mainly used to describe the resource of service composition. We abstract the element as the individual d_i=(it, i, RW_i), where $it \in \{w, c, d\}$ represents the described object of individual, w, c, d represent the service, component and data packet, i represents the position of individual. For example, service $WS_{i,j}$ in the service set WS, when it is equal to w, RW_i is used to describe the interface of service; when it is equal to c, RW_i is used to describe the binding of component; when it is equal to d, RW_i presents the content of data packet. $k\#(d_i)$ represents the kth element in the individual d_i. In addition, we denote $N_{i\bullet}x$ as the element x in net N_i.

The mapping $CutN$:$\{N_{i\bullet}x_j, \ldots N_{f\bullet}x_k\}$ is called a pointcut of the model, where $CutN$ is the name of pointcut, $N_{i\bullet}x_j, \ldots N_{f\bullet}x_k$ are joinpoints of the pointcut.

Definition 3 (Aspect): A pair asp=($CutN$, AD) is called an aspect, where $CutN$, AD represent the pointcut, and advice respectively. An advice consists of rules for service integration, and the main part of a rule is an introduction net that models the implementation logic for that pointcut.

Let Ω be a CN model, M is a marking of Ω. For transition $t_i \in T$, if $\forall p \in^\bullet t_i$, there is $M(P) \neq \varnothing$, and $A_T(t_i)$ is true under marking M, then transition t is enable under marking M, denoted by $M[t >$. All the enabled transitions under marking M are denoted by set $ET(M)$.

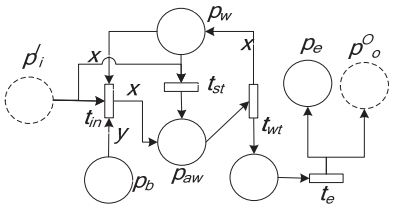

Fig. 1. BN model of component

The transition t is effective under marking M if and only if transition t_i is enable and there doesn't exist transition in $ET(M)$ whose priority is greater than t_i. All the effective enabling transitions under marking M are denoted by $FT(M)$. The model Ω will reach new state M' by effectively firing all transitions in $FT(M)$, denoted by $M[t_i > M'$, M' is a reachable state of M. The computation of M' is: $\forall p_j \in^\bullet t_i \cup t_i^\bullet$: $M^{'}(P_j) = M(P_j) - W(P_j, t_i) + W(t_i, P_j)$.

If there exists a firing sequence $t_1, t_2, \ldots, t_k$ and a marking sequence $M_1, M_2, \ldots, M_k$ such that $M[t_1 > M_1[t_2 > M_2 \ldots M_{k-1}[t_k > M_k$, then M_k is called a reachable state of M. All the possibly reachable states of M are denoted by $R(M)$.

B. The Modeling Method

a) Modeling composition net: The BN model of component C_i is shown in Fig.1, where the place p_i^I and p_o^O represent the input and output interface, p_{in}^I and p_{ou}^i represent the input and output interface in the top model. The process is: (1) if component C_i has got the input parameters p_i^I, then firing transition t_{in} to select an individual x from the library of available service p_w to complete its function; (2) if the component couldn't get the binding service, then calling transition t_{st} to randomly select an available service to complete its function; (3) if the service has completed the function, then calling the termination transition t_e to output the results φ to place p_e and p_o^O.

The composition net is constructed by the following steps.

(1) Constructing the *BN* model of all components in composition process by using the construction method of component.

(2) Introducing transition t_s and place p_s to describe the beginning operation and position, and doing the initialing operation for the system; transition t_e and place p_e are used to describe the termination operation and position, and merging the output of component based on their relationships.

(3) Modeling the basic relationships between components.

(4) Setting the initial marking $M_0(p_s)$ = φ

We obtain *CN* model of service composition based on the above steps, which is shown in Fig.2, the substituted node T_i is mapped into the page of component C_i.

b) Modeling aspect: From the principles of AOP, we can get that advice net is included in the introduction, therefore, we only give the model of introduction in the process of

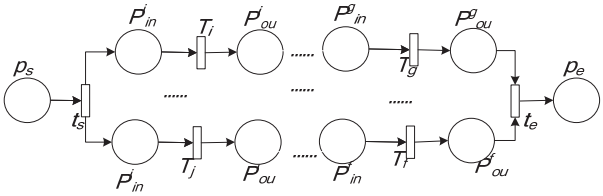

Fig. 2. Composition net Ω of service composition

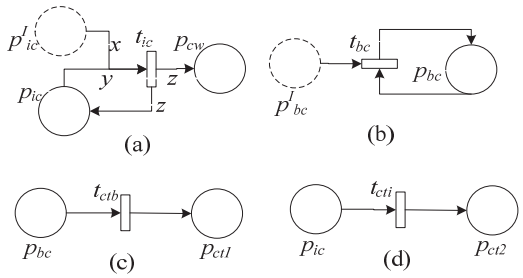

Fig. 3. Advices of crosscutting concern

modeling crosscutting concern.

- Interface aspect $con_{ic} = \{p_{ic}, AD_{ic}\}$

The pointcut of interface is defined as: p_{ic} : $\{CN_{1\bullet}p_w$, $CN_{2\bullet}p_w$, ..., $CN_{|C|\bullet}p_w\}$, the advice is shown in Fig.3(a). p_{ic} is used to describe the change process of service's interface. Place p_{cw} is used to save the evolution records of service. p^I_{ic} is used to store the current invoked service. When the interface of available service $WS_{i,j}$ has modified, then calling transition t_{ic} to update the interface information of place p_{ic}, and the result is stored in place p_{cw}. The weaving rules of con_{ic} are: for each connection point, the system will insert the point into the after set of advice and its associated subnet. The priority of weaving transitions is set to 3.

- Binding aspect $con_{bc} = \{p_{bc}, AD_{bc}\}$

The pointcut of interface is defined as: p_{bc} : $\{CN_{1\bullet}p_b$, $CN_{2\bullet}p_b$, ..., $CN_{|C|\bullet}p_b\}$, the advice is shown in Fig.3(b). Pointcut p_{bc} is used to describe the change process of component's banding. Place P^I_{ic} is used to save the current binding service. When the binding of component has changed, then calling transition t_{bc} to update the binding information of place p_{bc}. The weaving rules of con_{bc} are: for each connection point, the system will insert the corresponding point on CN_i into the after set of advice and its associated subnet, the priority of weaving transitions is set to 2.

- Evolution notify aspect con_{nc}= $\{\{p_{nc1}, p_{nc2}\}, AD_{nc}\}$

The pointcut is defined as: p_{nc1} : $\{P^1_{bc}, P^2_{bc}, \ldots, P^{|C|}_{bc}\}$, p_{nc2} : $\{P^1_{ic}, P^2_{ic}, \ldots, P^{|C|}_{ic}\}$, the advice is shown in Fig.3(c)-Fig.3(d). Pointcut p_{ct1}, p_{ct2} are used to notify the evolution of system to all components. Place p_{bc}, p_{ic} are used to save the current binding and the evolution data of interface. The weaving rules of con_{nc} are: The system will firstly weave the evolution advice concern, then weaving the evolution concern in the current evolved component. In order to handle the notify of evolution timely, the priority of weaving transitions is set to 1.

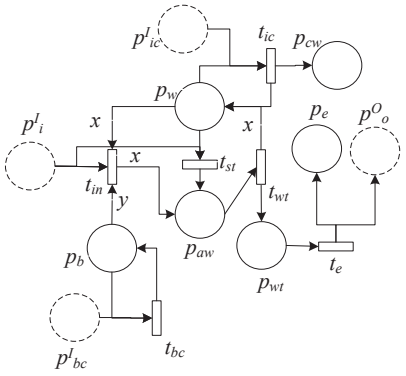

Fig. 4. Testing aspect of component

According to the above model, the steps of aspect weaving are:

(1) Adding all the advices in the set con to Ω, thus forming a new composition net;

(2) Adding the corresponding elements according to the weaving rules and merging the same element;

(3) Weaving aspects in decreasing priority order when more than one aspect is applied to the same pointcut.

The model got by weaving the above concerns into the composition net is called the test model Ω_t. If $M(p_e) = \varphi$, then M is called a normal termination marking. The testing aspect CA_i of component C_i is constructed according to the weaving rules of concern, which is shown in Fig.4.

III. Regression testing techniques

Regression testing of basic service is to ensure that its function and interface information can still meet the requirements after the evolution. When service provider does regression testing for basic services, the system selects the required testing path and test cases. In contrast, the service consumers can generally select and modify the test case according to the change of interface, and getting the results to complete the test based on the invoked services. When the original binding service is replaced by another service, it is necessary to re-run the test cases of all paths that called the replaced service, thus to verify whether the system can operate normally and the results are correct.

We first reduce the size of regression test by applying the following selection strategy.

(1) Initialing the regression set $CTC = \varnothing$, the component need to be tested is $DC = \varnothing$, the available service need to be tested is $DWS = \varnothing$;

(2) Computing DC: a. $\forall C_i \in C$, if the binding of C_i has changed, then $DC = DC \cup C_i$; b. $\forall C_i \in DC$, $\forall C_j \in C - DC$, $RL(C_i, C_j) =>$, then $DC = DC \cup C_j$;

(3)Computing DWS: $\forall WS_{i,j} \in WS$, if the interface of service $WS_{i,j}$ has changed, then $DWS = DWS \cup WS_{i,j}$;

(4) Constructing the test suite of regression test: $\forall tc_k \in TC$, if $TR(tc_k) \cap (DC \cup DWS) \neq \varnothing$, then $CTC = CTC \cup tc_k$;

(5) Filtering the test suite of regression test: $tc_k \in CTC$, if there exists $tc_f \in CTC$, which makes $TR(tc_k) \subseteq TR(tc_f)$, then $CTC = CTC - tc_k$.

According to the different types of evolution, the paths of regression testing p consist of two parts: the path set p_i affected by interface change and the path set p_b affected by binding change. The algorithm is shown in Algorithm 1. Let the path set of composition net Ω be *path*(Ω).

(1) Computing the set p_i: The system will compare the number of parameters in the interface, the definition of data type of each parameter in the interface, then do regression test in case any change occurs.

(2) Computing the set p_b: According to the relationship between the components, if the binding of component C_i has changed, then the associated components of C_i should be re-tested to ensure that the binding is effective.

Algorithm 1 Regression test path generating

Require: Composition net Ω' and its path set $path(\Omega)$;
Ensure: The path set needed to test by regression testing;

Analysis(Ω) //Computing the evolution service and component
{EC=EWS=ϕ;
For k=0,i≤| C |, k++ do
{ if $\exists d \in M_0(p_{bc}) \wedge 2\#(d) = k$ *then* $EC = EC \cup \{C_k\}$
For i=1,j<| WS_k) |, i++ do //Verifying the evolution of available service
{ If $\exists d \in M_0(p_{ic}) \wedge 2\#(d) = (k,i)$, then $EWC = EWC \cup \{WS_{k,i}\}$;}
Foreach $C_k \in C - EC$ do
Foreach $C_i \in EC$ do
If $RL(C_k, C_i) =>$, then $EC = EC \cup \{C_k\}$; }}
Compute_pa(EC, EWS, $path(\Omega)$)//Computing the paths of regression testing;
{ $Npath = \phi$;
Foreach $\delta \in path(\Omega)$ do
{If $\exists C_i \in EC \wedge CA_{i\bullet}t_{in} \in \delta$ then $Npath = Npath \cup \delta$;}
{ If $\exists WS_{i,j} \in EWS \wedge 2\#M_\delta(CA_{i\bullet}p_{ac} = (k,i)$, then $Npath = Npath \cup \delta$;}}

We will analyze the effectiveness of algorithm based on the state space of model, that is, (1) If the binding of component changes, then the related paths will be tested; (2) If the bindings of the afterward component of component C_i changes, then the related paths of component C_i will be tested; (3) If the interfaces of service changes and the service has been called, then the related paths of service will be tested.

Theorem: In the test model Ω_t, let the path set of composition net Ω be $path(\Omega)$, $Npath$ is the corresponding path set of regression test, $\forall \delta \in path(\Omega_t)$, there are:

(1) $\forall C_i \in C$, if $C_i \in Bi_n$, then $CA_{i\bullet}t_e \in \delta \rightarrow \delta \in Npath$;

(2) $\forall C_i \in C$, if $C_j \in c, RL(C_j, C_i) =>$, then $CA_{i\bullet}t_e \in \delta \rightarrow \delta \in Npath$;

(3) $\forall WS_{i,j} \in WS$, if $WS_{i,j} \in It_n \wedge 2\#M_\delta(CA_{i\bullet}p_{ac}) = (k,i) \rightarrow \delta \in Npath$;

TABLE I
EVOLUTION INFO OF EXPORT SERVICE

WS	It_o		WS	It_o		WS	It_o		WS	It_o	
	Pn	Pt		Pn	Pt		Pn	Pt		Pn	Pt
$WS_{1,1}$	1	{I}	$WS_{2,1}$	1	{I}	$WS_{3,1}$	2	{B,S}	$WS_{4,1}$	1	{I}
$WS_{1,2}$	2	{I,S}	$WS_{2,2}$	1	{I,B}	$WS_{3,2}$	2	{B,S}	$WS_{4,2}$	1	{I}
$WS_{1,3}$	2	{I,S}	$WS_{2,3}$	2	{I,B}	$WS_{3,3}$	2	{B,S}	$WS_{4,3}$	1	{I}
$WS_{1,4}$	1	{I}	$WS_{2,4}$	2	{I}	$WS_{3,4}$	2	{B,S}	$WS_{4,4}$	1	{I}
$WS_{5,1}$	3	{I,S,B}	$WS_{6,1}$	1	{S}	$WS_{7,1}$	2	{I,S}	$WS_{8,1}$	1	{D}
$WS_{5,2}$	3	{I,S,B}	$WS_{6,2}$	1	{S}	$WS_{7,2}$	2	{I,S}	$WS_{8,2}$	2	{D,B}
$WS_{5,3}$	2	{I,S}	$WS_{6,3}$	2	{S,I}	$WS_{7,3}$	2	{I,S}	$WS_{8,3}$	2	{D,B}
$WS_{5,4}$	1	{I}	$WS_{6,4}$	1	{S}	$WS_{7,4}$	2	{I,S}	$WS_{8,4}$	2	{D,B}

Proof: let the marking included in δ be the set $R(\delta)$, $\forall C_i \in C$, because $C_i \in Bi_n$, according to the modeling process of aspect, $\exists d \in M_0(p_{bc})$ which makes $2\#d = (k,i)$; and because $p^\bullet_{bc} = t_{ctb}, P^i_{in} \in t^\bullet_{ctb}$, therefore, it exists $M \in R(\delta)$, which makes $d \in M(CA_{i\bullet}p^I_{in})$; Because $CA_{i\bullet}p^I_{in}{}^\bullet$=$\{CA_{i\bullet}t_{in}, CA_{i\bullet}t_{st}\}$, $(CA_{i\bullet}t^\bullet_{in})^\bullet$=$(CA_{i\bullet}t^\bullet_{in})^\bullet$= $CA_{i\bullet}t_e$; and because $CA_{i\bullet}t_e \in \delta$, according to Algorithm 1, we can get $\delta \in Npath$.

Similarly, proposition (2) and (3) can be proved. Theorem 1 says that the regression path set can describe the evolution of the interface and the binding of service composition according to Algorithm 1.

IV. A CASE STUDY

This section presents a simple case study of Export Service System. The business process includes looking up the relevant information and selecting the destination (C_1) according to the requirements, and packaging services (C_2) responses for processing and packaging export products. The system will implement the operation of export transport ordering (C_3) and insurance processing (C_4) in parallel, while Export transport ordering include water transport ordering(C_5) and airport ordering (C_6). All the information is confirmed by exporter and will be sent to the regulatory authorities (C_7) for checking. Finally, financial services (C_8) is used to check the related instruments of product. The composition process can be represented by expression $C_1 > C_2 > (C_3 \parallel C_4 \parallel (C_5 + C_6)) > C_7 > C_8$, the specific available service and test cases are shown in Table I. Let the binding service set of each component be: $WS_{1,1}$, $WS_{2,3}$, $WS_{3,1}$, $WS_{4,3}$, $WS_{5,3}$, $WS_{6,4}$, $WS_{7,2}$, $WS_{8,3}$. The binding evolution of Export Service be $\{WS_{2,2}, WS_{5,2}\}$, that is, the binding of component C_2, C_5 have changed. The changing interface of available service be: $WS_{1,1} : \{2, \{\{Int, String\}\}\}$, $WS_{3,3} : \{1, \{\{String\}\}\}$, $WS_{4,2} : \{2, \{\{Int, String\}\}\}$, $WS_{6,4} : \{2, \{\{Int, String\}\}\}$, $WS_{8,1} : \{2, \{\{Double, Boolean\}\}\}$.

We can weave the evolution concerns into the composition net Ω, which is shown in Fig.6. the model mainly describes the composition process of Export Service. According to the construction method of state space, the reachable states of composition net and aspect are 216 and 312 respectively. $CA_{i\bullet}t_{bc} \in \delta(M, M_e)$, that is, the binding evolution of component C_2 has been tested, in the similar way, we can get the evolution of all services have been tested before the end of service composition. We can compute the paths in Export

Service(component and service), which are $< C_1, C_2, C_3, C_4, C_5, C_7, C_8 >$, $< C_1, C_2, C_3, C_4, C_6, C_7, C_8 >$, followed by regression testing paths and services $WS_{1,1}$, $WS_{6,4}$.

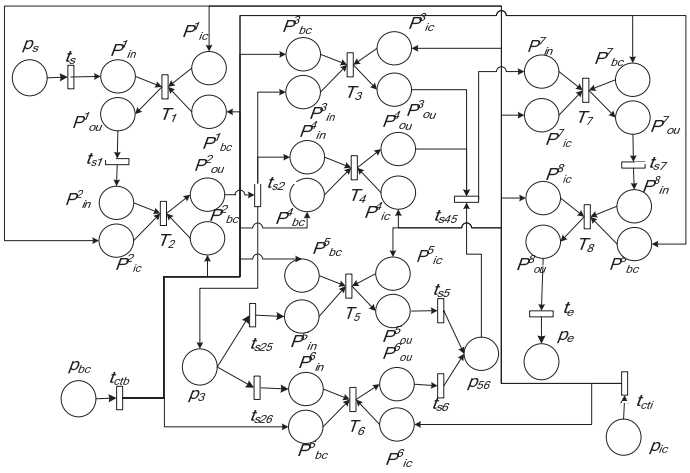

Fig. 5. Model of Export Service

In order to effectively estimate the proposed approach, we conduct an experiment. The system randomly generates 8000 services as service resource and 260 test cases. And each service contains the historical and the actual testing info. A test case can be used to test available service for several times, the testing results of each time may be different. The purpose of Experiment is to analyze the necessity of using *AOP* for regression test. The steps are:

(1) Taking 30 test cases and 1120 available services as the resource of 5 Export Service, and supposing component in each Export Service contain 10, 20, 30, 40 and 50 available services;

(2) Constructing the composition net, testing model of Export Service, and then computing the size of its state space.

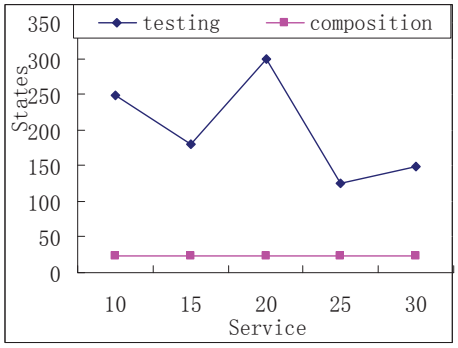

Fig. 6. The experiment result

The results of Experiment is shown in Fig.6. The result of Step(1) says that the state space of base net will not change with the number of service resource increasing, for example, the reachable states of base net of 5 Export Service is 24. The reason is: base net is mainly used to describe the implementation process of service composition, which is unrelated with the test case and service resource. Therefore, the state space of base net is unrelated with the test suite and the set of available service. The result of Step(2) means: (1) The state space of test model will not strictly decrease with the available services increasing, when the evolution is more complex, the state space of test model will be relatively large.

V. Conclusion

This paper proposes a regression test technique for analyzing the functionalities of service composition. Services and components are modeled by Petri nets, while service evolution is specified as crosscutting concerns, and in turn woven into the testing model of service composition by weaving rules. The benefits of this work include formal reasoning correctness of service composition, flexibility of composition process, and efficiency of regression testing. In the future, we plan to investigate more concerns such as performance and security and develop the related tools.

***Abstract*—Scrum is one of the agile methods gaining more relevance among academics and practitioners. It is mainly applied in the context of software development, which is a knowledge-intensive activity and depends on learning to evolve. Therefore, it becomes crucial to understand the question: *Does Scrum implementation trigger a process of Organizational Learning? If 'Yes', how does the OL occur?* This relation has never been established in previous studies. The answer to these questions was based on a qualitative research, involving key members from UOL - the most important Brazilian company regarding content and services on the Internet, key members from an academic project and an expert in agile methods implementation. Among the main findings, we highlight that the process of Organizational Learning could be verified through the individual members' learning and through the changes within the organization in management, people, process and technology. Beyond the relation established between Organizational Learning and Scrum implementation, this study contributes to academic and practical fields by the identification of changes occurred in type of knowledge valued, physical structure, promotion criteria, and individual dependence decrease when implementing Scrum. It is perceived that knowledge management, as a way of perpetuating the learning in the organization is still a challenge for agile software organizations.**

Keywords- Organizational Learning; Agile Software Development; Scrum implementation.

I. INTRODUCTION

Agile methods have been in evidence lately. Among these, one of the most popular agile methods is Scrum [1], which is focused on project management and holds ceremonies and roles that follow the agile values and principles formalized by the Agile Manifesto [2]. Its reputation is due to the increasing chances of project success, when applied properly [3].

Software development is a knowledge-intensive activity [4]. Given that, learning is crucial for organizations in this area. As more software development organizations are adopting Scrum, it becomes relevant to understand whether it contributes or not to the process of Organizational Learning (OL).

Every organization learns, as it is a basic requirement for its sustainable existence; and its learning is acquired through their individual members. Yet, OL is a more complex phenomenon than the simple sum of individual's learning [5, 6, 7, 8].

The definition of OL is not consensual and it involves multiple aspects. In this study, we take Nicolini and Meznar's definition that relates learning to change: OL corresponds to investigating why and how the organization changes [9]. Fiol and Lyles [7] associate change with behavior development and learning with cognitive development. Based on that, they add that not all changes imply on learning and that might be learning without any accompanying change in the behavior. Therefore, in this study we will consider cognitive developments and changes in behavior accompanied by cognitive development as learning.

Through a wide search on the topic, including several electronic databases pointed hereafter, the relation between Scrum implementation and the OL process has never been fully established in literature. However, it is quite relevant to study this relation since learning is decisive for software development organizations. For this reason, this research aims to perform an empirical study to understand whether the Scrum implementation triggers OL and, if positive, how it occurs. This study represents an innovative focus on Agile Software Development (ASD) field.

Cognitive and behavioral changes were verified through the analysis of whether the perceived individual learning of the organizational members increased with the Scrum implementation (as it is the first step for OL to happen). And also through the modifications in four aspects: management, people, process and technology. These aspects were pointed out by Nerur, Mahapatra and Mangalaraj [10] as the key issues in migrating to agile. Since they clearly relate them to organizational change, we used these key issues to guide our study. We complement their findings, as contributions for academy and practice, providing other identified changes, such as in types of knowledge valued, physical structure, promotion criteria and in individual dependence decrease.

This research consists of a qualitative analysis involving three lectures on the theme of Scrum implementation and six interviews with actively involved people on its implementation.

The structure of the paper is as follows. In Section II, we review the literature related to OL and ASD implementation. In Section III, the research methodology is described. In Section IV, we present the data analysis. In Section V, we discuss the findings. Finally, in Section VI, the conclusions are presented.

II. Literature Review

After searching within several electronic databases, such as ACM Digital Library, Compendex, EBSCO, Elsevier ScienceDirect, Google Scholar, IEEExplore, ISI Web of Science, JSTOR, SpringerLink, and Wiley Online Library, no specific study was identified exploring the relation between the Scrum implementation and the OL process.

However, there are few relevant previous studies relating ASD to OL concepts, such as Argyris double-loop learning [11, 12], maintenance of corporate experience repositories as a way to guarantee continuous learning [13], and March's exploitation-exploration balance [14] [15]. We also found studies outlining the importance of OL in Scrum/Agile adoption, but they stress the need to support the process itself to improve long-term learning [16, 17, 18, 19, 20, 21, 22]. Likewise, one study relates Scrum adoption as organizational becoming [23]. Also, two studies relating software process improvement to organizational change were identified [24, 25]. Besides, studies point out the need for future research on OL in ASD [21, 26, 27].

Despite the wide acceptance of OL and its importance to strategic performance, there is no theory or model largely accepted [7], and the concept is still evolving [8].

We use the definition of Nicolini and Meznar [9] that relates learning to change. They state that OL rely on exploring why and how the organization changes. Other authors support this view. Antonello [8], in a literature review about OL, stated that the literature promotes a strong relation between learning and change, and some authors contend they are synonyms. As stated by Fiol and Lyles [7], OL is the process of improving actions through better knowledge and understanding. The authors differentiate organizational learning (cognitive development) and change (behavior development). Therefore, changes in the organization can be considered learning as long as they are accompanied by cognitive development.

There is a consensus that OL is first acquired by the organization individual members, but OL is not the simple sum of each member's learning [5, 6, 7, 8]. It means that the first step onto OL comprehension is the understanding of its individual's learning. As the synergy of the shared understandings and consensus increase within groups through knowledge propagation and socialization, the organization starts to adjust its behavior as a response to performance problems [5].

Past studies in ASD acknowledge that there is learning at individual and group levels [1, 21, 28, 29], however none has actually described the OL process in ASD.

For a deep comprehension of OL, there are other aspects to be analyzed such as changes in management, people, processes and technology. Specifically in the software development area, it is important to take into account Nerur, Mahapatra and Mangalaraj [10] study where they detail key issues (Table I) that an organization may have to face when migrating to agile.

TABLE I. Key issues in migrating to agile

Management and Organizational: Organizational Culture, Management Style, Organizational Form, Management of Software Development Knowledge and Reward System.
People: Working effectively on a team, High level of competence and Customer relationships (commitment, knowledge, proximity, trust, respect)
Process: Change from process-centric to a feature-driven/people centric approach, Short iterative, test-driven development that emphasizes adaptability, Managing large/scalable projects and Selecting an appropriate agile method
Technology (tools and technique): Appropriateness of existing technology and tools and New skill sets (refactoring, configuration management, J-units)

These issues can be seen as causes and consequences of migrating to agile because at the same time that they represent assumptions or enablers for the implementation to happen, they are also affected when the implementation takes place.

Chang and Thong [30] have provided a critical review of the literature on the acceptance of agile methods. They found only eight case studies discussing the acceptance of agile methods. Only two of them were specifically about Scrum implementation [31, 32]. Table II depicts those main factors.

TABLE II. agile methodologies acceptance adapted from [30]

Factors for agile methodologies acceptance	Method studied
Negotiation skills	Scrum
External support, Career consequences, Micromanagement, Resistance due to past experience	Scrum, XP
Compatibility with agile methods	Scrum, Agile
Individual ability / competence/ motivation / Experience in software development	Scrum, Agile, XP
Teamwork, Management support, Communication, Project type, Team size, Organizational culture and form, Management style, Management of software development knowledge, Reward system, Customer relationship, Existing technology and tools, Training	Agile

After the Scrum implementation, several challenges related to Knowledge Management (KM) need to be faced to perpetuate and leverage the learning in the organizations. Levy and Hazzan [4] highlight how the agile approach initiates a culture change that is in line with the one needed for a KM initiative. They describe KM enablers that are embedded in the agile approaches. For Chang and Thong [30], KM is critical for ASD, but it has to be conducted in a different way, since agile methods are more people-oriented and deal mostly with tacit knowledge.

An important aspect related to OL observed in previous studies is the lack of KM practices integrated to the Scrum management process [4], even though the practices encourage the knowledge exchange among individuals in a team. In summary, the process of OL that started with Scrum implementation must be supported by KM practices in order to perpetuate the learning in the organization.

III. Research Methodology

This empirical study is a qualitative research [33], since it aims to discover and understand the complexity and interaction of factors related to the phenomenon in study. As Seaman [34] state, the main advantage of using qualitative methods is that they force researchers to deepen the complexity of the problem, rather than generalize it. Thus, the results are richer and more informative. On the other hand, they are more difficult and stressful than a quantitative analysis.

A. Research Question

This research can be classified as exploratory [35], since the goal is to examine a topic or research problem scarcely studied, for which we have many questions not addressed before [36]. We aim to answer the following research question:

- *Does the Scrum implementation trigger a process of OL? If 'Yes', how does the OL occur?*

B. Data Collection

Semi-structured questionnaires with open questions were held to allow improvisation and to invite a broad range of answers and issues from the phenomenon in study.

The questionnaires were constructed from the literature, in order to answer the research question, considering the necessary assumptions for Scrum implementation to happen and their perceived changes after the implementation (in areas related to Management, People, Process and Technology). There were also questions regarding the challenges related to KM (what is being applied to perpetuate the learning initiated with Scrum implementation). The questions were adapted to each interview. All interviews were recorded and transcribed.

C. Data Analysis Method

The analysis of the collected data was made inspired by open coding in grounded theory [37]. Interesting expressions were categorized to describe the phenomenon in study.

D. Data Sources

The empirical study considers the qualitative analysis of three lectures on the theme and six interviews involving three different data sources to provide data triangulation:

- Two key members from Universo Online (UOL), the most important Brazilian company regarding content and services on the Internet (http://sobreuol.noticias.uol.com.br/index_en.jhtm). The expansion of services offered to the web market has demanded changes in company's process, which has led to the Scrum implementation in some of the software development areas. We attended lectures of both professionals, which are actively involved on Scrum implementation, and we conducted two group interviews with them to investigate the OL process at the organizational level.
- Three members from the Workbench Project (WP), an academic project that applies Scrum method (http://www.groupwareworkbench.org.br/gt). This project is an initiative of the Institute of Mathematics and Statistics from University of São Paulo to develop components aimed at social interaction and collective intelligence for building collaborative applications on Web 2.0. We interviewed individually the Scrum Master, the technical leader and one of the developers to analyze the learning at individual and group level.
- Specialist in implementing agile methods, including Scrum, Heitor Roriz, from Massimus Consulting (http://massimus.com/) conducted a lecture and was also interviewed by the authors to deepen the understanding of the relationship between Scrum implementation and OL. Given his experience in several software development organizations, his point of view was important to triangulate data and to perceive if the results verified at WP and UOL could be found in other organizations or if they were restricted to their context.

IV. Data Analysis

Data analysis was performed by coding interesting expressions detected by the authors, considering their expertise on the research topic. This section presents them in detail.

The qualitative analysis highlighted the importance of what we have called "assumptions", factors that contribute to the acceptance of the Scrum implementation. They are endorsed by the literature. Also, it raised the changes identified in the study, representing evidences of learning that have occurred.

A. Assumptions for the Implementation

It is important to understand the assumptions adopted for the Scrum implementation as they allow the organization to benefit from the subsequent organizational learning generated. The assumptions identified are detailed as follows.

1) Understanding of the Scrum method: An understanding of the Scrum method is important once many organizations have lack of knowledge of the practices required to use Scrum effectively. As well, many organizations confuse some of their practices with other methods. The specialist interviewed supported this point by stating that "*It happens that some companies say that they are using Scrum, when they are not actually doing so. An example is when they use Kanban – which belongs to Lean – thinking it is Scrum*". This way, it is important to achieve a broad understanding and a full implementation of the Scrum method to perceive its benefits.

2) Make sense in the context: It is crucial that the implementation makes sense for the organization. In the case studied, some factors contributed to this aspect: team dissatisfaction and overload with the previous method, the need to have a fast method to keep up with the organization's startups, competitors already using Scrum as well as some of the team members getting in contact with Scrum by external conferences, academic influence and books. One of the interviewees from UOL argued that *"if everybody were*

comfortable with the process… 'oh, it is ok, it works'… or 'leave it like this', it wouldn't have changed";

3) Top management support: To change the work method, it is necessary to convince the top management that it is worth. An interviewee reported the need to also line up the Scrum implementation with the business expectations and adapt the technical to management vision to support top management convincement: *"the development area had to 'speak the language' of the top management to be able to convince them. It was of no use to talk about the method. We needed to focus on the benefits it might bring: reductions in time, cost…"*;

4) Shared vision establishment: In a change process, it is important to establish a shared vision of the future. It implies expectations alignment and also changes understanding. Metaphors may help in this task as it was used at UOL, as reported in the lectures: *"We were changing the airplane's wing during the flight… so it would not be an overnight change as it is difficult to do such thing"*. Another statement related to the expectation alignment was: *"we made clear for the development team as well as for the top management that Scrum was not the solution for all the problems"*;

5) Team's competency and commitment: It was also pointed out to have a competent and committed team. As an interviewee from UOL stated: *"You need competent people, with a strong knowledge base, committed to the job… this is the base… without it… it is an assumption"*;

6) Non hierarchical culture: Not all organizations can implement Scrum. It was reinforced by the specialist interviewed as well as at WP and UOL. A WP member summed up this need by saying that *"the culture cannot be the 'I impose and you obey'"*.

B. Changes and Learning

According to Nicolini and Meznar [1], in order to understand the phenomenon of OL, it is important to analyze the changes that occurred in the organization. Fiol and Lyles [7] add that change can be considered learning since it is accompanied by cognitive development. Given the basis provided by these authors, cognitive developments of the members and changes in behavior accompanied by cognitive development were considered learning.

Through the data analysis and consensus among the researchers, subcategories were created below within the categories proposed by Nerur, Mahapatra and Mangalaraj [10].

1) Management and Organizational

a) Types of knowledge: The organization undergoes significant changes in the types of knowledge. Individual tacit knowledge increases due to a higher communication and teamwork. Many interviewees state that the individuals end up increasing their knowledge because of the higher interaction with other team members. A Workbench project member endorsed it by saying: *"I saw that other people's level was above mine and it forced me to learn (…) not because somebody told me to, but for self motivation.* The organizational tacit knowledge also increases by the reinforcement of shared culture and process. However, we identified a more unexpected change in the explicit knowledge. Despite the decrease in the documentation related in all the interviews, it was possible to conclude that the explicit knowledge increases with Scrum implementation. It happens because the documentation that used to be generated rapidly became outdated and, therefore, people did not access them: *"in the past, people used to write a lot, but anybody read that"*. Knowledge is related to action [38], so a document that is not accessed and does not lead to any action, cannot be considered knowledge, but information instead. As the documents generated when working with Scrum contain only the essential knowledge, it is therefore accessed and turned into action: *"today, everything that is critical is documented"* as well as *"what is updated is what you have the obligation to update in order to make it work"*.

b) Hierarchical structure: This indirect change happened because as the development teams must work together and sit near each other, these individuals tend to become part of the same functional area. This is confirmed by an interviewee from UOL: *"the hierarchical structure changed […] some departments disappeared, some remained but changed their way of working"*. The change in the way of working refers to the team members that respond to a different area becoming really part of the team, even working in the same space/room.

c) Physical structure: As the team members sit close to each other when working with Scrum, the physical structure in the development area has changed. It was seen as a very important change, as now the cross-functional team work for the same product: *"it used to be resource competition among the areas"*.

d) Promotion criteria: The change in the type of knowledge already presented, alongside with the transparency increase by Scrum implementation may improve the promotion criteria: *"the promotion criteria became more legitimate, more the essence of the person's value and not the circumstance"*.

2) People

a) Values and behavior: As Scrum is usually implemented along with agile principles, there are joint reflexes in changes of team values and behaviors. This is one of the main changes pointed out by all the interviewees. One of the interviewees from UOL commented about the changes he observes in the team: *"just the fact that everybody is in a smaller team […], the daily exposition by the daily Scrum, the task visibility on the board, everybody talking about what they are doing, the deadline commitment… and even when a new member comes to the team, somebody just go there to help him… it is very good for the team"*. Some of the several aspects related to this topic and indicated during the research were: increase of communication and transparency in the relationships, less imposition by managers, bigger sense of commitment, responsibility, organization and freedom of expression (questionings, opinions etc), better understanding of the work processes, commitment to the final product and objectivity during the meetings. The specialist in Scrum

implementation supported theses changes as he observes in several organizations: *"the characteristic of every team when you implement Scrum: feeling of responsibility…. Everybody say that. The feeling of organization […] you know what you are doing. Then you compromise"*.

b) Individual dependence: An interesting impact of Scrum can be the reduction of the individual dependence for the organization. It happens because the knowledge is largely widespread through several members, reducing the need for one specific individual: *"knowledge is spread […]there were component owners previously[…] today it doesn't exist anymore. Now the team takes everything. When we started with Scrum, we had to make an effort to stop that. So I would say that the dependence has decreased"*. However, the human dependence as a whole remains strong, only the individual one decreases: *"[the dependence is] less from the individual. People dependence still exists because software is a human activity"*. It was pointed out by the interviewees from UOL that "dependence" must not be misunderstood: it does not mean that the organization has started to diminish the importance of each person, but quite the opposite. It was only the negative part of the dependence that has decreased (for example: a person who is not delivering a good job but cannot be fired because he/she is the only one who has a specific knowledge in the organization).

c) Roles: Scrum proposes different roles in the organization: Scrum Master and Product Owner as well as a different role for the team, demanding an active participation in the decision taking. The team becomes self-organized and the leadership operates as a coach more than a manager. One of the interviewees from UOL commented about his team active participation in the process: *"there isn't that attitude anymore of 'I have finished so I move the task ahead'"*.

d) Particular language development: Another change was the development of a particular language by the team. It is partly because of the shared work and values. It was commented that the team starts to say things such as *"that is a sprint thing"*, that has no meaning for a person of the organization outside the development team.

3) Process

a) Delivery model: The delivery model proposed by Scrum – iterative and incremental – differs from the traditional long term ones. It changes the way of thinking the job by the team members. An interviewee from UOL stated that *"We didn't have a culture of delivering in pieces […] and the thought of maximizing value at each delivery"*.

b) Tests: In order to cope with the new way of working, developers build the software and test it at the same time. It may represent an overlap with the tester role. However this is faced as a positive aspect: *"there is an overlap with the tester role, because the developer ends up implementing tests alongside with the development, but this is seen as a positive thing because it improves the test estimates"*.

4) Technology

a) Tools: While Scrum does not strictly recommend the use of tools, developers use them for purposes of facilitating project management and improving their source-code. A WP member said: *"Virtual tools help us seeing the progress of the project […] also, they force us to improve our work […] you realize that people are afraid of generating bad code"*.

V. Discussion of the Findings

Our research question was: *Does Scrum implementation trigger a process of OL? If 'Yes', how does the OL occur?* We verified that the answer to the first question is positive as an increase in individual's learning was identified – the starting point for OL – and several changes involving intellectual growth and improved actions could be seen in the organization that took place with the Scrum implementation. As our definition of OL involves the understanding of how organizations change, these changes are the basis to verify if a process of learning has occurred.

The study innovates by focusing on the relation between Scrum implementation and OL, never explored in previous studies. Besides, it contributes to the understanding of the issues in migrating to Scrum. It could be added in the study of Nerur, Mahapatra and Mangalaraj [10] the possible change with the physical structure of the organization, not only in the organizational form in the sense of hierarchy. Moreover, the promotion criteria is another point that may undergo change as Scrum increases transparency and disseminates knowledge within the team, making a contribution to a more fair criteria for promotions.

A very interesting finding is related to the change in types of knowledge in the organization. Nerur, Mahapatra and Mangalaraj [10] pointed out the shift in the balance of power from management to development teams that may occur as the majority of knowledge in agile development is tacit and resides in the heads of team members. However, we have concluded that explicit knowledge also increases with Scrum implementation (but not as much as tacit knowledge). This is based on the fact that the documentation developed in traditional methods could not be considered knowledge as it was hardly used because it rapidly became outdated.

Another interesting finding in the study is related to the organization's decrease in individual dependence. As the knowledge becomes more diffuse among team members, the organization becomes less dependent on individuals. Although it was noticed that people become more valued, the harmful dependence of a single individual is reduced.

Then, when Scrum implementation is overcome, a further challenge raises: how to manage the organizational knowledge in this context? In this study, some initiatives being established were identified, but the interviewees confirmed that this is a very important aspect to be dealt with in the near future.

VI. Conclusions and Further Work

The findings of the present study may be useful in several ways. First, it shows that Scrum implementation triggers a process of OL, a crucial process for software development

organizations. Besides, it clarifies some of the changes that an organization may undergo when implementing Scrum.

This qualitative study presents some limitations that reflect in threats to validity of the results. It is not yet possible to generalize the findings, since the sample is not extensive, but adequate to the research goals. Only one organization was studied and yet few people were interviewed. Moreover, although the people interviewed are considered key, we cannot guarantee that their views are consistent with other team members and the organization respectively.

Future studies may complement the identified factors in different organizations to increase the power of generalizing the results. Moreover, there is an opportunity for further research on how to manage knowledge in organizations that have already implemented Scrum [29].

ACKNOWLEDGMENT

We are grateful to UOL, Heitor Roriz and WP team for all the collaboration with this study. We thank Ana Paula O. Santos for indicating and introducing us to the WP team. This work was financially supported by CAPES, CNPq-Brazil and Fapesp.

***Abstract*—Software architectures and reference architectures have been playing a significant role in determining the success of software systems. In particular, reference architectures have emerged, achieving well-recognized understanding of specific domains, promoting reuse of design expertise and facilitating the development of systems. In another perspective, agile methodologies have been widely adopted as a promising iterative, incremental and collaborative software development process, including by the software industry. Considering the relevance of reference architectures, initiatives of agile methodologies exploring these architectures are also found. However, there is a lack of a panorama about the uses, impacts and perspectives of such architectures in the agile context. The main objective of this paper is present an detailed view about how reference architectures have been used in the context of agile methodologies. For this, we applied Systematic Review, a technique to systematically explore, organize, summarize, and assess all contributions of a specific research area. As main result, we have observed that reference architecture and agile methodology should be more investigated together. Furthermore, we intend to contribute to open perspectives of new and important research lines.**

I. Introduction

Software architectures have received increasing attention as an important subfield of Software Engineering [1]. Software architectures play a major role in determining system quality, since they form the backbone to any successful software-intensive system [2]. Motivated by these considerations, software architecture research area has grown up and, as known, it has accumulated important knowledge that has certainly contributed to the software development. In this context, reference architectures have emerged as a special type of architecture that provides major guidelines for the specification of concrete architectures of systems of a given domain [3]. They can therefore promote reuse of design expertise by achieving solid, well-recognized understanding of a specific domain. Considering their relevance, reference architectures for different domains have been proposed and successful used [4]–[7].

In another perspective, aiming at organizing the software development activities, different software processes has been proposed. At one extreme, there are industry-tested processes for software system development and for effective project management, such as RUP[1] (Rational Unified Process); at the other extreme, there are agile methodologies (also called agile methods or agile processes), such as XP[2] (eXtreme Programming) and Scrum[3], that have also attracted the attention of software industry, since by adopting these methodologies, industry has speed up the time-to-market of their products [8]. In general, agile methodology aims at achieving that by simplifying the release scopes and thus it generates less effort on complexity, management and keep the customer constantly satisfied and present during the software development [9].

It is worth highlighting that the agile methodology principles seem to contrast with the use of reference architectures in agile methodologies. However, considering the relevance of reference architectures, there are initiatives exploring reference architectures together with such methodologies [10]. Nevertheless, the extent of these researches are not broad enough to comprise how reference architecture has been explored within agile methodologies. In other words, there is a lack of an detailed panorama about why, how, when and which agile methodologies have currently been adopted reference architectures.

The main objective of this paper is present an detailed view about uses of reference architectures in agile methodologies. For this, we conducted the systematic review [11], a technique that comes from Evidence Based Software Engineering (EBSE) and makes possible to explore, organize, summarize, and assess all contributions of the current state of a research area. As results of our systematic review, we can point out benefits that can be gained by exploring reference architectures within the context of agile methodologies. However, we have observed that reference architecture and agile methodology should be more investigated together, aiming at exploring their advantages in a coordinated manner. Moreover, we intend that this work

[1]http://www-01.ibm.com/software/awdtools/rup/
[2]http://www.extremeprogramming.org/
[3]http://www.scrumalliance.org/

could identify interesting and important perspectives for future research.

This paper is organized as follows. In Section II background on reference architecture, agile methodology and systematic review are presented. In Section III we present the conducted systematic review. In Section IV we discuss about achieved results. Finally, in Section V we summarize our contributions and discuss perspectives for further work.

II. Background

During the 90s, the concept of reference architecture emerged [12] and since there it has more and more attracted attention of both academy and industry. Reference architecture is a special type of architecture that captures the essence of the architectures of a collection of systems of a given domain. The purpose of a reference architecture is to provide guidance for the development of architectures for new systems or extended systems and product families. In other words, they can be seen as a knowledge repository of a given domain. Therefore, as already stated previously by Basili et al. [12], when correctly implemented, reference architectures can yield to several benefits, including: productivity gains, accelerate the time-to-market, increase the overall product quality, streamline the software development, lower the production costs and the maintenance effort. It is worth highlighting that the increase of productivity, acceleration of time-to-market and the arise of quality are benefits shared with agile methodologies [8].

The first association of software process with the word *agile* was used in 1998 [13], although many claim that the agile methodologies themselves existed long before they were formalized. Later in 2001, a group of practitioners of those methodologies gathered and summarized their experience in what was named *The Agile Manifesto*[4]. In short, its main principles are [9]: individuals and interactions over processes and tools; working software over comprehensive documentation; customer collaboration over contract negotiation; and responding to change over following a plan. However, it is not possible to exactly define agile methodologies, since specific practices vary with the methodologies. In spite of that, short time boxed iterations with adaptive, evolutionary refinement of plans and goals is a basic practice that these methodologies share [9]. Even apparently against the agile methodology principles, the use of reference architectures in agile methodologies seems to be interesting, aiming at exploring advantages of both in a more effective software development.

In another perspective, it is noticed that when a research area is mature, there is almost always an increase in the number of reports and results made available. During the study of a new knowledge area, researchers usually conduct a bibliographical review (almost always an informal review) to identify publications related to a specific subject. However, this kind of review do not use a systematic approach and do not offer any support to avoid bias during the selection of the publications that will be analyzed. Thus, it is important to have mechanisms to summarize and provide an overview about an area or topic of interest. For this EBSE has investigated and proposed the use of systematic review technique [11]. In this context, an individual evidence (for instance, a case study or an experimental study divulged in a publication/paper) which contributes to a systematic review is called primary study, while the result of a systematic review is a secondary study. Systematic review aims at providing an overview of a research area to assess the quantity, quality and type of primary studies existing on a topic of interest. In short, systematic review is conducted by planning, conduction of search and screening of primary studies using inclusion and exclusion criteria [11]. Besides that, systematic review also conducts data extraction and quantitative and qualitative analysis through the of the primary studies. Thus, systematic review has been increasingly conducted in Software Architecture area [14], [15] and seems also to be interesting in our work.

[4]http://agilemanifesto.org

III. Conducted Systematic Review

The main objective of our systematic review was to possibly identify all primary studies that explore reference architectures in the context of agile methodologies. This systematic review was conducted from October/2010 to January/2011 and involved three people (one researcher in software engineering, one specialist in systematic review and one graduate student). In order to conduct the systematic review, we have used the process presented in Figure 1. In short, it is composed by three steps: (i) Planning of the systematic review; (ii) Conduction of the search and data extraction; (iii) Reporting of results of the qualitative and quantitative analysis. These steps are explained in more details during presentation of our systematic review. Following, we detail each step.

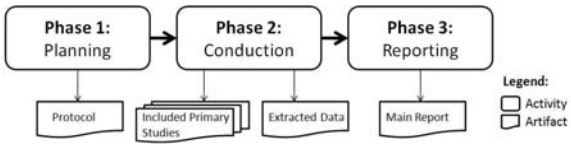

Fig. 1. Systematic review process (Adapted from [11])

A. Step 1: Planning

In this phase, we established the systematic review plan. For this, we specified: (i) research questions; (ii) search strategy; (iii) inclusion and exclusion criteria; (iv) data extraction and synthesis methods.

1) **Research Questions**: These questions are structured corresponding to the objective that is intended with

the systematic review and drive the review for further steps. Considering that our objective is the identification of the detailed view involving reference architectures and agile methodologies, the following research questions (RQ) were established:

RQ1: What is the current state of the adoption of reference architectures in agile methodologies?

RQ2: What are the benefits and limitations provided by the adoption of reference architectures in agile methodologies?

RQ3: Which are the agile methodologies that have adopted reference architectures?

2) **Search Strategy**: In order to establish the search strategy, considering the research questions, we identified initially the main keywords, as illustrated in Table I. We considered possibly all terms and their synonymous in order to cover the range of published studies. It is worth highlighting that the keywords chosen must be simple enough to bring many results and, at the same time, rigorous enough to cover only the desired research topic.

TABLE I
KEYWORDS SEPARATED BY AREA

Area	Keyword
Reference Architecture	"Reference Architecture", "Reference Model"
Agile Methodologies	"Agile Methodology", "Scrum", "Extreme Programming", "Agile Unified Process", "Feature Driven Development", "Agile Modeling", "Rapid Application Development", "Lean Software Development"

The search string is then built based on the keywords and using boolean connectors (such as AND/OR). The search string used in our systematic review was:

```
("Reference Architecture" OR
 "Reference Model")
AND
("Agile Methodology" OR
 "Scrum" OR "Extreme Programming" OR
 "Agile Unified Process" OR
 "Feature Driven Development" OR
 "Agile Modeling" OR
 "Rapid Application Development" OR
 "Lean Software Development")
```

In addition to the research questions and search strategy, we selected larger publications databases as sources of primary studies: IEEE Xplore[5], ACM Digital Library[6], Springer Link[7], Scirus[8], Web of Science[9], ScienceDirect[10], and SCOPUS[11]. Those sources are cited in [16] as trusted and efficient to the Software Engineering context. Furthermore, we decided that only papers written in English would be considered, since English is more widely adopted to write scientific papers.

3) **Inclusion and exclusion criteria**: The selected primary studies need to be assessed for their relevance, enabling the inclusion of studies that provide evidence for research questions as well as the exclusion of studies that do not. This is achieved by the definition of the Inclusion Criteria (IC) and Exclusion Criteria (EC). Thus, the inclusion criteria of our systematic review were:

IC1: The study involves software development using reference architectures and agile methodologies;

IC2: The study presents benefits and limitations by exploring reference architectures in the context of agile methodologies; and

IC3: The study presents which agile methodologies have explored the use of reference architectures.

The exclusion criteria established were:

EC1: The study does not address the use of reference architecture in agile methodologies;

EC2: The study presents an abstract and/or an introductory section that seem related to reference architecture and agile methodology; however, the rest of the text is not in fact related to;

EC3: The study does not present any abstract or it is not available for further reading;

EC4: The study is written in a different language than English;

EC5: The study is directly related to another primary study of the same author; and

EC6: The study consists of a compilation of work, for instance, from a conference or workshop.

4) **Data extraction and synthesis methods**: In order to extract data, we plan to analyze each research question. This analysis must synthesize results aiming at facilitating to obtain conclusions. During the extraction process, the data of each primary study will be independently extracted by two reviewers. If disagreement occurs, discussion will be conducted.

B. Step 2: Conduction

In this step, we conducted the search of primary studies and obtained them according to previously established plan. This was achieved by performing a search in the selected databases using the previously established search string. In order to enable the correct results to be delivered, the

[5]http://www.ieeexplore.ieee.org
[6]http://www.portal.acm.org
[7]http://www.springer.com/lncs
[8]http://www.scirus.com/
[9]http://www.isiknowledge.com
[10]http://www.sciencedirect.com
[11]http://www.scopus.com

search string were adjusted for each specific database and its mechanisms. As a result, a total of 351 primary studies were found; also, 85 studies were duplicated, and thus we analyzed in fact 266 studies. Domain experts pointed out two other studies, which we also included in our analysis, expanding the number of studies to 268.

To support the organization and manipulation of the primary studies, we used JabRef[12], an open source reference manager system. It made possible to store information on the primary studies (including, for instance, title, authors and abstract), as well as the inclusion/exclusion criteria applied to select the primary studies.

Following, the inclusion/exclusion criteria were then applied to select the relevant primary studies. Table II summarizes the number of primary studies obtained in each database and those selected after applying the selection criteria. From a total of 353 primary studies previously identified, only six studies (i.e. 1.70 %) were selected as relevant. It is observed that Scirus was the most effective source, because although it returned the smallest result set (two studies), one was relevant for our systematic review. In Table III we presents the six selected primary studies (S1 to S6). From a total of six included primary studies, one was published in 2003, another in 2006 and four in 2008. This does not indicate statistically a trend, but a growth in the interest for that research area. It is important to note that only studies published until December/2010 were considered in our systematic review.

TABLE II
PARTIAL AND TOTAL AMOUNT OF PRIMARY STUDIES INCLUDED AND EXCLUDED

Source	Included	Excluded	Total Found
ACM Digital Library	0	5	5
IEEE Xplore	1	96	97
Scirus	1	2	3

ISI Web of Knowledge	0	3	3
ScienceDirect	0	132	132
Scopus	1	6	7
Domain Experts	2	0	2
Total	6	347	353

C. Step 3: Reporting

In this step, a qualitative and descriptive analysis was conducted on each selected primary study, enabling us to achieve more accurate conclusions. Linden et al. [17] (study S1) presented a case study using a reference architecture together with XP methodology in order to develop a software system for the medical area as a distributed, component-based and standard-based system with a multi-tier architecture. For this, a reference architecture, more specifically the Reference Model for Open Distributed Processing (RM-ODP)[13], was used. According to Linden et al. [17], this architecture made possible the use of software components; component reuse and refactoring saved development time and cost, at the same time assuring the software quality. This study does not explicitly address the benefits or disadvantages of using reference architecture together with XP; however, besides advantages provided by XP, such as possibility of managing volatility in requirements and TDD (Testing-Drive Development), the adoption of reference architecture has contributed in a positive way. Since this system is based on a reference architecture, according to the authors, it could be ported to another domain without much effort.

Other two studies – S3 [20] and S5 [19] – adopted agile methodologies in the context of Software Product Line (SPL) [22], that has the reference architecture (also referred as product line architecture) as one of the main basis elements to the software development. Specifically, Kakarontzas et al. [20] adopted an agile practice — the TDD — as a complementary activity to the software development using SPL. As main result, TDD made easier the evolution of the software components of a product line and enabled better reuse decisions. In spite of SPL presents sometimes a more rigid process, TDD can work harmoniously in this context [20]. Another work was conducted by Hanssen and Fægri [19] that presented a case study in the context of the software industry where they integrated SPL and practices from agile methodologies. This case study observed that SPL and its reference architecture creates a controlled environment and solid planning while agile practice exploits the creativity potential of the developers and constant releases. In other words, SPL is more responsible for the long-term strategy planning, while agile practice enables the short-term dynamism. In the same perspective of SPL, Carbon et al. [18] (study S2) combined practices of agile methodologies and Product Line Engineering (PLE). In particular, Carbon et al. proposed an iterative process inserting agile practices within a reuse-centric environment of PuLSE-I, an application engineering process that is a part of PuLSE (Product Line System and Software Engineering), a process for PLE [23]. Its objective is to establish a reference architecture that is flexible in respect to a class of anticipated changes, at the same time that agile practices accelerate the application engineering process and the maintenance of the reference architecture. As main conclusions, they pointed out that for projects in which changes happen with frequency and can be predicted with certain accuracy, flexible up-front design pays off in the long run, despite being more time consuming at first. On the other hand, for projects which will last for an unknown period and

S3	Hanssen, G. K. and Fægri, Tor E. [19]	Process fusion: An industrial case study on agile software product line engineering	2008	ScienceDirect	IC2, IC3
S4	Fernándes, J.D., Martínez-Prieto, M.A., De La Fuente, P., Vegas, J., Adiego, J. [10]	Agile DL: Building a DELOS-Conformed Digital Library Using Agile Software Development	2008	Scopus	IC1
S5	Kakarontzas, G., Stamelos, I. and Katsaros, P. [20]	Product Line Variability with Elastic Components and Test-Driven Development	2008	IEEE Xplore	IC1
S6	Hadar, E. and Silberman, G. M. [21]	Agile architecture methodology: long term strategy interleaved with short term tactics	2008	Domain Expert	IC1, IC2

for which changes can not be anticipated, it seems better to use incremental approaches. Moreover, it was identified that there are several potential benefits of the adoption of both PLE and agile methodologies, such as increase of agility of a product line organization, error reduction, and increased time-to-market. Nevertheless, this work stated also that more researches are needed on the combination of those approaches.

Fernándes et al. [10] (study S4) described a development team that used Scrum to implement a digital library system using a reference architecture of that domain. As main benefits, this study pointed out reduction in the development effort and less misunderstandings during the software development. The nature of Scrum allowed the delivery of several intermediate versions of the software. Scrum enabled the creativity in a controlled environment and constant feedback on the deliveries, where the reference architecture dictated the horizon.

Hadar et al. [21] (study S6) introduced the CA Agile Architecture (C3A) method, which aims at providing a view for both long-term strategic architectural evolution and short-term agile incremental development. The method proposes a reference architecture documentation granularity, with a set of one-page architecture component contracts, where each of them has a responsible which keeps the contract updated. The evolution of the reference architecture together with its implementation is modeled into a cyclic process, composed by evaluation and evolution. Thus, it is possible to have agile software development at the same time that the reference architecture is built and maintained.

Following the description of each primary study, we discuss each research question established previously:

RQ1: This question is related to the current state of the adoption of reference architectures in agile methodologies. We can observe that although agile methodologies have been increasingly adopted in the software industry [8], their adoption together with reference architectures has not been sufficiently explored as a research line up to this date;

RQ2: It refers to benefits and limitations provided by the adoption of reference architectures in agile methodologies. The most of the studies have pointed out on benefits of the adoption of reference architecture together with agile methodologies than limitations. Amongst the benefits, the most cited are the reduction of the overall error rate in the projects and also the reduction of the delivery time. On the other hand, there is a lack of more detailed analysis about the negative impacts of reference architecture in the context of agile methodologies; and

RQ3: It refers to agile methodologies that have adopted reference architectures. We have observed that Scrum and XP have been used in projects involving reference architectures. It is worth highlighting that those methodologies have been pointed out as one of the most used in the software industry and, according to [8], Scrum has been used in 10.9% and XP in 2.9% of the all companies. Thus, more case studies involving Scrum, XP and reference architecture could be interesting. Furthermore, some agile practices, such as TDD, have also been explored together with reference architectures.

IV. DISCUSSION

In spite of considerable relevance of reference architecture in the software development, as well as also positive impacts of agile methodologies in the software development, including in the software industry, exploring reference architecture and agile methodologies in the coordinated manner seems to be interesting. However, our systematic review found only six works in the published literature. This works are in general recent and are important initiatives in this direction.

Regarding research questions established for our systematic review, it is observed that all of them were answered. This suggests that, the general, knowledge about reference architectures in agile methodologies has been mapped. We

believe that results presented in this work are representative of the whole software engineering domain, since systematic review has provided mechanism to achieve it.

We have also observed that the included primary studies have been published in different vehicles (four in conference proceedings and two in journals, including of different subjects, such as related to medical area). In other words, they are not concentrated, for instance, in only software architecture or agile methodology conferences. In this perspective, the conduction of a systematic review seems to be an adequate choice, aiming at finding possibly all primary studies in this context.

In spite of the achieved results, our systematic review could be conducted again, aiming at inserting also primary studies published until now. For this the systematic review protocol has been established and divulged. Besides that, relevant primary studies written in other languages can have been ignored, since we considered only paper in English. Although the databases used in our systematic review are usually considered efficient sources to Software Engineering area, other databases, such as Compendex[14] and Google Scholar[15], could be included.

Considering knowledge arisen from this work, it is possible to identify interesting and new research lines, such as (i) conduction of qualitative and quantitative analysis regarding, for instance, cost/effort reduction and software quality improvement, of using reference architecture in specific methodologies, such XP and Scrum; and (ii) exploring reference architectures in other agile methodologies.

V. Conclusions

The main contribution of this work is to present an encompassed view about the adoption of reference architectures together with agile methodologies. For this, we applied systematically a set of steps provided by systematic review. As main result, we can conclude that more attention should be given for that topic, since both reference architecture and agile methodology have contributed with considerable advantages to software development. Furthermore, we intend that this view opens perspectives of new and important research lines, contributing to a more effective and successful software development.

Acknowledgments: This work is supported by Brazilian funding agencies: FAPESP, CNPq and Capes. The authors would like also to thank the anonymous reviewers for their valious comments and suggestions, which certainly contributed to improve this paper.

***Abstract*—Agile processes are expected to follow a set of well known agile principles and practices. This paper analyses the utilization of an agile process in a project that imposes certain difficulties in meeting such principles and practices in their totality, particularly those that refer to daily face-to-face communication among team members and frequent delivery of new versions of the product in short periods of time within a predictable schedule. A process based on Scrum was adapted to be utilized in a project which had its members distributed in different locations and that required the utilization of emergent technologies not familiar to the developers.**

Keywords-Agile principles; agile methods; agile practices; Scrum

I. INTRODUCTION

Since the appearance of agile methods [1], several software development companies that refused to adopt traditional software processes (e.g. the Unified Process [2]), started to adopt agile methods. Such methods value "individuals and interactions over processes and tools" and "working software over comprehensive documentation". What can be observed in practice is that the development of low complexity applications, when performed by small teams, does not require a bureaucratic software process, which explains why agile methods seem like a good fit in those situations.

Agile methods are defined according to agile principles [1]. The processes described by such methods include the so called agile practices, that is, practices that help developers follow those principles accordingly. Some of these principles are focused on having people working together and meeting in a daily basis. In the agile method Scrum [3], for example, these principles are followed by the practice of daily meetings. Other agile principles state that working software must be delivered frequently, preferably in short periods of time within a predictable schedule. That can be accomplished in Scrum by simple practices such as having Sprints restricted to a specific duration. However, constraints eventually imposed to the development process may prevent the team from adopting even simple practices such as daily meetings or time-boxed Sprints.

This paper analyses the utilization of an agile process in a project (case study) that imposes certain difficulties in meeting agile principles and practices in their totality, particularly the ones mentioned above. The case study in question refers to the development of a web application for storing and managing electronic documents. One of the difficulties faced in this project was that the development team, though small, did not work every day at the same place, which prevented the adoption of daily meetings. Another difficulty was that the application being developed, though of relatively low complexity, involved the use of emerging technologies that the development team was not familiar with. This generated certain uncertainty around iteration planning in the sense that iterations might not be set to a fixed duration or offer the guarantee to produce working software at the end, thus neglecting the agile principles and practices already mentioned. This process utilized in the referred project was based in Scrum, adapted with practices that try to compensate for the difficulties in following agile principles and practices in their totality.

The paper is organized as follows. In Section 2, agile principles are revisited, along with the agile practices proposed in Scrum. Section 3 briefly describes the case study. Section 4 presents the constraints imposed to following all agile principles and practices for the case study, along with adaptations made to compensate for those constraints. Section 5 presents the process utilized in the case study in more detail. Section 6 contains a discussion about the adaptations necessary to the agile process. Section 7 concludes the paper.

II. AGILE METHODS AND SCRUM

Agile methods are software development methods which apply the iterative and evolutionary development, employ adaptive planning, promote incremental delivery, and include other values and practices that encourage agility. They are best suited for projects characterized by changing, speed and turbulence.

In beginning of 2001, a group of agile methods followers created the agile manifesto containing agile principles that all agile methods should follow [1]. These principles are reproduced below:

"1. Our highest priority is to satisfy the customer through early and continuous delivery of valuable software.

2. Welcome changing requirements, even late in development. Agile processes harness change for the customer's competitive advantage.

3. Deliver working software frequently, from a couple of weeks to a couple of months, with a preference to the shorter timescale.

4. Business people and developers must work together daily throughout the project.

5. Build projects around motivated individuals. Give them the environment and support they need, and trust them to get the job done.

6. The most efficient and effective method of conveying information to and within a development team is face-to-face conversation.

7. Working software is the primary measure of progress.

8. Agile processes promote sustainable development. The sponsors, developers, and users should be able to maintain a constant pace indefinitely.

9. Continuous attention to technical excellence and good design enhances agility.

10. Simplicity--the art of maximizing the amount of work not done--is essential.

11. The best architectures, requirements, and designs emerge from self-organizing teams.

12. At regular intervals, the team reflects on how to become more effective, then tunes and adjusts its behavior accordingly."

A development method is considered agile if it provides agile practices that follow the principles listed above. Among the most common agile methods are: Scrum, XP, DSDM, Lean, Crystal, FDD and ASD [4]. The agile method Scrum is detailed next for being the basis of the agile process utilized in this work.

A. *Scrum*

The method Scrum was created by Ken Schwaber and Jeff Sutherland in the 90's and its purpose is to manage the system development process [3]. As it is generally devoted to process management, practices related to more specific software development activities such as requirements gathering, software design and programming are not detailed in Scrum. As observed in [5], those practices are usually borrowed from XP, and are out of the scope of this paper.

Scrum defines the following agile practices:

- *Scrum Master*. The person who is responsible for ensuring that Scrum values, practices, and rules are enacted and enforced.
- *Product backlog*. A repository containing all system requirements (features, functions, technologies, enhancements, and bug fixes). These requirements are organized in a priority list.
- *Scrum Team*. A group of people that will develop a set of items from the Product Backlog during an iteration (Sprint). It is recommended to include seven people, plus or minus two, but teams with 3 people are also allowed.
- *Daily Scrum Meetings*. 15-minute meetings that promote the face-to-face communication among Scrum Team members. During this meeting, members of the team are supposed to explain what they have accomplished since their last meeting, what they intend to do before the next meeting, and what difficulties they are facing.
- *Sprint*. This refers to one development iteration. The development must be divided into fixed sprints that take, each one, 30 days. Once project members have developed more experience with Scrum, adjustments can be made to the duration of the sprints.
- *Sprint Planning Meeting*. This is the meeting to plan the next sprint. At this meeting, the Scrum Team decides what functionalities and technologies will be developed during the sprint.
- *Sprint Review Meeting*. 4-hour meeting that happens in the last day of the sprint. This is the meeting for the team to present and review the product increment developed during the sprint. It must be coordinated by the Scrum Master.
- *Sprint Backlog*. A repository containing those requirements selected from the Product Backlog to be developed during the next sprint.

Fig. 1 briefly shows the Scrum process. Initially, all functionalities, features, and technologies are included as items in the Product Backlog. During the project, instead of being static, the Product Backlog evolves along with the product. In each sprint, the Scrum Team selects as many items from the Product Backlog as they think they can develop during the iteration, and these items are included in the Sprint Backlog as a list of tasks. Throughout the entire sprint, a short meeting conducted by the Scrum Master, called Daily Scrum Meeting, happens to review the progress and identify impediments. At the end of each sprint, an increment of the product including new functionalities is delivered; members of Scrum Team all gather for a meeting, the Sprint Review Meeting, where that product increment is inspected. Finally, the Product Backlog is reorganized and prioritized, and the items with higher priority are selected for the next sprint.

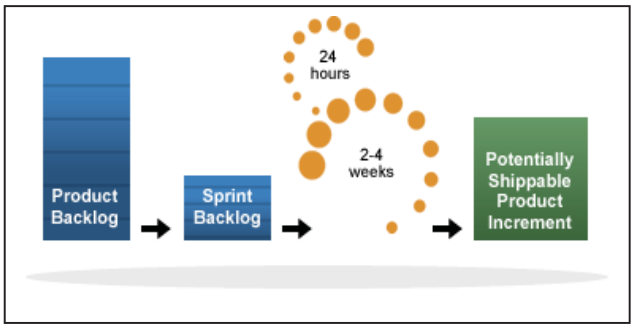

Figure 1. Scrum Process *(http://www.scrumalliance.org/learn_about_scrum)*

Scrum members can play the following roles:

- *Scrum Master*: the person responsible for the success of the project. As already mentioned, it is the Scrum Master who has to ensure that the values, practices and rules of Scrum are performed and enforced accordingly;
- *Product Owner*: the one person who is responsible for managing and controlling the product backlog;
- *Team Members*: those responsible for achieving the target goal set for a sprint.

III. CASE STUDY

The case study utilized in this paper refers to the development of a web application for storing and managing electronic documents. It consists essentially of a web-based user interface to a core document service already implemented. That core service was made available to team members as an API for the Java language. A non-functional requirement was that the implementation of such a web application should rely on the latest version of the JSF framework (i.e. Java Server Faces version 2.0) that had been recently released.

The team was composed by four people. All of project members had significant experience with Java. The Scrum Master had good experience in project management and could spend four hours a week in this project. The Product Owner also played the role of a team member (i.e. developer). This person had developed the code of the document service back end to be utilized in this project, thus having good knowledge about the application domain, which is why was assigned the role of Product Owner. This person could spend ten hours a week in this project: four hours as Product Owner, and six hours as a development team member. The remaining two people were regular team members and they were considered beginners in regard to the technology utilized in the implementation, particularly the JSF-2 framework. They could dedicate twenty hours a week to this project.

The entire project should not exceed four months due to budget restrictions, which is why adopting some sort of agile process was considered imperative by all project members.

IV. CONSTRAINTS TO THE AGILE PROCESS

The development process utilized in the case study had to be defined with the following constraints in mind:

- *Distributed Team.* Team members would not be working at the same place every day and face-to-face meetings could be held only once a week.
- *New Development Technologies.* Team members were not very familiar with some of the development technology utilized in the project.

It is important to note that, although all the participants did not work at the same place, they were all in the same city. In fact, they could meet once a week. They could also schedule sporadic face-to-face meetings in case some crucial issue had to be addressed. Therefore, this project did not have most of the difficulties commonly found in distributed agile development such as culture, time zone, communication, customer collaboration, trusting, training and technical issues [6].

The process utilized in the case study was based on Scrum. However, some of its practices had to be modified in order to cope with the constraints mentioned above. Therefore, the following decisions regarding the adaptations necessary to the process were made:

- *Utilize a web-based tool to support the process.* As project members would be working at different places in the same city, they decided to utilize a web-based tool to support the process, not only to allow all members to monitor the execution of sprints, but also to serve as a means of communication between them. In addition to providing support for managing the Product Backlog and monitoring the development of sprints, the tool in question should have some sort of wiki or blog associated with Product Backlog items (stories and their tasks) with the capability of notifying (preferably through e-mail) those involved about new entries in the wiki.
- *Eliminate daily meetings.* Despite daily meetings being one of the most important practices of Scrum [3], it was necessary to remove them from the software process because project members were unable to meet daily. The possibility of having daily meetings through video web-conferencing was considered, but there was the additional difficulty of team members having disparate working hours on certain days of the week. So, they decided to adopt only weekly meetings for monitoring the sprints. It would be up to the Scrum Master and other project members to monitor and update the entries in the wiki daily in order to identify and resolve any issues that might come up during the development of sprints.
- *Permit sprints with extendable length.* Most of the programming to be carried out in sprints was expect to utilize a new technology not yet dominated by developers. Initially, the sprints had their duration set to two weeks. However, some of the first sprints showed a delay between 10% and 25% compared to the estimated time. Project members realized that the main reason for the error in estimating sprints was the difficulty in predicting the time developers needed for learning the new technology. In a situation like that, it is recommended that the Scrum Master speak with people who understand the technology [3]. However, no one with that knowledge was available to contribute to the project. It was then decided that the Scrum Master would have the power to increase the duration of the sprints by 25% in case the delay had been caused by the lack of experience with the technology involved. Therefore, instead of being sent back to the product backlog in order to be incorporated into a new sprint (as recommended in [3]), the tasks that could not be completed by the end of a given sprint would remain in

that same sprint, which would have its length increased by up to 25% (the exact percentage should be set by the Scrum Master during the weekly meeting). The idea behind that decision was to prevent a newly created sprint from causing team members to lose their focus on the issues related to learning the new technology, and also to save the team from unnecessary frustration resulting from a significant number of sprints not being completed.

These adaptations introduced into the process were shown to be adequate to the project in question and to the profile of the project team. Table 1 summarizes the agile principles and practices that had to be neglected due to such adaptations and why they were considered necessary.

TABLE I. AGILE PRINCIPLES AND PRACTICES NEGLECTED

Principles/Practices	Constraint	Adaptation
Agile Principle: The most efficient and effective method of conveying information to and within a development team is face-to-face conversation. Scrum Practice: Daily Scrum Meeting	Team members do not work at the same time or place and are not capable of meeting every day	Longer weekly meetings to monitor the sprint Web based tool to support the process and communication between all project members
Agile Principle: Business people and developers must work together daily throughout the project	Project Owners are not available for meeting with the development team every day	Web based tool to support the process and communication between all project members
Scrum Practice: Time Boxed Sprints	It is not always possible to make a precise estimate of the time taken by sprints because of new technologies involved	Extendable Sprint that can last up to 25% beyond its initially estimated length (according to the judgment of the Product Owner at the Sprint Meeting)

V. DEFINING A NEW AGILE PROCESS

The agile process that resulted from the modifications mentioned above is generically described by the steps below. Note that the roles played by project team members are the same ones defined in Scrum: Scrum Master, Product Owner and Team Member.

A. *Definition of the Product Backlog*

This step aims to define an overview of the application, and it consists of a list with an initial description of the stories and a list of non-functional requirements. The stories are included in the Product Backlog, just like in Scrum, with the exception that, in this case, it assumes the utilization of a workgroup tool (preferably web-based) that provides support to creating and managing the backlog and monitoring the development process. As new stories are identified, they are included into the Product Backlog.

B. *Sprint Planning*

The duration of each sprint should be 1 to 3 weeks. The sprints can have their time length increased by 25% in case of error in the estimate due to the lack of experience with new technologies. Sprints of 4 weeks are not permitted because a 25% increase would result in a sprint of five weeks, inconsistent with the recommendations of Scrum.

The stories of the Product Backlog that will be part of the sprint should be selected according to the time estimated for its development, following the method Planning Poker [7] with the participation of all project members. However, considering that team members may not be familiar with the technology to be utilized in application development, or difficulties imposed by the distance between team members, it is acceptable to have only the Scrum Master and Product Owner participate in Planning Poker time estimations.

After stories have been allocated to the Spring Backlog, it is necessary to verify that the description of each selected story is detailed enough to be understood by team members. If necessary, the description of the story should be more detailed. These details could include the sketch of a screen layout, an operating example, or even part of the programming code. This is important to avoid fundamental questions about the story descriptions that would normally be resolved during the daily meetings.

Once reviewed, each story is divided into tasks. The tasks, in turn, may also be detailed, and each task is assigned an estimate of effort and time for execution. It is not required that a story is sub-divided into tasks, but it may be necessary to define a task within the story if the tool utilized to support the process requires it.

Finally, tasks are distributed to developers. This distribution is so that developers can benefit from the knowledge acquired in previous tasks regarding the technology (or component) necessary to perform those tasks.

C. *Daily Notification Monitoring*

As this process does not include the daily meetings originally proposed in Scrum, it is necessary to monitor notifications triggered by the Scrum Master or other team members. This assumes that the Scrum Master and team members are not always at the same place, and the execution of this step requires the utilization of a workgroup tool that allows team members to submit their questions and complaints to the Scrum Master.

D. *Sprint Design and Coding*

This step is devoted to applying any design techniques considered appropriate for a given project, such as sequence diagrams and design patterns, and writing the corresponding implementation code to be compiled and run in the target platform.

E. *Weekly Meeting*

Participants must schedule a weekly meeting to be held by all project members. Whenever possible, members should meet in person, otherwise through video conference. If the meeting is held at the end of the sprint (Sprint Meeting), it may last up to three hours. In such a Sprint meeting, the Scrum Master can evaluate how the stories that were not completed will be handled and whether or not the sprint will have its duration augmented. If it is just a regular meeting to monitor the sprint, the Sprint Backlog must be partially reviewed and discussed, and it can last no longer than 2 hours.

F. *Code Delivery*

After each sprint, the code must be made available to both the Product Owner and the Scrum Master so they can verify the functionality implemented in that sprint.

VI. DISCUSSION

The development of an application that utilizes emerging technologies not well known by the developers brought up some important aspects related to utilizing agile methods for that task, which are discussed next.

When a new technology is being utilized, the time spent to learn this technology has to be computed in the time allocated for the development of the stories selected in a sprint. However, it is often quite difficult to determine the time required to learn that technology, which normally leads to errors in estimation. One solution to avoid that problem is to allocate a period of training for developers prior to development. However, this can cause an unnecessary delay to the start of the project as developers can be more efficient to learn about the new technology while they are trying to address specific issues related to the tasks of each sprint. For this reason, the process described here assumed that the time required to learning that technology should be estimated as part of each sprint.

Another solution to the problem of incorrectly estimating the time allocated to each sprint would be to assign the stories and respective unfinished tasks back to the Product Backlog, as suggested originally in Scrum [3]. This solution was not adopted here to prevent team members from being held responsible for unfinished sprints. Project team members found better to allow the length of the sprint to be increased in up to 25%, provided that the delay was related to technologies that developers were not familiar with.

It is important to point out that as developers become familiar with new technology, it is no longer considered new and therefore the time that was once required for learning that technology can no longer be included in the sprint time estimation.

In the case study described earlier, the time originally allocated for development was 3 months (13 weeks), divided in 8 sprints. As a considerable number of sprints have had their duration time increased, the development ended up taking 16 weeks to complete. Fig. 2 presents a graphic showing the estimated time and the actual time spent in each sprint. Note that this project involved the development of a graphical user interface (UI). Some agile processes suggest that the design of all UI must be done prior to regular iterations [8] and some suggest that UI design is performed in parallel to product development [9]. Since the project in question could not count on a UI specialist in usability, as suggested by [10], and considering that the UI was relatively simple, it was up to the Product Owner to sketch some of the UI screens, which were utilized to complement the description of the stories.

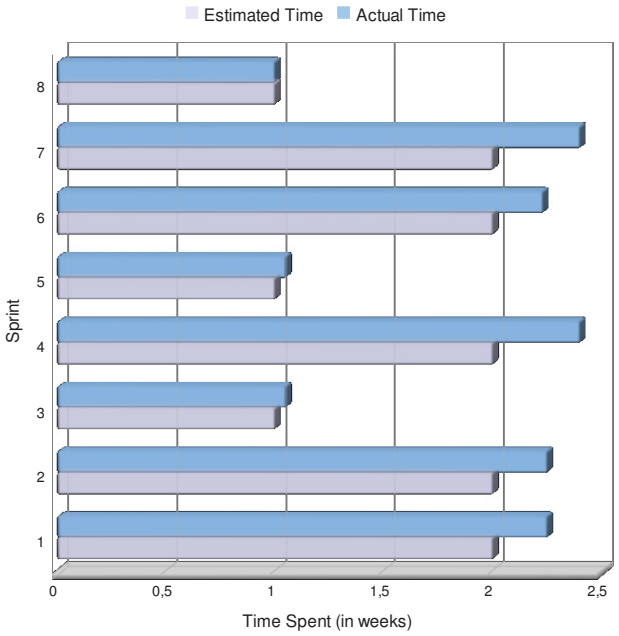

Figure 2. Duration of each Sprint

Another point of discussion is the amount of description included in each story and task. As suggested in [11], the stories can be detailed to make them more understandable for the developers. Usually, this description should be concise. However, when developers have no prior knowledge of a technology being utilized or lack a complete understanding of application requirements, detailing the stories and tasks increases their productivity in development. That also helps in situations where project members are physically apart.

As suggested in [12], it is important to modify or replace a practice, rather than simply delete it. Regarding daily meetings, an agile practice defined in Scrum, it seems possible to replace them by electronic communication without large apparent losses, provided that an appropriate tool is utilized. When there is no possibility of having daily meetings, the communication through a tool seems to be the best option to keep track of problems that are occurring daily as opposed to address these problems only after the weekly meeting.

A common practice of Scrum is to use a task board. Since the development team was not working at the same place, the use of a task board to record tasks not started, in progress and completed seemed useless. However, that was compensated by the web tool selected, which allowed to have tasks assigned to each team member and keep track of the status of each task (not started, in progress and completed).

VII. CONCLUSIONS

This paper presented the development of an application using an agile process. This process was based on the agile method Scrum, but it was adapted according to some development and project team constraints. Although neglecting some of the most known agile principles and practices, the resulting process was successfully applied to a software project without affecting the agility of its development.

The agile process defined in this work neglects two agile principles defined in the Agile Manifesto [1], particularly those that say that development teams must work together daily and that information should circulate among team members in face to face conversation. However, it was possible to observe that agile processes can also be applied to projects that do not allow such agile principles and practices to be completely followed, provided these are compensated by appropriate practices or tools. In the case study presented here the daily meeting practice had to be replaced by a weekly meeting. The lack of a daily face to face communication was compensated by the adoption of a web based tool that notifies project members about questions or issues faced throughout the sprint.

One important adaptation incorporated to the development process described here was to allow extendable sprints. Instead of having time-boxed sprints, the time allocated for each sprint could increase by 25% provided that the delay was caused by errors in estimating the time required for the developers to become familiar with the new technologies utilized in development.

***Abstract*—This paper deals with a tool developed to support training and education in the field of security and safety in work areas, plants, or industrial environments. The tool comprises the dashboards enabling administrators and users to simulate risks and accidents to be ready for interventions in case of occurrence. Based on a computational model of risks, able to identify the causes and the signs which precede accidents, to enact prevention mechanisms, and to execute repair actions in order to avoid accidents, this paper presents a Risk Simulation Management (*RSM*) system and its functioning on some examples.**

Keywords-risk; simulation of risks; preventive strategies.

I. INTRODUCTION

Most accidents in work areas (e.g., plants or construction) are announced by events signalling risky situations, which may be identified and managed through preventive strategies before they evolve into actual accidents. In other cases, an accident determines an emergency situation that should be addressed through corrective strategies. The advances available in IT, service-based software, telecommunications and sensors networks, and safety garments may be exploited successfully in the identification of the risky situation which usually precedes and announces accidents, and their proper and timely management in order to avoid accidents or limit their damages.

In this paper, we describe our approach to risks in work areas and a prototype aimed at promoting education and risk-awareness through the simulation of risks. The idea behind our prototype is that risks are explicitly modelled, computed, and managed. To achieve this objective, we propose a prototype based on a risk computational model which identifies the environmental entities meaningful for the representation and computation of risks.

The contribution of this paper consists in the explicit modelling and computation of risks and their management functions. We define thresholds to identify operating modes (e.g., normal, risky and emergency), and propose a *probabilistic* computational model to handle risks in work areas and to put in places preventive strategies. When the situation is beyond the emergency threshold, a *deterministic* approach is applied and the system provides corrective strategies to handle the emergency. Software and hardware components for risk detection (e.g., sensors and detection devices) are simulated, so that we are able to embed simulated features of the available advances in areas such as location-awareness through antennas or tagging through RFID technologies. A risk is treated in a person-centred way, in that we handle a risk only when it occurs to persons during their interaction with tools, during the movement of machineries, or in relation to their protection from risky events. Currently, we deal with single risks only. The issues concerning compositions of risks are part of future developments.

The paper focuses on the architecture for implementing a *Risk Simulation Management (RSM)* system and introduces a scenario to train people to work in a risky environment by using our *RSM*. In particular, in previous work [9] we have explored how technologies can provide information about the individual who wears the computer sensors and services and the world which this individual interacts with. We also assume a Gaussian distribution for each risk source [14].

This paper is organized as follows. Section II introduces the risk management and assesment issues. Section III presents our approach to risk modeling. Section IV describes the simulation prototype. Section V addresses related work. Section VI contains conclusions and further work.

II. RISK MANAGEMENT AND ASSESSMENT ISSUES

The purpose of risk management is to obtain a balance between success, challenge, and failure. Risk management is aiming to foresee risks and prevent failures. But as the risk has its price, the prevention is not costless. For this reason, the central element of an enhanced risk management method is to make risks and the mitigating actions financially opportune. This makes it possible to establish the wanted balance.

A risk is the product of the possible effect of a threat and the chance that this threat occurs. In this paper we present our approach to risk identification and management based on the *Monitoring, Analyzing, Planning, Executing (MAPE)* loop [6].

The main elements in risk management are to identify and classify threats and to define the mitigating actions. For the identification of threats, there are two basic methods. The first is by brainstorming and collecting possible hazards to the desired situation (can be a steady state or project). A more

systematic method is to use predefined lists of hazards. Those lists are industry related e.g., banking and insurance, chemical industry, ICT [8], aerospace and circumstance related e.g., ICT outsourcing in banking and insurance [1], projects (e.g., the Prince2 project management method).

In Figure 1, the overall model for risk management with all affecting factors is shown. We see that a risk has an interaction with Actors, is of different Types, has various Effects and receives different Responses. Such modeling framework tackles risks from all viewpoints: technical, organizational, operational/tactical/strategic, and human-related issues.

For the classification of a risk effect, the simplest approach is to evaluate the effort in *financial terms*. Every ultimate effect of a threat is that it costs money to remove this effect. However, there are more possibilities to classify the effects of a risk. In the banking and insurance industry these are 'reputation' and the 'license to operate'. In other industries (like healthcare and the chemical industry) the amount of human damage will be a more important class of effects. In the end it helps to align all the classes to make it possible to count the balance between risk and remedy.

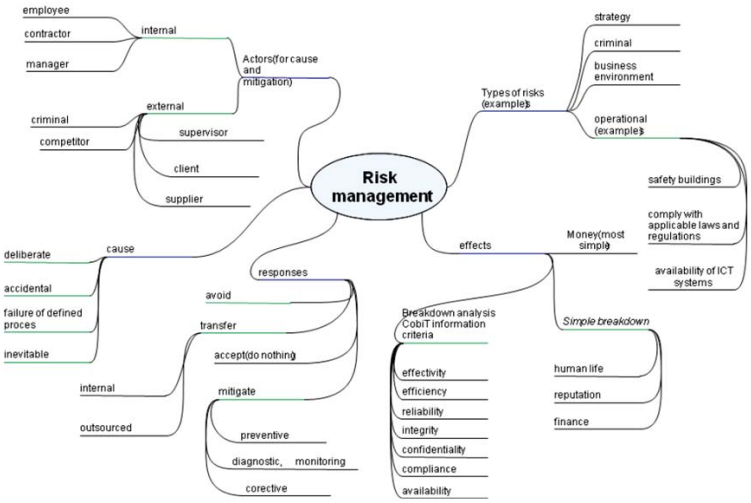

Figure 1. Comprehensive Risk Management Model

The mitigating actions consist out of three classes which are *prevention* (making the hazard cannot occur and/or the effect of the hazard minimal), *monitoring* (checking if the hazard does not occur) and *correction* (minimizing and removing damages when the threat takes place). *Simulation* is an example of a preventive risk management method. It makes it possible to check the completeness of mitigating actions and to train how to monitor and to act when a threat takes place.

III. RISK MODELING

Our approach *to risk modelling and simulation* starts with the technical points of the Risk Model in Figure 1. Using the MAPE loop, we observe an environment, detect the anomalies by analyzing the data collected through monitoring, decide if a risky situation occurred and if intervention/change is needed (and of what type), and put in place (execute) the planned modifications in the environment. Such a loop implements a self-healing [6] *RSM* able to detect and manage risky situations through *preventive* and/or emergencies through *corrective* actions. Specific preventive actions are put in place when the risk is between the *Risk Threshold* and the *Emergency Threshold.* Since some monitored parameters (e.g., the temperature) can reveal arising risks, the idea of preventive actions is that parameters can be evaluated using a *probabilistic* approach that computes the probability for the out-of-range parameter to evolve into a dangerous situation. *Preventive actions* are then suggested by the system to take the abnormal parameter back to normal values before the risk evolves further. Such actions range from checking a source of gas loss to sending preventive alarms to persons thorough their PDAs. Beyond the Emergency Threshold, there is an emergency and we move to a deterministic approach, using off-the-shelf, real-time *corrective actions* that patch the situation immediately.

A risk (or risky situation) occurs when one or more parameters through which the environment is monitored are out of their ordinary operation range. The causes (or sources of risks) may be various: loss of substances, machinery movements, or the interaction between the workers and tools. The computation of the risk (or emergency level) is supported by the pre-computed risk map related to the environment. The risk map is determined considering the location of risk sources and protection elements (including emergency exits).

The remaining of this section introduces the environment model and the risk computation through an example.

A. Entities Modeling

The overall modelling at the basis of Risk Simulation is centred on the *Environment*, the *Persons*, the *Tools* and the *Machineries*. These elements are both subject to risks and generate risk. *Informative Devices* (e.g. sensors) and *Protection Elements* (e.g., security garments) allow risks to be identified, avoided and/or faced. An entity can be either *static* (its location is fixed within the work area: a tool for example) or *mobile* (its location changes along time: persons or machineries).

A *plant* is a *ComplexEnvironment*, which may include open and closed areas. The topology of a plant is defined by the physical location of each area, its dimension attribute, and the proximity relationship. Each area has at least one access point (for entrance and exit), which may be used as emergency exit. We indicate the plant elements which may either be the source of risks or influence the computation of risks and their level, namely: access points (in/out openings); location of water and gas pipes and electrical wires; and windows, doors, emergency exits, and other unprotected open spaces.

A *person* represents a worker in the environment with an associated profile, containing: (1) *skills*: related to ability in use of tools and machineries; (2) *experience*: related to knowledge of security procedures and work organization; and (3) *roles*: worker, team head, visitor, administrator.

Persons use *tools* (e.g., hammers, saws, drills, diggers) or *machineries* (e.g., trucks). Both *tools and machineries* are characterized by the functionalities they offer and their fabrication date (an indicator of the risk in using them).

Informative devices model the technological elements needed for surveillance of the environments. They collect information from the environment and convey it to the *RSM* and receive information from a surveillance centre, allowing persons to be notified about the current situation in the area.

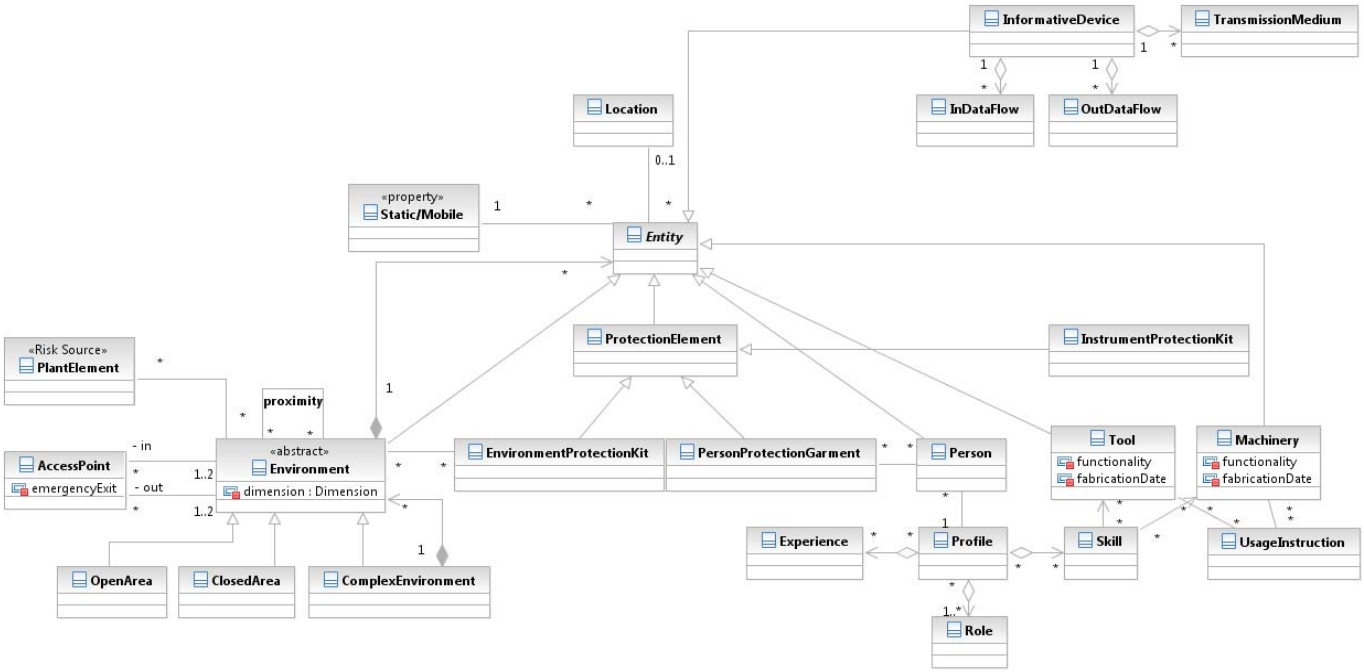

Figure 2. Modeling Entities for Risk Simulation

Protection elements are entities whose role is to prevent risks/emergencies by providing protection to persons, tools, and machineries. They are of three types (see Figure 2): (1) *person protection garments*: objects providing physical protection to persons (i.e. helmet, boots, jacket); (2) *environment protection kits*, which help persons to protect the environment in case of difficulty, or to escape quickly if necessary (e.g., fire protection kits and evacuation kits); and (3) *instrument protection kits*, which provide physical protection to devices, tools, and machineries.

B. Risk Computation

Suppose the environment structure is composed of five areas (see Figure 3). For each area, a risk map is defined. Assume that area A has a gas pipe loosing gas slowly and a team is present with tools and one machine (e.g., a truck).

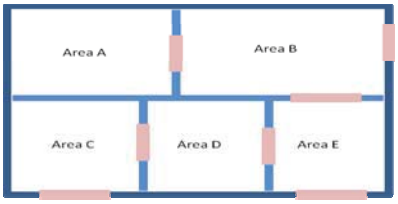

Figure 3. Map of a Work Environment

The *Risk Map* of Area A is defined as follows.

RiskMap (A) {
Fixed_Part = {Access Point (*Xap*,*Yap*), Window (*Xw*,*Yw*), GasPipe(*Xgp*,*Ygp*), DetectionDevice},
Dynamic_Part = {Team [(person,role)], [Tools], Moving Machine, Activity}
}

where *X* and *Y* are coordinates of access points, windows, gas pipe and informative devices. The fixed part describes the area structure while the dynamic part describes who is in the area doing which activity and is computed through functions illustrated in what follows. Detectors signal a situation of increasing gas saturation and a risk event is reported. The risk in Area A is computed by the function:

Evaluation_Value=REF(Risk Map, parameters)

where *REF* denotes a *Risk Evaluation Function,* the Risk Map is as given above and *parameters* identifies all elements monitored in the environment not included in the Risk Map which are meaningful to determine the risk (e.g., gas). *Evaluation_Value* is a value expressing the risk for each parameter. If the value is beyond a given value (fixed for that particular parameter), a potential risk is signalled.

The *RSM* contains the definitions of the *REFs* which may be set through a dashboard: the system administrator sets an evaluation function for each parameter, which associates an evaluation to each value detected by the informative devices.

Each person has an associated *Personal Risk Level (PRL)* which has to be combined with the Risk Map of the area. The *PRL* depends on the: (1) physical location in the environment, (2) role of the person; (3) tools and machineries used; (4) physical state of the person.

Formally:

PRL=f (location, role, tools and machinery)

Role, tools, and machinery are evaluated using an opportune evaluation function, while the location is evaluated using the risk map; *f* is a suitable evaluation function. A possible choice is given by the following function (where eval stands for evaluation), namely:

PRL= Σ (eval(location), eval (role), eval (tool,FabricationDate), eval(machinery,FabricationDate))

Each person has also an associated *Personal Protection Level (PPL)* dependent on the: (1) role and experience; (2) protection garment, that protect persons; and (3) device (e.g., a PDA) enabling a person to communicate with other persons.

Formally, we have:

$$PPL=f(role, experience, protection, device)$$

Role, experience, protection garment and device are evaluated using an opportune evaluation function; *f* is a suitable evaluation function. A possible choice for *f* is:

$$PPL = \Sigma(eval(role), eval(experience), eval(protection), eval(device))$$

where *eval* is a function defined to evaluate the various components of the *PPL*. *PRL* and *PPL* are continuously computed for each person, using the evaluation functions onto the values measured from the environment. Using the environmental risk map, the risk related to the location of workers can be retrieved, and using the information on tools/machinery used and protection garment the risk level of the worker is computed. When a person moves around the environment, his *PRL* is compared instantaneously with the *PPL*, defining the *Personal Risk Index (PRI)* as follows:

$$PRI=PRL-PPL$$

This is an indicator of the existing risk for the person at a given moment determined as a statistic measure computed without considering how the person influences the environment, but rather how the environment creates risky situation for a person. If the computed *PRI* exceeds the risk threshold, the *RSM* tries to reduce the *PRI* by choosing the best strategy. Risk Facing Rules are defined as sets of strategies to face a risk (gas leak in our example). A *Strategy* is an ordered list of actions to be executed in the indicated sequence to mitigate the risk or to handle the emergency. A simple *Risk Facing Rule* putting in *or* two strategies for "gas leakage" risk are reported in Table 1. In order to choose the most appropriate Risk Facing Rule and strategy, the root causes of the high value of *PRI* have to be identified. By knowing the *f()* used to compute the *PRL*, the inverse function f^{-1} *(PRL, Parameter)* returns the main parameter causing the risky situation. Based on this information, the suitable preventive strategy can be chosen.

Here, the *Risk Facing Rule* has two alternative strategies: *Strat1* is a "softer" preventive strategy, where actions allow a team to plan their leaving from the dangerous area, while *Strat2* is a preventive strategy whose set of actions implies evacuation. Strategies contain actions made of a message part (denoted under the *to* part) directed to a tool, a team and even to a single person, such as Team Leader in *Strat1* and Worker n. 7 in *Strat2*. For instance, in Table 1, Worker 7 might have special health requirements and hence is directly notified, while in *Strat1* both the Team leader and the specific Team (Team A) are specified as targets of the alarms.

TABLE I. RULES AND STRATEGIES FOR A GAS LEAKAGE RISK

Strategy	Action	
	To	***Message***
Strat1	Gas Sensor 1	Check gas concentration level
	Team leader	Send sms
	Team A	Recover work tools
	Team A, Team leader	Leave area A and go in area B
Strat2	Gas Sensor 1	Check gas concentration level
	Sound alarm 1	Activate
	Worker 7	Group people in area D

IV. THE SIMULATOR

The *RSM* prototype is composed of the following elements [15]. The Data Collector receives the current values of the monitored parameters related to the environment from the informative devices (e.g., sensors, RFID, antennas), which are located in the environment to monitor its status and to generate alarms. Data can arrive also from users. The Data Collector forwards these data to the Environment Data Manager, which stores them in the Environment Database. The System Database contains data regarding the observed system (e.g., topology, user profiles workers) which do not change frequently over time. The main task of the Data Analyzer Manager is to check the current values of parameters (i.e., if they are out of the admitted range). When it detects parameters beyond of a given threshold, it notifies the Risk & Emergencies Manager, which is composed of a Risk Detector, an Emergency Detector and a Strategy Manager. While the first two identify the current risk/emergency based on the parameters values received from the Data Analyzer module, the Strategy Manager identifies the appropriate strategy to be put in place to address the current situation, based on a set of risk facing rules available in the Risk & Emergency Database containing the description of all the risks/emergencies which can be addressed by the system. Once the strategy has been identified, the Risk & Emergencies Manager contacts the Execution Manager to apply the strategies. The messages to be sent to the environment elements (persons, informative devices or protection elements) are managed by the Communication Manager, which chooses the appropriate format for the messages (e.g., sound, alarm, sms). A Business Intelligence Module analyzes the risks and emergencies (e.g., the frequency of their occurrence, reaction time, number of involved persons) to improve the future results of the *RSM*.

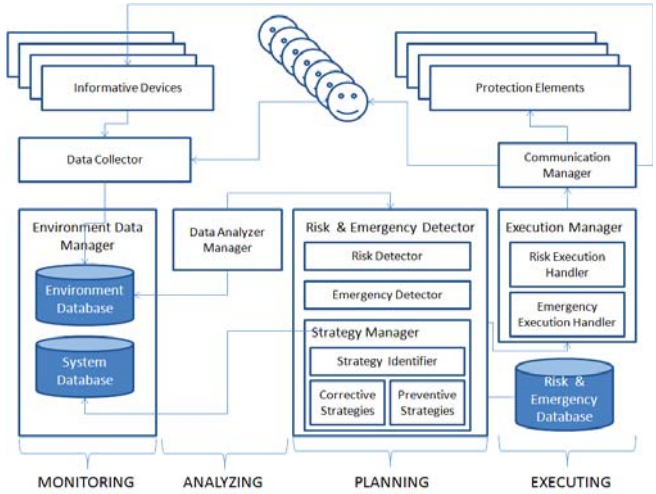

Figure 4. *RSM* Prototype Architecture (taken from [16])

The aim of our simulation is: (1) to make available to the *RSM* the data that would be collected by sensors and devices (sensor networks, RFIDs, antennas, tags), (2) to simulate the sensor communication techniques, and (3) to simulate the risk reaction process in terms of alarms, actions, and strategies.

To wrap the environment in a simulation, each entity of the environment has a corresponding simulated element, so that a

1:1 correspondence exists between the object instantiated in the simulation and the physical object/person to be controlled. The simulation is centred around the user's (Worker) actions, to focus on the Human-Environment interactions. One basic case is the Simulation of Worker's Actions. These actions are described in external XML files containing the sequence of actions and their duration. The actions currently implemented in the prototype concern movement actions (*goto*), use of tools (e.g., *usehammer*), use of transport means (e.g., *ontruck*, *offtruck*), and health-related actions (e.g., faint). An action has a duration, a maximal execution time to be completed, and an attribute denoting the number of times it has to be repeated.

Our simulator models the behaviour of environment elements which provoke risk events. A selected set of resources have been implemented: (1) *Gas Pipe*: in one use case of our simulation, one pipe breaks due to hammer misuse; this is modelled as a buffer filled one unit at a time corresponding to each hammer blow; and (2) *Gas*: this is simulated through a linear function that augments the radius of a circle centred in the pipe breakpoint, and covering an area equal to that of the area interested by the expanding gas.

The simulator shows the communication and protocols of instruments and devices in order to provide data from sensors and tags to the *RSM*. Such communication occurs as the value change of some variables: each simulated object that transmits data has and associated modelled object. To modify these parameters (e.g., a value read by a sensor) the sensor uses the reference to the object of System and that, via suitable methods, modifies the values of the attributes. Some simulated objects have no reference to objects of the environment. For example, a gas pipe in the simulation is used only to model the interactions with other elements of the *RSM* to show what occurs in the environment, but is not an active technological component and has no direct link to the *RSM*. Such object has a software component counterpart in the *RSM*, necessary for the localization services, in case, for instance, during a gas leak, the identification of the leak source is needed.

A screenshot of our prototype shows a sample Risk Map (see Figure 5): the third box of the first row reports the risk map of the working area showed in the second box. On the upper side of the room, an emergency exit is located, while on the right side a source of risk - a gas pipe - is located. The gas pipe creates a risk zone, identified by a red and yellow area, while the emergency exit decreases the risk in its vicinity. The workers present in the area also contribute to the risk map. The current prototype implements a set of simple prevention and correction strategies and allows one to modify the description of the environment by allowing the upload of a Risk Map definition in an external XML file.

V. RELATED WORK

Risks in work environments are usually addressed technically through sensors, ad-hoc devices (wearable devices [9]) and suitable software for empowering the individuals' lives. A general approach to risk management has to consider also social, knowledge management, and decision-making approaches. In [12], emphasis is on key decision structuring steps and analytical tools to help ensure the systematic treatment of fact-based and value-based risk knowledge claims. The introduction of intelligent capabilities in work protective equipment through ICT technologies is one of the priorities of several international safety and health organizations [22]. The overall problem of risks and safety, with particular attention to the way of communicating risks to people and companies is discussed in [20]. From the technical perspective, sensors and sensor networks [3], [4], [13], [18] are popular in the development of software for various application domains (i.e., scientific contexts [21], habitat monitoring [2], structural health monitoring [7], augmented reality [17]). [11] considers that sensors provide some of the basic input data for risk management of natural and man-made hazards. A current problem pointed out in the literature [11] is achieving interoperability between different sensor networks. In practice, each remote data source may use distinct encodings, formats and even communication protocols [5] leading to a lack of standardization and interoperability problems when multiple sensor networks are combined. From the software viewpoint, interesting approaches are service-oriented [3], [4] due to their modularity, standardization

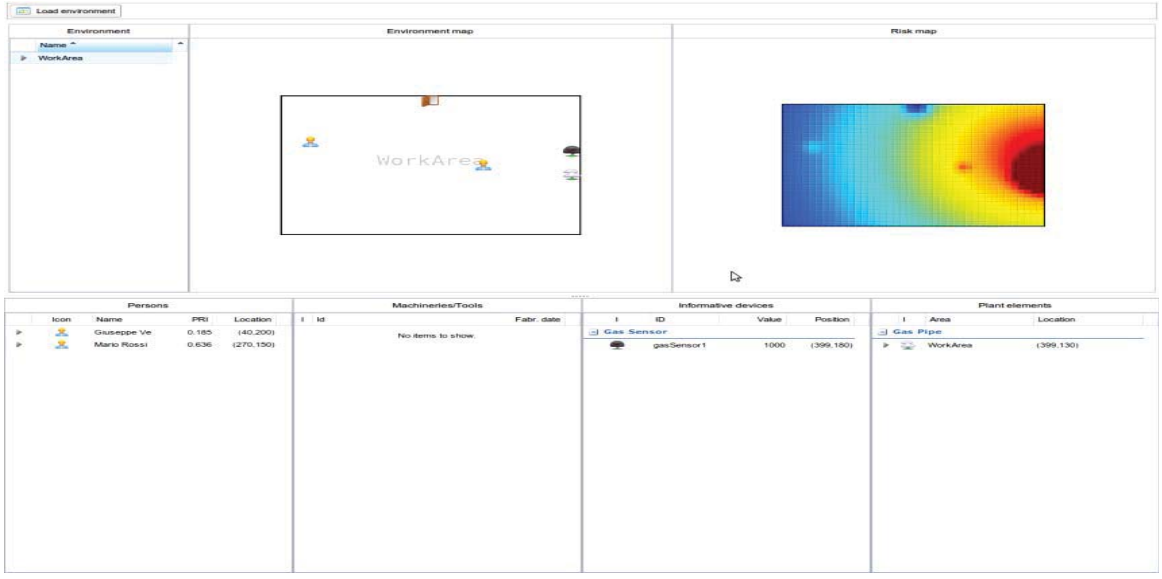

Figure 5. Risk Map of a Work Area

possibilities, support to self-healing approaches and adaptation. In [19], environmental risk assessment and decision-making strategies use comparative risk assessment and multi-criteria decision analysis for the incorporation of project stakeholders' opinions in the ranking of alternatives.

The European Commission (EC) has funded a number of Integrated Projects concerned with the accessibility of data and services for risk management (e.g., ORCHESTRA, http://www.eu-orchestra.org/ and SANY, http://sany-ip.eu/).

VI. Conclusions and Further Work

This paper has presented an approach to simulate the monitoring and prevention of risks in work areas. The definition of risk is related to the characteristics of the environment, the persons working in it, the work machineries and the tools used in the environment and of the work actions performed by the persons inside this environment. Design problems arise when an attempt is made to identify the relations among these entities in order to identify the risk. We have therefore introduced a model relating people, tools, machinery moving in a space, and elements and locations which are potential risky elements. We have described risk sources generating and subjected to risk and ways to prevent, monitor and correct risky situations. Technology devices are modelled in that they offer a protection (e.g., sensors, antennas, RFID, alarms) as well as protection garments (helmets, protection shoes and so on), which embed no IT elements but are a must for accessing the work areas. Finally the behaviour of persons must be modelled. This is one the hardest modelling tasks, since it implies the determination of what a worker can do at each moment, the teams he is participating in (more than one at a time, in general), and other run-time aspects. There are further approaches we plan to consider in the next future such as the PDCA (Plan-Do-Check-Act) or Deming cycle [10]. Risk management starts with analysis of the actual plans, in- and external rules and threats. For serious risks (relative high chance and large effects) responses (mitigating actions) are planned. Responses must be controlled and further, the actual risk determined. Our current work regards the implementation of a full- fledged simulator endowed with the administrator's dashboard of the *RSM*. We are also working on refinement of the choice of suitable risk evaluation functions related to the personal risk in real environments, and on criteria for the selection of best strategies to face risk and the evaluation of a strategy application in terms of risk mitigation.

Acknowledgment

This research has been partially financed by the Italian TEKNE Project. We thank G. Tomasino for implementation of the simulator.

***Abstract*—Typical complex software and systems engineering projects involve a set of different engineering disciplines and therefore heavily rely on systems integration approaches. Service-oriented architecture and Enterprise Service Bus provide a valuable basis for systems integration; however often depend on tedious manual work or invasive and therefore inflexible adaptations in case of even minimal changes to engineering processes or engineering tools. In this paper we describe the Engineering Service Bus (EngSB), an integration platform which not only integrates tools and systems, but also provides a bridge between engineering processes and existing engineering tools. We evaluate the EngSB by implementing a standard software engineering process for multi-engineering environments. Major results were that the EngSB allows for non-invasive and flexible integration of well-established tools in multi-engineering environments, while enabling the integration to take place on the level of engineering processes.**

Keywords-(software+) engineering, non-invasive integration, component-based architectures.

I. INTRODUCTION

Todays real-world and large-scale software and systems engineering projects such as the engineering of water power plants or steel mills typically involve a wide range of different engineering disciplines such as mechanical engineering, electrical engineering and software engineering [1]. Each of the disciplines already provides its specific engineering tools and engineering systems to manage specific engineering processes. Each of these processes heavily relies on different technical platforms and heterogeneous data models. Well-established software engineering methods and approaches (e.g., iterative development processes, issue tracking systems etc.) could provide additional value for building and managing such information systems engineering projects, but require careful integration and seamless collaboration with other engineering fields to achieve industrial acceptance. Therefore, this kind of cooperation can be considered as "(software+) engineering" [2].

There is already individual tool-support available for each engineering process step, but the integration of those tools to form a single integration solution heavily relies on manual work and invasive changes to tools, and thus does not provide an automated and non-invasive solution including support for the integration of entire engineering processes. Furthermore, current rigid integration solutions introduce complete tool sets supporting the whole engineering process, but are inflexible regarding even minimal changes in standard engineering processes or tool sets. However, typical real-life engineering processes very often comprise specific and highly specialized tools and also often alter existing standard engineering processes according to their needs. Therefore, large-scale engineering projects seek for a flexible framework that facilitates a non-invasive support of multi-disciplinary engineering processes in case of tool exchangeability, as well as reusability and adaptation of process descriptions without changing existing tools.

In this paper, we describe in detail the Engineering Service Bus (EngSB) integration platform we have successfully used in several industrial projects for the integration of heterogeneous automation systems engineering tools. The EngSB is an integration platform based on the ESB and not only integrates different tools and systems, but also provides a bridge between engineering processes and existing engineering tools [1, 3]. The so-called engineering workflow is used as basis for the non-invasive engineering tool integration and to automate the integration; this workflow is directly related to the original engineering process and represents the implementation of the engineering process in the EngSB platform. The EngSB addresses requirements such as the capability to integrate a mix of user-centered tools and backend systems, mobile work stations that may go offline, and flexible and efficient configuration of new project environments and SE processes.

In this work we focus on the application of the EngSB to multi-engineering environments and describe the detailed architecture of the relevant EngSB integration platform components. Furthermore, we discuss the EngSB concept as a technical platform for the integration of different engineering tools and for bridging engineering processes and engineering tools. Additionally, we evaluate the EngSB by applying it to a standard software engineering process for the information systems engineering domain, the Continuous Integration and Test (CI&T) process [4], and comparing the results to other related approaches, like with the general Application lifecycle management (ALM) approach and as a specific implementation of

the process with Hudson[1]. The specific configuration of the EngSB with respect to the given process results in the concrete OpenCIT[2] (a continuous integration and test server) implementation.

The remainder of this paper is structured as follows: Section 2 summarizes related work on aspects of technical integration and related implementations of research groups or industrial projects. Section 3 describes the use case scenario. Section 4 details the EngSB implementation, which is evaluated and discussed in section 5. Finally, section 6 concludes the paper, and identifies further work.

II. Related Work

This section summarizes related work on current methods, concepts and approaches to integrate distributed environments, architecture concepts for tool integration, and integration framework specifications.

A. Tool Integration in Distributed Environments

The most common integration patterns have been summarized in [5] whereas messaging pattern results in a huge number of middleware frameworks available [6], mostly with the Enterprise Service Bus (ESB) concept [7]. The ESB has been successfully applied as agile integration platform for back-end services in distributed heterogeneous business software environments [7]. Key strengths of the ESB [8] are providing distributed integration and separating the description of the business logic from the integration logic in contrast to design patterns such as client-server architecture [9] or Messaging. Nevertheless it has to be taken into consideration that too much abstraction does not help software engineers integrate their environments [10, 11] as the reusability of the different components is limited. ESBs provide components which can be reused to integrate different functionality or protocols, but only little research is done regarding tool and process abstraction, requiring system integrators to start again nearly from the scratch for each new project.

The ESB is also used as the underlying infrastructure for Service-oriented Architectures (SOA) [11] which intend to support service composition and application evolution [12] aiming at higher reusability, shorter time to market and lower costs. Although the concepts are well adapted [11, 13], the large number of different standards, specifications, technologies and high requirements in analyzing the organization make SOA hard to understand and complex to implement. Additionally, SOA itself does not provide any concepts for business process event handling. SOA notifications are basically implemented by defining services which directly call other services. This requires rewriting the service, notifying the system, for each logical change. With the help of service orchestration the logic can be extracted from the services themselves into a meta layer. However, this only moves the problem into a higher level of abstraction as the meta-layer has to be rewritten every time an additional service has to be notified.

B. Integration Environments

In general, analyzing the different concepts for integration developed over time, three approaches were able to become defacto standards for integration in software engineering:

Script based integration approaches describe the build process of software only. Modern approaches like Maven [14] also integrate test-, deployment-, announcement- and documentation environments to cover the complexities of current software engineering projects. Although Maven is one of the most used build systems for software development in the Java world, its reusability and flexibility is limited: first, the Maven workflow is hard coded into its core. It can be extended by attending plug-ins to the different lifecycle goals, but it cannot be changed completely and adapted for other uses.

Another approach of tool integration is to focus on the developer within its **Integrated Development Environment** (IDE) [15] like in Eclipse[3] or Microsoft Visual Studio[4]. They provide integration modules like Mylyn which supports a complete, task centered integration of issues retrieved from a wide range of different issue trackers. Although an IDE brings the entire engineering environment to the developer the logic and process models have to be implemented with each environment. Furthermore, they do not support automation of complex processes over multiple, different IDEs.

Application lifecycle management (ALM) based integration approaches usually comprise source control system and integration workflows, deployment, monitoring, project management and testing, while at the same time covering the entire project lifecycle [16]. An ALM is the Eclipse Application Lifecycle Framework (ALF) [17] which handles integration challenges by introducing a central negotiator that manages interactions between applications. By using an intermediate communication format the event manager prevents to integrate applications several times with several other applications. It allows a single integration on the central node, which carries out communication with other ALM applications through orchestration of their corresponding web services. However, ALF is no longer supported by the Eclipse Foundation [18].

III. Use Case

This section presents a (software+) engineering industrial use case from signal engineering that has been retrieved from an industrial partner developing, creating, and maintaining hydro power plants. The standard mo del of the Continuous Integration and Test (CI&T) process known from software engineering consists of a set of activities: checking out source code artifacts from a source code management system, building the system, running tests, performing analyses regarding the outcome of these tests, and finally reporting test results to interested roles. The CI&T use case shows a key feature of an iterative software development process: if parts of a system or engineering model get changed, the system has to be rebuilt and tested in order to identify defects early and to provide fast feedback on the implementation progress to the project manager and the owners of the changed system parts.

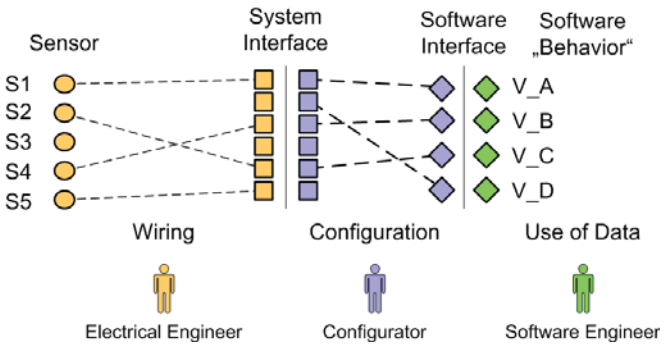

Figure 1: Overview End-to-End Analysis [19, 20].

In distributed multi-engineering environments (see Figure 1), typically a set of different tools and data models are used along the engineering chain. In difference to single system models, where changes of model values have direct impacts on other model elements, model value changes in cross-domain modeling require additional transformation and checks before the actual impact of a value change can be estimated or measured. To cooperate, the engineers have to exchange relevant parts of the data structures in their tools with each other with the goal of a consistent overall view on certain aspects in the project, e.g., when producing a specification for a subcontractor. This requires exhaustive communication between engineers to keep models consistent and thus introduces a variety of error sources as well. Currently, every role uses organization-, domain-, and tool-specific data formats and terms, thus the data exchange also takes considerable expert knowledge on the receiving end to make sense of the incoming data, typically as large PDF document or tool-specific import file. Applying the automated continuous integration and testing process in such an environment increased consistency and minimize the number of potential error sources.

IV. EngSB Implementation

This section gives a description of the components (Figure 2) of the Engineering Service Bus (EngSB) architecture:

Core Components. The concept of Core Components contains additional developed components providing services which could not be provided by external tools or which are not usable from external tools as required. The two most important components for the architectural need of the EngSB are the registry and the workflow component. Since different projects may be running in parallel on the EngSB, each project requires carrying a context which contains at least the project identifier allowing the ***registry*** to map onto endpoints for each accessed tool. The ***workflow component*** is responsible for engineering rule, process and event management in the EngSB. The Drools[5] business logic integration platform builds the backbone for the workflow management system since it provides a consistent solution for BPM, knowledge and event management. It includes Drools Expert as rule engine, Drools Fusion for complex event processing, Drools Flow for business process management and finally Drools Guvnor as a centralized knowledge repository to manage processes and rules centralized. The important part of the workflow component is its indirection layer between engineering rules and processes and the EngSB Tool Domains.

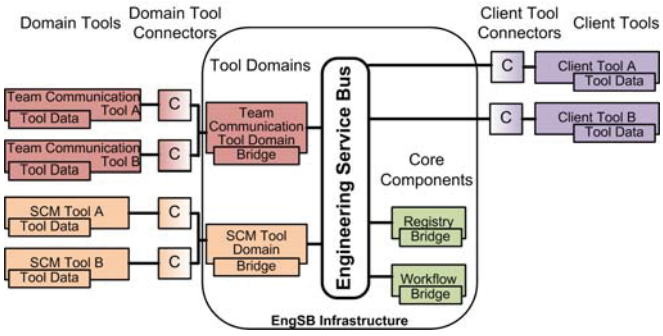

Figure 2: Components of the Engineering Service Bus.

Tool Domains. Although each tool provider gives a personal touch to its product their design is driven by a specific purpose. For example, there are many different issue tracker available, each having its own advantages and disadvantages, but all of them can create issues, assign and delete them. Tool Domains [3] are based on this idea and distill the common functionality for such a group of tools into one Tool Domain interface. They can contain code, workflows, additional logic and data, but they are useless without a concrete implementation.

Bridge. JBI does not allow components that are not deployed in the JBI infrastructure to directly interact with services. This means that tools deployed to the EngSB can directly access neither external components nor the other way round. The bridge provides a connection between these two worlds.

Client Tools. Client Tools in the EngSB concept are tools which do not provide any services, but consume services provided by Tool Domains and Core Components instead.

Domain Tools. Domain Tools, compared to Client Tools, denote the other extreme of only providing services. Classically, single purpose server tools, like issue tracker or chat server, match the category of Domain Tools best.

Domain and Client Tool Connectors. Although most (back-end) tools provide interfaces to integrate and automate them in distributed environments, they do not directly fit the needs of the EngSB. Instead, they have to be wrapped up to allow external, distributed tools to access them via the EngSB. These required bridges are called Tool Connectors. Tool Connectors wrap tools as Domain Tool Connectors to provide their services to accommodate the relevant Tool Domain with the expected interface. As Client Tool Connectors they provide a Client Tool with an access to the EngSB services. Tools can be integrated with more than one connector to act in many different domains.

V. Evaluation and Discussion

In this section we evaluate the capabilities of the EngSB related to flexibility and non-invasive support for integrating software engineering processes by reporting on conducted feasibility studies. The evaluation is based on the OpenCIT framework by applying the standard software engineering

[5] http://www.jboss.org/drools/

CI&T process (see left hand side of Figure 3) to multi-engineering environments.

With respect to the CI&T process, the right hand side of Figure 3, shows OpenCIT integrating common tools via five different domains, namely Source Code Management, Build, Test, Analysis and Notification. For each of these domains, a concrete tool instance from each used engineering environment (e.g., electrical engineering and software engineering) is connected using a tool connector. In addition, the core Engineering Workflow Rules component is used to configure the defined CI&T process as a workflow on the EngSB and to orchestrate the specific runtime events of the individual tools accordingly.

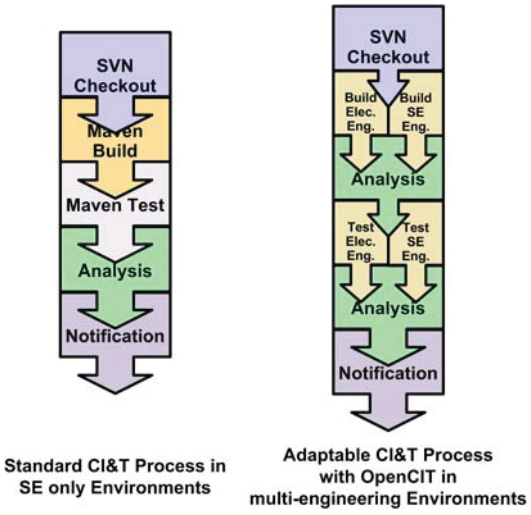

Figure 3. Overview CI&T and OpenCIT.

The evaluation has been conducted with two different tools in two phases. First, we compare OpenCIT with a highly popular CI&T tool suite (Hudson) to demonstrate how EngSB can address standard software engineering integration problems. Second, we compare EngSB with a general purpose integration framework (Eclipse ALF), which is a set of tools designed to support an enterprise application from its initial inception through its deployment and system optimization. The high level goal is to analyze the effort of adopting a new CI&T tool suite, from the viewpoint of software administrators, building tool connectors and defining/customizing the process.

Phase 1. In order to compare the effort required for integrating new tools to the frameworks, we compared the effort required for developing a connector and the mechanisms available for extending the core in Hudson and EngSB. We examine initial adoption effort and the possibility to make changes to standard CI&T workflow. Hudson provides extension points, where new plugins can be added to extend the application logic. This mechanism is used to integrating new tools to the framework. EngSB provides interfaces, which can also be extended. The extensions provide the functionality via JMS, or REST, or Web Services, allowing programming language independent integration facilities. As Hudson is meant for use in software engineering, event processing is specialized and hardcoded and may be customized only via tools integrated using extensions points. Workflows are hardcoded, which means that the core has to be extended for this purpose. In EngSB events can be designed for domains but also completely independent, which allows one to decide how tight the tools should be integrated to the workflows. Workflows are basically defined in drools.

Phase 2. We investigated the key characteristics of Eclipse ALF, a system that allows reusable process definition and adaption regardless of low-level technical details. We analyzed the flexibility regarding event processing, effort needed to modify workflows, and tool exchangeability capabilities. In Eclipse ALF events are SOAP messages which are defined in the core. New tools may react to the SOAP messages to achieve workflow modifications. In EngSB events can be designed for domains but also completely independent, which allows one to decide how tight the tools should be integrated to the workflows. In Eclipse ALF workflows are defined in BPEL leading to a heavy-weight solution which has to be defined programmatically and cannot be modified or extended at runtime. In EngSB workflows are defined in Drools. While in Eclipse ALF exchanging tools requires redefinition of the processes and event handling, EngSB supports tools to be freely exchangeable, as the workflow is defined on the level of tool domains.

While CI&T suites such as Hudson enable the integration of software engineering tools, there is no CI&T suite available for enabling CI&T processes for multi-engineering environments such as the scenario presented in Figure 1. As shown in the right hand side of Figure 3, OpenCIT can be used for migrating the CI&T process, which originally comes from the software engineering domain, to multi-engineering environments. This we define as (software+) engineering, as software engineering provides additional value to systems engineering. The tool domain concept of the EngSB allows for a non-invasive exchange of single tool instances, since tool domains define and provide the domain-specific functionality usually provided by single engineering tools. Therefore, OpenCIT has no restrictions regarding the tool sets to be used, but relies on the tool domain concept of the EngSB to specify and integrate already existing tool functionalities.

In order to enable the CI&T process for multi-engineering environments, the standard CI&T process is adapted as shown in the right hand side of Figure 3. In comparison to the standard software engineering CI&T process, the multi-engineering CI&T implementation of OpenCIT allows the definition of multiple tool domains (often from different engineering disciplines) to define the same CI&T process step (e.g., the *build* process step). When this process step is executed, OpenCIT triggers the functionalities of all tool domains that are linked to this specific process step. Furthermore, different strategies can be implemented related to the order of the triggering, e.g., the workflow engine of the EngSB can be used to implement and enforce project-specific reporting strategies regarding the outcome of a specific process step (e.g., a build failure notification). The tool domain concept of the EngSB can additionally be used to simulate engineering tool instances on the level of an engineering process. This feature can be used to test engineering process (e.g., whether they work as planned), without the need to have individual tool instances available and connected to the EngSB.

Additionally, EngSB showed more flexibility regarding the continued use of favored tools by engineers, whereas standard tool suites allows the integration of some standard software engineering tools, which may or may not be used by the engineers in a certain organizational setting. The possibility to use known tools (thorough the possibility of integrating arbitrary tools) results in minimal training effort for project participants, since the used engineering tools are already familiar to them.

VI. CONCLUSION

Today's large-scale information systems engineering projects typically involve a range of different engineering disciplines with their specific engineering tools. However, for building and organizing information systems engineering projects to manage specific engineering processes a cooperation of each discipline is required to form an integrated engineering system. Although, there is already individual tool-support available for each engineering process step, the integration of those tools to form a single integration solution heavily relies on manual work and invasive changes to tools. However, typical real-life engineering processes very often comprise specific and highly specialized tools and also often alter existing standard engineering processes according to their needs. In this paper, we presented the Engineering Service Bus (EngSB) as an integration platform based on the ESB that does not only integrate different tools and systems, but also provides a bridge between engineering processes and existing engineering tools. We demonstrated the use of the EngSB to migrate a standard software engineering process - Continuous Integration and Test (CI&T) – to multi-engineering environments and compared it with popular tools, like Hudson or Eclipse ALF. The comparison showed that OpenCIT, the multi-engineering environment integration of CI&T using the EngSB, can replace an integration framework like Hudson for projects involving multiple engineering disciplines. Adaptations to the standard workflow are more flexible in the case of EngSB because it allows arbitrary extensions through flexible event handling and exchangeability of tools. Mutual restrictions between tools and processes can be minimized through the use of workflow rules that are formulated on the level of tool domains. Furthermore, we compared EngSB with Eclipse ALF to demonstrate the EngSB provides higher abstraction level for tool integration, which makes it easier to adopt For future work we intend to perform empirical evaluations in case studies and implementations as well as creating domain-specific process definition tools to support non-experts in defining information systems engineering processes to be deployed in the EngSB.

ACKNOWLEDGMENTS

This work has been supported by the Christian Doppler Forschungsgesellschaft and the BMWFJ, Austria. We are thankful to Alexander Schatten and Andreas Pieber for their valuable input in several discussions.

Automated Detection of Likely Design Flaws in Layered Architectures

Aditya Budi, Lucia, David Lo, Lingxiao Jiang, and Shaowei Wang

Abstract

Layered architecture prescribes a good principle for separating concerns to make systems more maintainable. One example of such layered architectures is the separation of classes into three groups: Boundary, Control, and Entity, which are referred to as the three analysis class stereotypes in UML. Classes of different stereotypes are interacting with one another, when properly designed, the overall interaction would be maintainable, flexible, and robust. On the other hand, poor design would result in less maintainable system that is prone to errors. In many software projects, the stereotypes of classes are often missing, thus detection of design flaws becomes non-trivial. In this paper, we provide a framework that automatically labels classes as Boundary, Control, or Entity, and detects design flaws of the rules associated with each stereotype. Our evaluation with programs developed by both novice and expert developers show that our technique is able to detect many design flaws accurately.

1 Introduction

Layered architecture is a recommended industry practice as it promotes separation of various concerns into layers [17]. By using this architecture, when requirements change, most of the changes could be localized to a limited number of classes in a particular layer. Thus, no changes would be needed for classes in unrelated layers as long as the interfaces between the layers remain the same. As software evolves over time, layered architectures are more likely to have better reusability, improve comprehension and traceability, and ease maintenance and evolution tasks than single-tier architectures.

One commonly used layered architecture is the separation of classes into three stereotypes, namely: Boundary, Control, and Entity, following the Unified Modeling Language (UML) and its suggested objectory process [15, 14]. *Boundary* classes are responsible to interface with external systems or users. *Control* classes are responsible to realize particular functionalities or use cases by coordinating the activities of various other classes. *Entity* classes are responsible to model various domain concepts and store and manage system data.

Class stereotypes are not just symbols; they come with design rules governing their behaviors and responsibilities. If the nature of a class is not apparent to developers or its behaviors do not match its stereotype label, developers are prone to make mistakes, violating the rules, especially as the code evolves over time. There are two common rule variants: *robustness rules* [15], and *well-formedness rules* [14].

Unfortunately, many software projects, during development or maintenance, have little documentation. Many design documents, including those specifying stereotype labels of the classes in a program, are often missing. Such information is often not obvious in the source code either due to poor variable and class names, code changes, etc. Also, keeping design documents and stereotypes up-to-date manually could be time-consuming and error-prone.

To address the above issues, we propose a framework that can automatically reverse engineer class stereotypes and detect violations of design rules associated with them.

We empirically evaluated our proposed system on a number of student projects and a real software system. Our preliminary experiments are promising. Compared with manually stereotyped labels, our approach achieves on average 77% of accuracy. Design defects resulted from violations of robustness and well-formedness rules could be detected with up to 75% precision and 79% recall.

The rest of the paper is organized as follows. Section 2 describes related work. Section 3 presents the concept of class stereotypes and their associated design rules. Section 4 describes our design flaw detection framework. Section 5 presents evaluation results. We discuss limitations and applicability in Section 6 and conclude in Section 7.

2 Related Work

There are a number of studies on the characteristics of class stereotypes [2, 8, 1, 12]. Andriyevska et al. study the effect of stereotypes on program comprehension [1]. Kuz-

niarz et al. also study the effects of stereotypes on program comprehension but focus on user-defined stereotypes rather than the standard three (i.e., Boundary Control, and Entity) [12]. Atkinson et al. propose different de facto ways in which stereotypes are used [2]. Gogolla and Henderson-Sellers analyze the part of the UML metamodel that deals with stereotypes and provide recommendations for improving the definitions and uses of stereotypes [8]. Dragan et al. investigated an automated way to infer class and method stereotypes [6, 7]. To the best of our knowledge, we are the first to propose an automated way to automatically detect likely violations of design rules governing stereotypes based on automatically identified stereotype labels.

Various studies also address the problem of detecting and correcting design flaws and code smells [9, 11, 19, 13, 18]. Guéhéneuc et al. [9] find code segments that do not conform to a particular design pattern and transform them accordingly. Khomh et al. use Bayesian Belief Networks to detect code and design smell [11]. Vaucher et al. study *god* classes and propose an approach to distinguish good *god* classes from bad ones [19]. Moha et al. extract concepts from text descriptions and establish formal specifications of code smells so that they can detect code smells automatically [13]. Trifu and Reupke also detect structural flaws in object oriented programs and use optimization-based techniques to automatically restructure programs [18]. Our work in this paper focuses on detecting class stereotypes and checking violations of design rules involving stereotypes, which enriches the type of design information and defects detected by past studies and helps users to reverse engineer their designs.

3 Design Rules of Class Stereotypes

This paper provides a mechanism to identify class stereotypes automatically and detect design flaws in programs. The class stereotypes and design rules associated with the stereotypes are described in the following subsections.

3.1 Class Stereotypes

Identifying class stereotypesis an important step for designing, analyzing, understanding, and maintaining a software system. In particular, this paper focuses on automated identification of three class stereotypes, i.e., *Entity*, *Control*, and *Boundary*, which was introduced as an extension to the standard UML [14, 3]. The UML extension describes the responsibilities of classes belonging to each stereotype. It promotes separation of different concerns into different class stereotypes, and thus software changes related to one concern would only affect one particular stereotype involving a limited number of classes [17].

Classes with the *Entity* stereotype store and manage information in a system. In this paper, we further distinguish *Regular Entity* from a special kind of entity called *–Data Manager*, which is used to persist to storage systems (e.g., databases, file systems, etc). As an example, *Course* is a possible entity class in a University Management System (UMS) and *CourseStore* is a possible data manager class that stores and retrieves course data from databases.

Classes with the *Boundary* stereotype serve as an interface between a system and external systems interacting with it. External systems, represented as *Actors*, could be other computing systems or the users of the system. These interface classes would be the ones affected if the behavior of external systems change. In a typical UMS, *CourseManagementUI* is a possible boundary class.

Classes with the *Control* stereotype act as a glue among entity and boundary classes, and control the activities of other classes for particular tasks. For example, *CourseRegistration* class is a possible control class that interacts with a user interface class and related entity classes, e.g. *Course*.

3.2 Design Rules

Class stereotypes, based on their supposed responsibilities and the principle of separation of concern, should follow certain design rules, such as, an *Entity* class cannot call a *Boundary* class directly. Regulating the interactions among different classes of various stereotypes can help to ensure the understandability and maintainability of a software system.

Our work provides an automated mechanism for checking compliance of design rules governing the interactions among class stereotypes. In particular, we instantiate the checking against two sets of rules which reflect various architectural styles, namely *robustness rules* and *well-formedness rules*. Our checking mechanism is designed to be flexible enough to take various rules for checking.

3.2.1 Robustness Rules

Robustness analysis, as described in Rosenberg and Scott's UML book [15], provides a set of rules that indicate all valid and invalid interactions among different class stereotypes. The rules are paraphrased as follows, where *Actors* represent users of a system which could be humans or classes/objects outside the system under analysis

- R1 Actors can only call boundary objects.
- R2 Boundary objects can only call controllers or actors.
- R3 Entity objects can only call controllers.
- R4 Controllers can call entities, other controllers, and boundaries, but not actors.

3.2.2 Well-Formedness Rules

The *well-formedness rules* are defined in the UML extension [14], and rephrased as follows: [1]

[1]The complete set of rules in the UML extension also allows the subscriber-publisher style of interaction. This paper considers only interactions via direct calls and thus omits a part of the rules governing subscribe-publish interactions.

Caller	Callee							
	Actor		Entity		Control		Boundary	
Actor							R1	W1
Entity				W3	R3			
Control			R4	W4	R4	W4	R4	W4
Boundary	R2	W2		W2	R2	W2		W2

Table 1. Robustness and Well-Formedness Rules

W1 Actors can only call boundary objects.
W2 Boundary objects can call entities, controllers, other boundaries, and actors.
W3 Entity objects can only call other entities.
W4 Controllers can call entities, other controllers, and boundaries, but not actors.

The two sets of rules can also be represented as a matrix shown in Table 1. Each entry indicates a rule that validates the corresponding caller-callee relation. Unmarked entries signify bad caller-callee relations that violate the rules.

4 Design Flaw Detection Framework

Our framework are shown as a flowchart in Figure 1. We use a classification framework that has two phases, namely training and violation detection. In the training phase, we build a statistical model using a machine learning technique that can discriminate the class stereotypes based on a set of classes with given stereotypes, i.e., training data labeled with Regular Entity, Data Manager, Control, and Boundary stereotypes. In the violation detection phase, given a class or a program containing more than one class with no stereotype labels (i.e., test data), we first predict the corresponding stereotype for each class based on the model. We then detect design defects by using the inferred stereotypes verified against either robustness or well-formedness rules.

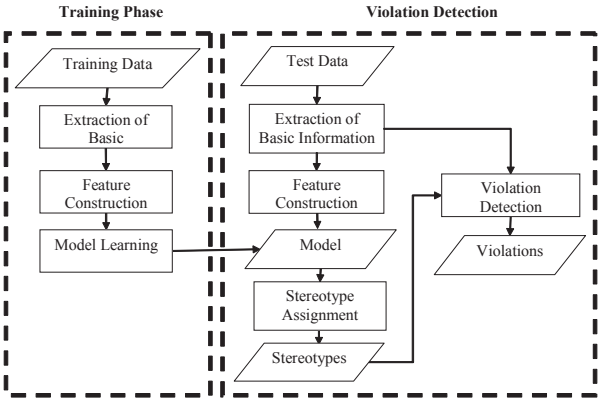

Figure 1. Design Flaw Detection Framework

There are five processes in the framework: extraction of basic information, feature construction, model learning, stereotype assignment, and violation detection. The following paragraphs describe these processes in more detail.

Extraction of Basic Information. In this process, we extract information about the classes in each Java program from its source code. The basic information we extract includes all the methods in each class, all the instructions contained in each method, the call-relations among classes (represented as call graphs), and the classes that contain operations related to I/O or database operations. We built our information extractor upon WALA [20].

Feature	Description
Size	Number of instructions that a class has
NOM	Number of methods that a class has
ASize	Average size of all the methods in a class
Fan-out	Number of other classes that a class calls
Fan-in	Number of other classes that call a class
GetCnt	Number of getters method in a class
SetCnt	Number of setters method in a class
CRUD	Number of methods performing create, read, update, or delete to data sources in a class

Table 2. Features Used in Our Statistical Model.

Feature Construction. Based on the basic information, we form features that could help in differentiating the training classes belonging to each of the four given stereotypes. In this work, we compute the set of features shown in Table 2 for each class. Instead of using absolute values for the features, we normalize their values to be in the $[0, 10]$ range.

Model Learning. In this process, we take the training data with its features and learn a model that could discriminate the four stereotype labels: Regular Entity, Data Manager, Boundary, and Controller. We use Support Vector Machine (SVM) [5] for this task since it is a well-known machine learning technique that has been shown to have good accuracies in many application domains. Regular SVMs learn models that only discriminate between two labels. We use an SVM extension handling multiple class labels [4]. Implementation-wise, we use the publicly available $SVM^{multiclass}$ [16].

Stereotype Assignment. We use the model learned in the training phase and the features extracted from the test data to assign stereotype labels to each class in the test data. We use the classification capability of $SVM^{multiclass}$.

Procedure Violation Checking
Inputs:
R : A set of rules (e.g., robustness, well-formedness)
C: A set of classes
L: The corresponding stereotypes for the classes
Output: V: A set of violations against R
Method:
1: Let V = {}
2: Let $RMap$ = Process R and represent it as a pair $\langle Caller, \{Callee\}\rangle$, where $\{Callee\}$ is the set of stereotypes that can be called by the stereotype $Caller$ as expressed in R.
3: **For each** class c in C
4: Let $Caller$ = c's stereotype
5: Let $\{Callee\}$ = $Caller$'s information in $RMap$
6: Let C' = All other classes that are called by c
7: **For each** class c' in C'
8: **If** c''s stereotype $\notin \{Callee\}$
9: $V \leftarrow V + \{c'\}$ // A violation is found
10: **OUTPUT** V

Figure 2. Violation Detection

Violation Detection. After the stereotypes are inferred, we can check for violations against a set of class design rules by

leveraging the caller-callee relations extracted from code, and the inferred stereotypes. In this paper, we consider *robustness rules* [15] and *well-formedness rules* [14]. For a set of rules, the automated rule checker performs the steps shown in Figure 2 to search for violations. At line 1, we initialize the output set. At line 2, we represent a set of rules as a set of pairs of valid interactions from a stereotype (i.e., classes with this stereotype) to other stereotypes. At line 3-10, we visit each class and for each, we extract its stereotype (line 4), other valid stereotypes that it could call (line 5), and the set of other classes called by it (line 6). At line 7-8, we check if any of the called classes has a stereotype that violate the rule (i.e., not in the set $\{Callee\}$). If this is the case, we record this violation at line 9. We finally report all violations found (line 10). For example, for the robustness rule R3, given a class with stereotype *Entity*, any call from the class to other Entity or Boundary classes will be reported as a violation. As another example, for the well-formedness rule W4, any call originated from a Control class is valid.

5 Empirical Evaluation

In this section, we describe our dataset and evaluate the accuracies of our approach in inferring stereotypes and detecting design flaws.

5.1 Dataset

We perform our evaluation on 15 Java projects developed by students of an object-oriented application development (OOAD) course. The projects are all about a single player hunting game. The number of Java classes per project ranges from 36 to 67 with an average of 45. Each project has 3431 to 9220 lines of code (including comments and blank lines), with an average of 5168. We also perform experiment using a real open source software namely OpenHospital, which is a hospital management system. The system consists of 233 classes, with 59,087 lines of code.

For each project, we manually labeled the classes with either *Boundary*, *Control*, *(Regular) Entity*, and *Data Manager*. The manual labels provide us valid classes stereotypes for the training phase and an oracle to measure the accuracy of our approach in the testing phase.

5.2 Accuracy of Stereotype Inference

We employ ten-fold cross validation to evaluate our approach. It divides all data points (i.e. classes in a project) into ten disjoint subsets of (approximately) equal size. To obtain a representative training data, the classes of the same stereotype are distributed over the subsets. Then, one subset is used as test data, while the others are used as training data. This process is repeated ten times (iterations); each iteration uses a different subset as test data.

We evaluate the accuracy of a trained model in inferring stereotypes as a ratio of number of correctly inferred class

Real Vs. Inferred Label	Number and Proportion of Predicted Classes			
	Boundary	Control	Entity	Data Man.
Boundary	81.35%	9.84%	1.04%	7.77%
Control	10.37%	58.54%	23.78%	7.32%
Entity	3.21%	2.88%	92.31%	1.60%
Data Manager	18.33%	6.11%	12.22%	63.30%

Table 3. Confusion Matrix of the Stereotypes Inferred

```
1  public class InventoryController{
2  private TrapDataManager trapDM;
3  private BaitDataManager baitDM;
4  private PlayerDataManager playerDM;
5  public InventoryController(){
6  {    trapDM = TrapDataManager.getInstance();
7       baitDM = BaitDataManager.getInstance();
8       playerDM = PlayerDataManager.getInstance(); }
9  public void setTrap(Player p, int trapID)
10 {   trapDM.setTrap(p, trapID); }
11 public ArrayList<Trap> retrieveAllTraps(String username)
12 {   return trapDM.retrieveAllTraps(username); }
13 public void setBait(Player p, int baitID)
14 {   baitDM.setBait(p, baitID); }
15 public ArrayList<Bait> retrieveAllBaits(String username)
16 {   return baitDM.retrieveAllBaits(username); }
17 public ArrayList<InventoryItem> retrieveAllInventory(String username)
18 {   return playerDM.retrieveAllPlayerInventory(username); }
19 public void readPlayerChoice(Player p, String choice)
20 {    …
21      if (tOrBChoice == 'T')
22      {    InventoryUI inventoryUI = new InventoryUI(); …}
23      else if (tOrBChoice == 'C'){
24      {          InventoryUI inventoryUI = new InventoryUI(); …}
25      else{      InventoryUI inventoryUI = new InventoryUI();
26              System.out.println("Please enter a VALID item ID > "); }}
27 public String getBaitInUse()
28 {   return baitDM.getBaitInUse(); } }
```

Figure 3. Example of a Wrongly Labeled Control Class

stereotypes with number of classes in test data. We compute the accuracy for each iteration for each project and average them as the accuracy of each project. The accuracy of our approach is then computed by taking the average of the accuracies of all projects, which is 77%.

We draw a *confusion matrix* to evaluate the accuracy of each stereotype prediction produced by the trained model [10]. A confusion matrix is a table with rows corresponding to real labels and columns corresponding to inferred labels. A cell (X,Y) in the matrix corresponds to the number of test data points with real label X that are assigned label Y by a classifier/model. Table 3 shows the accuracy of the inferred stereotypes in percentages.

Considering the diagonal entries of the matrix, we notice that boundary and entity classes can be detected with very good accuracies of more than 80%. However, it is less accurate when assigning labels to control classes. Control classes are often confused with entity classes. Upon inspection, we find that many students implement their control classes poorly. For example, consider the control class named *InventoryController* in Figure 3. It is assigned an entity stereotype by our approach. This is the case, as all of

the methods in this class except *readPlayerChoice* method perform either get data operation (e.g., *retrieveAllTraps*) or set data operation (e.g., *setTrap*). The control class simply delegates the execution of these operations to the respective data manager classes.

5.3 Accuracy of Design Flaw Detection

After the labels are inferred, we can detect design flaws as violations of the robustness and well-formedness rules. In this subsection, we show sample detected violations and analyze the quality of our violation detection mechanism.

Sample Violations. Figure 4 shows an example where violations occur in a Boundary, a Control, and an Entity.

According to the robustness rule R2, a boundary can only call controllers or actors. We detected a violation of R2 in Code-1: the boundary class named `RegistrationPage` calls an entity class named `RegistrationManager` (lines 8 and 13). Note that this is not a violation when we check it against the well-formedness rule W2.

Both robustness and well-formedness rules allow a controller to interact with any class but not actors. In Code-2, we detect a violation of the rules: the controller class named `SendingController` calls `System.out.println` (lines 6, 8, and 12) to display a message directly to a user (i.e., an actor) and uses `Scanner(System.in)` (line 16) to elicit inputs directly from the user.[2]

Robustness and well-formedness rules deal differently with entity classes. The robustness rule R3 allows an entity to call only controllers, while the well-formedness rule W3 allows an entity to call only entities. Code-3 of Figure 4 shows that an entity class named `Player` violates both of the rules: `Player` uses another entity `Inventory` (line 4) and thus violates R3; It also uses a controller `StarbugsController` (line 8) and thus violates W3. In addition, this class interacts with an actor directly via `System.out.println` (line 15), violating R3 and W3.

Quality of Detected Violations. With correct stereotype labels, our checking mechanism will detect all violations perfectly (i.e., no false positives or negatives) as both robustness and well-formedness rules are well specified. However, since stereotypes inferred by our approach could be wrong, we may detect wrong violations (false positives) or miss some violations (false negatives).

To measure false positives and negatives, we can simply compare the violations detected with inferred labels against those detected with correct labels: The size of the intersection of the two sets relative to the sizes of the two sets are indicative of false positive rates and negative rates, which can be measured by the notion of precision and recall. Precision is the ratio of inferred violations that are true and recall is the ratio of true violations that are inferred.

[2] We have (manually) predefined a list of classes and functions that send or receive messages to users which are treated as actors'.

	Class & Type		Class Only	
Evaluation	**Rob.**	**Well.**	**Rob.**	**Well.**
Precision	61.2%	74.6%	68.6%	69.9%
Recall	68.7%	61.8%	78.8%	59.8%

Table 4. Precision and Recall of Detected Anomalies for Robustness Analysis (Rob.) and Well-Formedness Analysis (Well.)

$$Precision = \frac{\|\{Inferred\,Violations\} \cap \{True\,Violations\}\|}{\|\{Inferred\,Violations\}\|}.$$

$$Recall = \frac{\|\{Inferred\,Violations\} \cap \{True\,Violations\}\|}{\|\{True\,Violations\}\|}.$$

When comparing violations during the intersection operation, we consider two equivalence criteria. One criterion considers two violations are matched only if both the violating class (i.e., the class where the violation occurs) and the type of the violation are matched (Class & Type). The other considers only the violating class (Class Only).

The total numbers of true violations of robustness and well-formedness rules are 244 and 138 respectively. The total numbers of inferred robustness and well-formedness violations are 255 and 112 respectively. The overall precision and recall of our approach is shown in Table 4. The precision and recall values are aggregated averages across many model building and testing iterations. We calculate them using the two equivalence criteria.

Table 4 shows that violating classes (Class Only) can be detected with precision and recall of 68.7% and 78.8% (robustness), and 69.9% and 59.8% (well-formedness). When considering both violating classes and violation types (Class & Type), the precision and recall are reduced by 7.5% and 10.1% (robustness), and increased by 4.7% and 2% (well-formedness), due to some violations are detected with correct violating classes but wrong violation types.

6 Discussion

Effects of Features Used. We used eight code features in our experiments. It would be interesting to consider other features, such as code complexity metrics, which might help to improve the accuracy of the stereotype inference further. The confusion matrix shown in Section 5.2 particularly suggests more features related to controllers should be used to reduce the number of confusion occurrences.

Effects of Dataset Investigated. We perform experiments on software systems written by novice programmers and one real medium-sized software system. These systems are chosen based on the availability of the class labels. None of the processes in our framework is expensive: basic information extraction, feature construction, model learning, and stereotype assignment make use of an inexpensive static analysis technique and a scalable classification engine, i.e., SVM. We believe the framework is able to process larger programs. We plan to analyze larger systems in the future.

Effects of Design Rules Checked. We detected violations against only robustness and well-formedness rules. There

16       } } catch (Exception e) {}
17   return this.gold; }
```

Figure 4. Violations in Boundary, Controller, and Entity Stereotypes

are other design rules, for example, some design rules relax the robustness rules by allowing direct interactions between Entity objects. Our approach can be easily extended to handle such variants. However, if the design rules involve constraints such as conditional call-relations, our violation checking mechanism would then need further improvements, such as, taking control-flow conditions embedded in inter-procedural call graphs into consideration.

Threats to Validity. To reduce the threats to construct validity, we used standard evaluation metrics, namely accuracy, precision, and recall, which are commonly used in data mining and information retrieval tasks. However, it remains a question what is the effect of inaccuracies on program comprehension. To answer this question, a user study would be needed and is left as future work. To reduce the threats to internal validity and selection bias, the 15 projects used in the experiment are chosen randomly from a pool of 93 student projects. However, as aforementioned, there are still threats to external validity on the generalizability of our results. We plan to evaluate our framework on various types of software systems of various sizes to alleviate the threats.

7 Conclusion & Future Work

In this paper, we present a framework that detects likely design flaws in layered object-oriented architecture with classes belonging to various stereotypes, which should follow certain design rules. Also, to accommodate to systems without sufficient stereotype annotations, our framework learns a statistical model to distinguish various class stereotypes available from a training set. This model in turn is used to give labels to unannotated classes. Likely design flaws are later detected by finding violations of well-known design rules. We have evaluated our approach on Java projects developed by novice and expert developers. The results show that our approach can identify class stereotypes with 77% accuracy on average and can detect violations of the design rules associated with each stereotype with up to 75% accuracy and up to 79% recall.

In the future, we plan to further investigate more useful features for the inference of class stereotypes and more software systems. We believe our framework is general and can be adapted for reverse engineering other kinds of domain-specific stereotypes.

Acknowledgement. We would like to thank Yeow-Leong Lee for providing some stereotype labels.

***Abstract*—Most existing techniques for the design and implementation of fault tolerance use resource redundancy. As such, due to scarcity of resources, it is difficult to directly apply them for adding fault tolerance to sensor nodes in Wireless Sensor Networks (WSNs). Thus, it is desirable to develop techniques that implement fault tolerance under the constraints of memory and processing power of sensor nodes. We present a novel method for designing recovery from transient faults that cause non-deterministic bit-flips in the task queue of the scheduler of TinyOS, which is the operating system of choice for sensor nodes. Specifically, our approach exploits computational redundancy for the design of recovery instead of using resource redundancy. The presented fault-tolerant task queue recovers from bit-flips with significantly lower space/time overhead compared with the Error Correction Codes.**

I. Introduction

Wireless Sensor Networks (WSNs) are increasingly used in mission-critical applications (e.g., body sensor networks, habitat monitoring, flood forecasting, etc.), where they have to be deployed in harsh environments (e.g., volcano, forest, battle field, etc.). On one hand, WSNs must exhibit a high degree of service dependability due to application requirements, and on the other hand, unexpected environmental events, i.e., *faults*, may negatively affect their quality of service. For example, *transient faults* may cause non-deterministic bit-flips in the main memory of sensor nodes (a.k.a. *motes*), thereby perturbing the state of the running program to an arbitrary state in its state space. Since the quality of the service provided by the entire sensor network heavily relies on the dependability of the controlling software of motes, fault tolerance techniques should be applied to improve the dependability of motes. Nonetheless, due to their limited computational (e.g., memory and processing power) and energy resources, it is impractical to apply the traditional fault tolerance methods (e.g., Error Correction Code (ECC) [9]) to motes. This paper proposes a novel method that exploits computational redundancy for the addition of recovery to transient bit-flips in the task queue of TinyOS [14].[1]

Most existing techniques [12], [4], [10], [1], [13] present solutions for the design of fault-tolerant protocols for WSNs rather than focusing on the fault tolerance of individual sensor nodes. For instance, techniques for reliable transmission are mostly based on redundant and/or multi-path retransmission [10]. Several methods exist for (i) designing self-stabilizing WSN communication protocols [1] that ensure a correct synchronization among sensor nodes starting from an arbitrary non-synchronized state, and (ii) providing recovery for data dissemination in WSNs [13]. ECC methods (e.g., Hamming code [9]) often require extensive memory redundancy for storing extra parity bits in code words. Moreover, decoding/coding algorithms in these methods are computationally expensive.

We propose a novel approach that enables space/time-efficient recovery to transient Bit-Flips (BFs) in motes. The proposed approach is based on the detection of the violations of invariance conditions that must always be true and dynamic corrections of such violations. Specifically, we focus on the task queue of the TinyOS as it is one of the most critical components of the kernel of TinyOS and its structure is heavily sensitive to BFs. We first define conditions under which the task queue has a valid structure, called the *structural invariant*. Then, before and after the addition/removal of a task to/from the task queue, we check whether the structural invariant holds. In case of the violation of the invariant, we identify different failure scenarios created due to the occurrence of BFs and systematically correct them, thereby recovering to the structural invariant. The proposed approach enables the detection and correction of multiple BFs in a single-byte variable in a space/time-efficient fashion. Compared with the Hamming Code (HC) [9], our approach needs at least 20% less memory and performs at least twice as fast as HC. The time complexity of our approach is linear in the size of the task queue. We also note that HC cannot correct multiple BFs whereas our approach enables the correction of multiple BFs as long as they occur in the same variable. Furthermore, for some special cases, the proposed approach corrects BFs in multiple variables as well.

Organization. Section II illustrates the structure of the TinyOS task queue. Then, Section III presents our approach for the detection and correction of transient bit flips in the TinyOS task queue. We also demonstrate the superiority of the space/time efficiency of the proposed approach compared with the ECC methods. Section IV makes concluding remarks and outlines future research directions.

[1] TinyOS is the operating system of choice for sensor nodes in WSNs.

II. Structural Invariance of TinyOS Task Queue

In this section, we define what constitutes a valid structure of TinyOS's task queue. In Tiny OS version 2.x, the task queue is a linked list of task identifiers implemented as a statically allocated array of 256 entries (see Figure 1). Figure 2 illustrates the implementation of the task queue in nesC [8], which is a component-based variant of the C programming language used for application development on TinyOS. Each identifier (ID) is an integer between 0 and 255 inclusive. The set of variables of interest are `m_head`, `m_tail` and `m_next[256]`. `m_head` holds the index of the oldest ID in the queue, and `m_tail` holds the ID of the most recent task inserted in the queue. Every value in `m_next` is an ID for the next task to be executed and an index (i.e., pointer) to the successor entry in `m_next`. A distinguished task has the identifier `NO_TASK` $= 255$. `NO_TASK` is the value of `m_next[m_tail]` and it is the successor of all non requesting identifiers. For example, as depicted in Figure 1, a queue state s_1 consists of `m_head`=12, `m_next[12]`=3, `m_next[3]`=255, `m_tail`=3, and $\forall j : (j \neq 12) :$ `m_next[j]`=255.

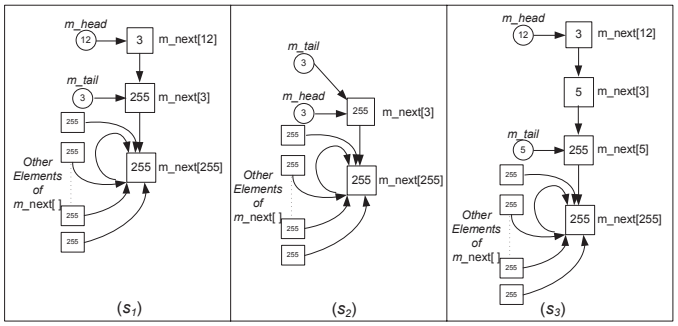

Fig. 1. Example states of the task queue.

The state s_1 represents a task queue having only two pending tasks of identifiers 12 and 3 respectively. The effect of `popTask()` on s_1 is a transition to state s_2 (see Figures 2 and 1). In state s_2, `m_head`=3, `m_next[3]`=255, `m_tail`=3, and $\forall j : (0 \leq j \leq 255) :$ `m_next[j]`=255. The effect of `pushTask(5)` on s_1 is a transition to state s_3 (see Figures 2 and 1), where `m_head`=12, `m_next[12]`=3, `m_next[3]`=5, `m_next[5]`=255, `m_tail`=5, and $\forall j : (j \neq 12) \wedge (j \neq 3) \wedge (0 \leq j \leq 255)$: `m_next[j]`=255.

Structural Invariant. A *valid* state of the task queue is a state where the queue has a linear structure with its head (`m_head`) pointing to its beginning and its tail (`m_tail`) pointing to the most recently added identifier to the task queue. Each element of `m_next` with a non-255 ID is reachable from the head. Each entry of `m_next` that is not in the queue holds the value of `NO_TASK`, and `m_next[m_tail]` is equal to `NO_TASK`. Moreover, the task IDs belong to the interval $0 \leq ID \leq 255$. Figure 3-(a) illustrates a sample valid state of the task queue. Furthermore, any operation performed on the queue should remove an element from the head (i.e., `popTask()`), add an element to the tail `pushTask()` or leave the structure of the queue and the task IDs unchanged.

```
inline uint8_t popTask()
{
 if( m_head != NO_TASK ) {
   uint8_t id = m_head;
   m_head = m_next[m_head];
   if( m_head == NO_TASK )   m_tail = NO_TASK;
   m_next[id] = NO_TASK;
   return id;   }
  else       return NO_TASK;
  }

bool isWaiting( uint8_t id )
 { return (m_next[id] != NO_TASK) || (m_tail == id); }

bool pushTask( uint8_t id )  {
 if( !isWaiting(id) )  {
   if( m_head == NO_TASK ) { m_head = id;  m_tail = id; }
   else  {  m_next[m_tail] = id;  m_tail = id;   }
   return TRUE;
 } else   return FALSE;      }
```

Fig. 2. Excerpt of the Tiny OS Scheduler.

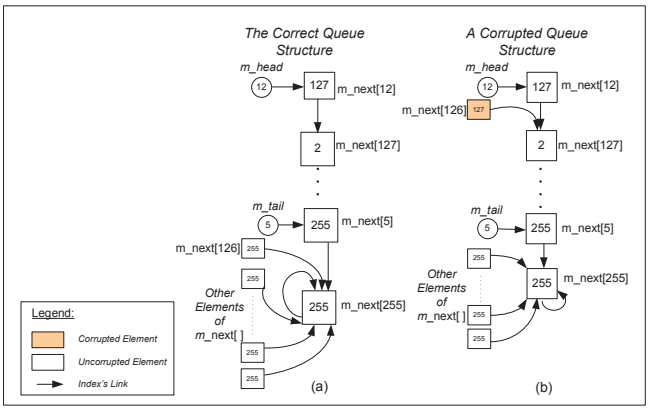

Fig. 3. Valid and invalid task queue structures.

Transient faults. Transient faults may toggle multiple bits in a single variable; i.e., `m_head`, `m_tail` or a memory cell of `m_next[]`. The case of multi-variable corruption is the subject of our current investigation. Bit-flips may perturb a task ID and the structure of the task queue to an invalid state. For example, Figure 3 demonstrates how resetting the most significant bit of `m_next[126]` could change its content from 255 to 127, thereby pointing to `m_next[127]` instead of pointing to `NO_TASK`.

III. Addition of Recovery

Section III-A analyzes the memory and time requirements of correcting BFs with the Hamming code. Section III-B illustrates how our approach enables recovery from BFs by detecting invalid queue structures and correcting them.

A. Correcting Bit-Flips with ECC

One approach for recovery from transient faults that cause bit-flips is to use error detection and correction codes such as the Hamming Code (HC) [9]. However, due to high memory/CPU cost of the encoding/decoding algorithms these approaches seem impractical in the context of WSNs. For example, there are two ways to deal with bit-flips in the task queue using HC; consider either individual memory cells of the `m_next[]` array as separate data words, or the entire 256 bytes of the task queue as one data word.

In the first case, each cell of the `m_next[]` array should be encoded before storing a value and it should be decoded before reading its contents. To encode 8 bits of data with HC, we need 4 extra parity bits, which results in a code word with 12 bits in the following format: $p_1p_2d_1p_3d_2d_3d_4p_4d_5d_6d_7d_8$, where d_j denotes data bits for $1 \leq j \leq 8$, and p_i represents the parity bits for $1 \leq i \leq 4$. The encoding algorithm of HC determines the 12-bit code word by multiplying a 12×8 matrix by a vector made of the data bits. Such a matrix multiplication takes 96 multiplications and 84 additions; i.e., totally 180 *basic operations* in addition to one read and write operation on each memory cell, where a basic operation includes arithmetic and logical operations as well as comparisons and load/store. The decoding algorithm also multiplies a 4×12 matrix by a vector containing the 12-bit code word, which results in a 4-bit syndrome vector representing the position of the corrupted bit. (Thus, each decoding takes 48 multiplications and 44 additions, totally 92 basic operations.) Notice that for each byte allocated in `m_next[]` 4 extra bits should be considered for parity. That is, $256/2 = 128$ extra bytes should be allotted along with the 256 bytes allocated for `m_next[]`. Besides, every time a task ID is stored/retrieved to/from a memory cell in `m_next[]`, the encoding/decoding algorithm must be executed. That is, for one round of detection and correction, $256 \times (180 + 92) = 69632$ basic operations should be performed.

In the second case, the queue comprises a bit pattern with $256 \times 8 = 2024$ bits, for which $1 + log\ 2024 = 12$ parity bits are needed in HC. Thus, the size of the code word is equal to $2024 + 12 = 2036$ bits. The encoding takes $2024 \times 2036 = 4120864$ multiplications and $2023 \times 2036 = 4118828$ additions; i.e., totally 8239692 basic operations. For decoding, we will need 12×2036 multiplications and 12×2035 additions resulting in 48852 basic operations. This analysis clearly illustrates the impracticality of using HC on sensor nodes with a small memory and a limited processing power. While other ECC methods (e.g., , Forward Error Correction (FEC) [3] and Reed-Solomon (RS) [15]) can correct cases where multiple variables are corrupted, they are even more expensive than HC in terms of either space or time. For example, the RS method needs t bits for the correction of $\lfloor t/2 \rfloor$ bits and $\mathcal{O}(t^2)$ is its time complexity.

B. Adding Recovery to Task Queue

This section illustrates how we enable recovery to a valid queue structure from transient BFs. Figure 4 depicts a state machine that demonstrates the impact of transient faults and how recovery should be achieved. Since the task queue is a centralized program running on a single CPU, we can benefit from a high atomicity model in which a set of instructions can be performed atomically. In fact, the nesC language provides atomic blocks that capture a sequence of statements that are supposed to be executed without interruption. The essence of the addition of recovery in high atomicity [6] is based on detecting the violation of the invariant due to the occurrence of faults, and providing recovery from every invalid state to the invariant. Thus, we present the function `DetectCorrect()` (see Figure 5) that we add to the Tiny OS scheduler to enable the detection and correction of BFs before and after any push/pop operations on the task queue. The function `DetectCorrect()` should be invoked in an atomic block (i.e., `atomic{DetectCorrect()}`) to ensure that detection and correction are not interrupted during execution. Depending on the harshness of the environment where the motes are deployed, the period of invoking `DetectCorrect()` could be changed by the developers; i.e., `DetectCorrect()` can be invoked in an adaptive fashion by the scheduler of TinyOS in order to enable a tradeoff between the degree of dependability and the energy cost of providing recovery. Next, we explain different parts of `DetectCorrect()` to illustrate how detection and correction are achieved.

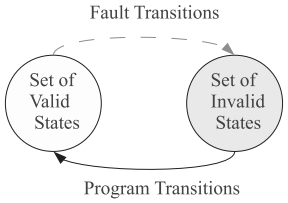

Fig. 4. Adding recovery to the task queue.

Data structures. To detect and correct corruptions of the task queue, `DetectCorrect()` gathers some information about the structure of the queue and stores them in these data structures (see Figure 5):

```
DetectCorrect(int q_size) {
 uint8_t previous;
 uint8_t current=m_head;
 uint8_t Index=0;
 uint8_t dangleElem=0;
 uint8_t non255 =0;       // Number of non-255 elements
 uint8_t qLength =0;      // Number of elements in the queue
 uint8_t cyclePoint =0;   // The corrupted element that
                          // points back and creates a cycle

 component visited = new BitVectorC(256);
 visited.clearAll();
 component pointedTo = new BitVectorC(256);
 pointedTo.clearAll();
 component pointsToNoTask = new BitVectorC(256);
 pointsToNoTask.clearAll();

 bool cyclic = FALSE;
 bool pointedByHead = FALSE;
```

Fig. 5. Data structures.

(1) `previous, current, dangleElem` and `cyclePoint` are pointers that are used during the traversal of the queue; (2) `non255` keeps the number of memory cells in `m_next` that contain non-255 values; (3) `qLength` stores the number of non-255 elements reachable from the head of the queue (`m_head`); (4) the `visited` bit vector allocates one bit corresponding to each element of `m_next` illustrating whether or not it has been visited previously in a queue traversal for cycle detection; (5) the `pointedTo` bit vector keeps a bit for each element of `m_next` demonstrating whether or not that element is being pointed to by some other element; (6) the `pointsToNoTask` bit vector allocates a bit corresponding to each memory cell of `m_next` that

contains NO_TASK; (7) the cyclic flag is set if a cycle is detected in the structure of the task queue, and (8) the pointedByHead flag is true if and only if there is an element in the queue that is pointed by both m_head and another element in the queue. We use the pointedByHead flag in detecting/correcting the corruption of m_head. Notice that, we allocate 96 bytes for the bit vectors and 7 bytes for other variables (i.e., 103 bytes totally) capturing local variables; i.e., when DetectCorrect() returns this memory is released.

Initialization. In this step, we first count the total number of elements in m_next that contain non-255 values. Then, we initialize the pointedTo and pointsToNoTask bit vectors. This step incurs $256 \times 15 = 3840$ basic operations on our solution.

```
// Count the number of non-255 elements in array m_next
 for(Index=0; Index<NO_TASK; ++Index)
    if (m_next[Index] != NO_TASK) non255++;
// Determine the elements that are being pointed to
 for(Index=0; Index<NO_TASK; ++Index)
    pointedTo.set(m_next[Index]);
// Determine the elements that point to NO_TASK
 for(Index=0; Index<NO_TASK; ++Index)
    if(m_next[Index] == NO_TASK) pointsToNoTask.set(Index);
```

Detection and correction of m_head. Since the traversal of the queue for subsequent processing is performed using the m_head pointer, we first ensure that m_head is corrected. If m_head points to NO_TASK (see Figure 6), then we set m_head to the index of the element to which no other element points, and exit (because, by assumption, our focus is on single-variable corruption). Otherwise, we detect whether m_head points to another non-255 element in the queue. (Please see Figure 7 and the first for-loop in the else part of Figure 6.) If so, then we set m_head to the index of the non-255 element to which no other element points. (See the second for-loop in the else part of Figure 6.) Figure 7 illustrates a case where the value of m_head has been corrupted from 12 to 4.

```
if (m_head == NO_TASK)  {
  for(Index=0; Index<NO_TASK; ++Index)
    if(!pointedTo.get(Index) && m_next[Index] != NO_TASK) {
            m_head = Index;  return; }      }
else {
  for(Index=0; Index<NO_TASK; ++Index)
    if(pointedTo.get(Index) && Index == m_head) {
                    pointedByHead = TRUE; break; }
  if (pointedByHead)
   for(Index=0; Index<NO_TASK; ++Index)
    if(!pointedTo.get(Index) && m_next[Index] != NO_TASK) {
                  m_head = Index;  return; }
      }
```

Fig. 6. Detect and correct m_head.

The time complexity (and energy consumption) of this step is proportional to the maximum number of basic operations. If m_head = NO_TASK, the for-loop in the if part of Figure 6 will be executed, which has one comparison and one increment for the loop counter in each iteration. Moreover, the if-statement inside the for-loop performs two load operations, one comparison and two logical operations per iteration. Thus, in the worst case, we have 7 basic operations in each iteration of this for-loop, which results in $256 \times 7 = 1792$ basic operations if m_head = NO_TASK. A similar reasoning illustrates that, in the worst case, we perform $256 \times 15 = 3840$ basic operations if m_head $\neq$ NO_TASK. Therefore, since either the if part or the else part is executed in Figure 6, the correction of m_head takes at most 3840 basic operations.

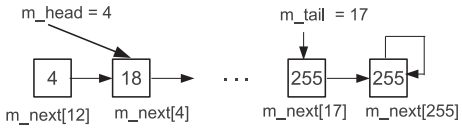

Fig. 7. Corruption of m_head.

Detection and correction of cyclic structures. The do-while loop in the below code uses the visited bit pattern to determine whether there is a cycle in the queue. This loop also stores the number of elements in the queue that are reachable from m_head in the qLength variable.

```
// Detect cycles
do {
   if(!visited.get(current))       visited.set(current);
   else { cyclic = TRUE;
          cyclePoint = previous;     break;  }
   previous=current;
   current=m_next[previous];
   qLength++;
     } while(current != NO_TASK && m_tail!=previous);

// Correct cycles
if (cyclic && (cyclePoint == m_tail)) {
          m_next[cyclePoint] =  NO_TASK; return; }
if (cyclic && cyclePoint != m_tail)
  for(Index=0; Index<NO_TASK; ++Index)
    if(!pointedTo.get(Index) &&
          (m_next[Index] != NO_TASK) && (Index != m_head)) {
          m_next[cyclePoint] = Index;  return; }
```

A cycle could be formed in two ways: either the tail points back to some element including itself (see Figure 8-(a)), or another element points back to some element including itself (see Figure 8-(b)). If a cycle is detected, then the cyclic flag is set and the index of the element pointing back is stored in cyclePoint. In case cyclePoint is equal to m_tail, then that means the tail of the queue is pointing back to some element instead of pointing to NO_TASK. Otherwise, to fix the cycle, we set the contents of m_next[cyclePoint] to the index of the element that has become *dangled* due to the cycle creation; i.e., the element to which no element points, does not point to NO_TASK, and is not equal to m_head. This correction will take at most $256 \times 26 = 6656$ basic operations.

Detection and correction of queue size and non-255 elements. To detect discrepancies in the size of the task queue, we add a new variable q_size to the TinyOS scheduler to store the size of the queue outside the DetectCorrect function. Nonetheless, q_size could be perturbed by transient faults. The first if statement in Figure 9 corrects q_size. Notice that DetectCorrect can simultaneously correct q_size and m_head, which is a special case of correcting MBFs in multiple variables. Moreover, faults may change the value of an array element from 255 to some other value. This means that that element points to some queue element. Such a link is not part of the task queue and should be eliminated.

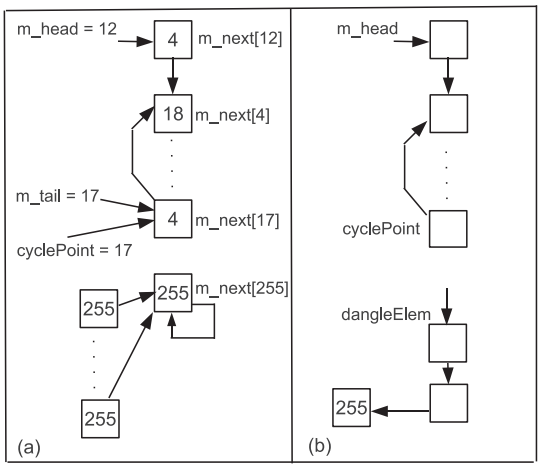

Fig. 8. Cyclic corruption of the task queue.

To this end, we assign 255 to an element to which no other element points, points to a non-255 element and is not equal to `m_head`. The `for-loop` in the second `if statement` could take at most $256 \times 11 = 2816$ basic operations.

```
if (qLength == non255) {
    if (q_size != qLength)  { q_size = qLength; return; }
        else return;  // Task queue is NOT corrupted.
         }

if (non255 > q_size) // some 255 element has become non255
   for(Index=0; Index<NO_TASK; ++Index)
     if (!pointedTo.get(Index) &&
        (m_next[Index] != NO_TASK) && (Index != m_head)) {
                m_next[Index] = NO_TASK;  return;  }
```

Fig. 9. Detect and correct queue size.

Detection and correction of `m_tail`. To detect and correct the corruptions of `m_tail`, we set `m_tail` to the index of the first element whose contents point to `NO_TASK` (see below). For example, in Figure 10, `m_tail` is set to 17. The `for-loop` in the below code performs at most 2560 basic operations.

```
for(Index=0; Index<NO_TASK; ++Index) {
    if ((!pointsToNoTask.get(Index)) &&
        (m_next[m_next[Index]] == NO_TASK) &&
                (m_tail != m_next[Index])) {
               m_tail = m_next[Index];  return;  } }
```

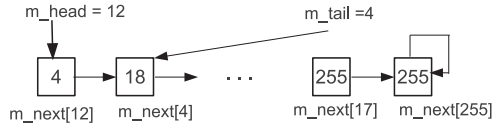

Fig. 10. Corruption of `m_tail`.

Detection and correction of corrupted acyclic structures. If faults corrupt a non-255 element so it points to one of its successors, then a structure similar to Figure 11 could be created. In this example, the contents of `m_next[4]` is changed from 18 to 25 and `m_next[18]` becomes unreachable from head; i.e., a *dangling* element. One way to detect this case is to simply compare `qLength` with the number of non-255 elements; if `qLength` $\neq$ `non255`, then either this case has occurred or the corruption of `m_head`. Nonetheless, if the code of the `DetectCorrect()` routine reaches this point, then it means that `m_head` has the correct value.

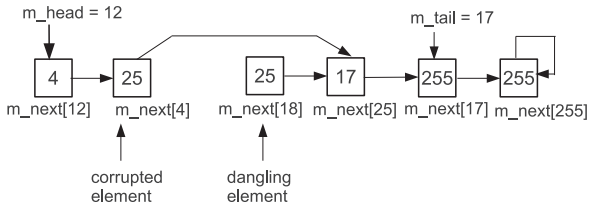

Fig. 11. Corrupted acyclic structure.

The identification of the `corrupted element` in Figure 11 is not straightforward. Our strategy is to determine the index of the element in the queue that is pointed by two internal elements of the queue (see `m_next[25]` in Figure 11). Such an element must be in the fragment of the queue that starts with the dangling element. Thus, we first find the index of the dangling element by the first `for-loop` in Figure 12. If there is such a dangling element, then we reset the `pointedTo` bit vector. Then, in the first `do-while` in Figure 12, we start setting the bits of `pointedTo` corresponding to the fragment of the queue that starts with the dangling element. In the second `do-while`, we search the first fragment of the queue (starting from `m_head`) for the element that points to an element whose corresponding bit is already set in the `pointedTo` vector. Once we find such an element, we set its content to the index of the dangling element, and the queue is corrected. This step includes $27 \times 256 = 6912$ basic operations in the worst case.

```
dangleElem = NO_TASK;
for(Index=0; Index<NO_TASK; ++Index)
   if(!pointedTo.get(Index) &&
       m_next[Index] != NO_TASK &&
       Index != m_head) {
                  dangleElem = Index; break; }

if (dangleElem == NO_TASK)  return;

pointedTo.clearAll();
current = dangleElem;

do {
     pointedTo.set(m_next[current]);
     previous=current;
     current=m_next[previous];
     } while(current != NO_TASK && m_tail!=previous);

current = m_head;

do {
    if (pointedTo.get(m_next[current]) {
              m_next[current] = dangleElem; return; }
    previous=current;
    current=m_next[previous];
     } while(current != NO_TASK && m_tail!=previous);
   }
```

Fig. 12. Detect and correct acyclic structures.

Time complexity of `DetectCorrect()`. Since the code of `DetectCorrect()` does not include nested for-loops, its time complexity is linear in the size of the task queue. Figure 13 presents a comparison of the time/space cost of the proposed method of this paper with two scenarios of using

the Hamming code for correction of BFs: HC1 represents the case where each element of `m_next` is encoded with HC, and HC2 denotes the case where the entire `m_next` is encoded as a single word. Notice that, our approach outperforms HC1 in terms of both time and space efficiency, respectively by a factor of 20% and 60%. More importantly, the required memory (i.e., 103 bytes) is temporary; i.e., when `DetectCorrect()` returns this memory is released. The HC2 method seems impractical due to expensive computing requirements.

Approach	Memory Cost	# of Operations
Hamming Code for each element of `m_next` (HC1)	128 Bytes	$\simeq$ 70000
Hamming Code for the entire `m_next` (HC2)	12 bits	$\simeq$ 4.17 million
Proposed Method	103 Bytes	28000

Fig. 13. Space/Time cost of correction of BFs.

Scope of correction. The scope of correction in these three methods is different. Figure 14 demonstrates that our approach can correct multiple bit-flips in a single variable, which cannot be achieved by HC1 and HC2. However, HC1 can correct single bit-flips in multiple variables, which we do not currently have a solution for it.

Approach	Corrects SBFs	Corrects MBFs in a Variable	Corrects SBFs in Multi Vars	Corrects MBFs in Multi Vars
HC1	Yes	No	Yes	No
HC2	Yes	No	No	No
Proposed Method	Yes	Yes	No	No

Fig. 14. Scope of correction for Single Bit-Flips (SBFs) and Multiple Bit-Flips (MBFs).

Fault tolerance of `DetectCorrect()`. In case transient faults perturb the local variables and/or the control flow of `DetectCorrect()`, the current round of execution of `DetectCorrect()` may not recover the structure of the task queue. However, since `DetectCorrect()` is executed repeatedly and transient faults eventually stop occurring, `DetectCorrect()` will eventually provide recovery.

IV. Conclusions and Future Work

We presented a novel method for the detection and correction of transient Bit-Flip (BF) in the task queue of the TinyOS, which is the operating system of choice for sensor nodes. Since motes have limited computational and energy resources, instead of using resource redundancy, the proposed approach exploits computational redundancy to efficiently recover from transient BFs that corrupt the contents and the structure of the task queue. The essence of our approach is based on the detection of invalid structures of the queue that might be created due to transient faults. Upon reaching an invalid structure, we analyze the structure of the task queue to determine which failure scenario has occurred and recover to a valid state. Using this method, we can correct Multiple BFs (MBFs) in single-byte variables. We illustrate that the proposed approach can provide a better time/space efficiency with respect to Error Correction Codes such as the Hamming code [9] (see Figures 13 and 14).

Several techniques exist for designing fault-tolerant data structures. Aumann *et al.* [2] present alternative implementations for pointer-based data structures by adding redundant links. Finocchi *et al.* [7] provide resilient search trees through periodic checkpoints. Jørgensen *et al.* [11] devise a method that ensures the resilience of priority queues by storing pointers in resilient memory locations. By contrast, our approach continuously monitors a structural invariance and provides recovery if the invariant is violated.

Future/ongoing work focuses on techniques for the correction of MBFs in multiple variables. Moreover, we would like to leverage our previous work [5] on automated addition of fault tolerance for the addition of recovery to data structures. Specifically, our previous work models a state as a unique valuation of variables of primitive types (e.g., Boolean and integer). Nonetheless, we need to create richer models that capture the topological state of complex data structures. We will also work on models where ECC methods and our approach are used in a hybrid fashion.

Abstract

Fault tolerance by redundancy is a key technique for improving web services reliability. But, the reliability and fault tolerance are not well supported by Service-oriented architecture (SOA) conceptual model.Most of the existing analytical models to predict the reliability of web services assume their structures are static which do not conform to reality and the estimated reliability precision is lower. In this paper, first, an extended SOA model is proposed for improving the reliability of web services. Then, a reliability model is presented to evaluate the reliability of web services based on the birth-death process. Last, the reliability of web services is evaluated using simulation approach and a case study is designed, implemented and analyzed to support our model. The results of experiment show the feasibility, validity of our reliability model.

***Keywords*-Web Service Reliability; Birth-Death Process; SOA Conceptual Model**

I. Introduction

Fault tolerance is considered to be an effective way to improve system reliability. In traditional software development, fault tolerance is expensive and only some crucial module can be designed by redundancy. However, at the present time, there are many function-equivalent web services in the Internet which are often provided by different service providers. So, it is practicable to upgrade the reliability of web services by redundancy.

Web services reliability is more hard to predict than general software system. There are several fault-tolerant reliability analysis approaches which have been proposed in [1][2][3][4] and etc, most of their reliability models are based on architecture, mainly considering the static structure and transition probability, without taking into account their dynamic change with time, so the precision is not higher. In fact, the reliabilities of services are influenced by many factors in the Internet environment and a failure can occur at any arbitrary time. The reliability of a service is not a constant but a function of time[5]. Fault tolerance is not well supported by SOA conceptual model, hence, in this paper, we extend the SOA conceptual model by redundancy, propose a fault-tolerant conceptual model and present a reliability model for estimating fault-tolerant web services based on birth-death process.

The rest sections of the paper are organized as follows: Section II describes a fault-tolerant reliability model. Section III describes the reliability prediction algorithm. Section IV does some experiments to verify our model. Section V discusses the conclusion and our future works.

II. Fault-Tolerant Reliability Model

A. Extended SOA Conceptual Model

The ESOACM (extended SOA conceptual model) is shown in Figure 1. The web services manager is responsible for all web services. Web services are defined as $WS = \{S, S_1, S_2, \ldots, S_n\}$, S is the primary service and $S_1, \ldots, S_n$ is the backup of S. The web service manager will choose the best service as the primary service. When service requesters send a request for WS, the UDDI

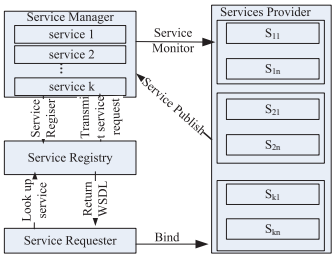

Fig. 1. Extended SOA Conceptual Model

registry will transmit the request to web service manager to look up which service S_i is available in sequence. First, it check S, if S is available, the service manager will return its address to the UDDI registry, then the UDDI registry will return its address to the service requesters. When S fails, the service manager will substitute backup service S_1 for S and notify service provider to repair it and so on.

B. Reliability Model

Now, we discuss how to estimate the reliability of web service in the extended SOA conceptual model. In the extended model, when a service fails, the next backup will replace it. The number of failed web services can be counted by a stochastic process. Stochastic process $\{X(t), t \geq 0\}$ denotes the number of failed web service which have occurred by time t and the state space is $\{0, 1, 2, .., n\}$. The stochastic process can be described by a birth-death process which satisfies some properties:

- Failed, repaired probability for service i in an interval $(t, t + \Delta t)$ is $\lambda_i \Delta t$, $\mu_i \Delta t$.
- Probability of two failures occurred at the same time is zero.
- State can only be transferred between two adjacent state.

State i means the number of failed web services is i and so on. When the process is in state n, the system means failure and no service is available. When a web service occurs failure, the system will go to the next state and when is repaired, it will go back to the previous state. The failure and repair rate of the web service S_i is denoted by $\lambda_i(t)$,μ_i. If failure rate of a web service is a constant, then $\lambda_i(t) = \lambda_i$. The state transition diagram of our stochastic failure model is shown in figure 2.

III. Reliability Prediction Algorithm

In this section, we discuss how to design algorithm. The failure behavior of web services can be denoted by

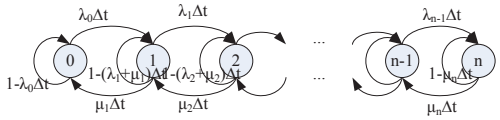

Fig. 2. State Transition Diagram

TABLE I. Notations of our algorithm

Notations	Explanation
r_i	reliability of service i;
R	reliability of the Redundant web services;
λ_i	failure rate of web service i;
μ_i	repair rate of web service i ;
$time$	a variable of $[0, total\_time]$;
dt	time step;
$flag$	failed flag of the process.
$fault\_count$	total number of faults;
run_count	total number of runs;
$total\_time$	the total execution time during a run;

reliability, failure rate. First, we define some notations which are shown in table I.

A. Reliability

Algorithm 1 simulates how to calculate the reliability if the failure behavior is denoted by reliability. It accepts as input the reliability of every service, the number of services including the primary and back-up services and returns the reliability of web services with fault tolerance. The run_count represents the total run times. For each run, if $r_i < x \ and \ i < n$, the procedure will check next service. The service is failed if and only if $r_i < x$ and the state is n. The variable $fault\_count$ records the number of faults. This procedure repeats run_count times and the reliability can be computed just like in algorithm 1.

Algorithm 1 Getreliability1(r, n)

```
Initialize some variables run_count, run, fault_count;
while run ≤ run_count do
    for i = 1 to n do
        Generate a random number x in the range of [0, 1];
        if r_i < x then
            if arrive the state n then
                the model failed and increase fault_count by 1;
            else
                transferred to next state;
            end if
        end if
        increase run by 1;
    end for
    R = 1 − fault_count/run_count;
end while
return R;
```

B. Constant Failure Rate

When failure behavior is denoted by constant failure rate. The stochastic failure procedure is described by a pure-birth process. Algorithm 2 simulates how to calculate the reliability of our model. For each time step dt, we compare $\lambda_i * dt$ with a floating random number x between 0 and 1. If $\lambda_i * dt > x$, we say the ith service fails and turn to check the $(i+1)th$ service by the same way until the nth service. Simulate the above procedure run_count times to obtain the reliability of web services with fault tolerance which can be computed by the expression $R = 1 - fault\_count/run\_count$. The $total\_time$ can be varied and the reliability with time can be computed just like in algorithm 2. From these, we can analysis the change trend of reliability with time.

Algorithm 2 GetReliability2(λ, n)

initialize $run\_count, dt, t, runflag, fault\_count$;
for all $total\_time$ in a range **do**
  for $run = 1$ *to* run_count **do**
    $time = 0, i = 1, flag = false$;
    while $time < total\_time$ *and* $flag$ is $false$ **do**
      $time = time + dt$;
      generate a random number x in range of $[0, 1]$;
      if $\lambda_i * dt > x$ **then**
        if arrive the state n **then**
          $fault\_count[total\_time] + +$;
          $flag = true$;
        else
          transferred to next state;
        end if
      end if
    end while
  end for
  $R(total\_time) =$
    $1 - fault\_count(total\_time)/run\_count$;
end for
return array R;

C. Constant Failure Rate and Repair Rate

When failure behavior is denoted by failure rate λ_i and repair rate μ_i, the procedure is a birth-death process. We presume the repaired time follows an exponential distribution with a parameter μ_i. The simulation procedure is shown in Algorithm 3. Firstly, sample a time t from exponential distribution with parameter $(\lambda_i + \mu_i)$; Secondly, the transition probability from state i to state $i+1$ and to $i-1$ is $p_i = \lambda_i/(\lambda_i + \mu_i)$ and $1 - p_i$. Generate a random number x from $\{0, 1\}$ with probability p_i, the state is transferred to $i+1$ when x is 1 and to state $i-1$ when x is 0. Repeat the above procedure for run_count times and reliability can be computed just like in algorithm 3.

Algorithm 3 GetReliability3(λ, μ, n)

initialize $run\_count, run, flag$ and array $fault\_count$;
for all $total\_time$ in a range **do**
  for $run = 1$ *to* run_count **do**
    $time = 0, i = 1, flag = false$;
    while $time < total\_time$ *and* $flag$ is false **do**
      sample time t from an exponential distribution with a parameter $(\lambda_i + \mu_{i-1})$;
      generate a random number x from $\{0, 1\}$ with probability p_i;
      if x is 1 **then**
        the state is transferred to i+1;
      else
        the state is transferred to i-1;
      end if
      $time = time + t$
      if arrive the state n **then**
        $fault\_count[total\_time] + +$;
        $flag = true$;
      end if
    end while
  end for
  $R(total\_time) =$
    $1 - fault\_count(total\_time)/run\_count$;
end for
return array R;

D. Parameter Estimation

We discuss how to estimate the parameters in our algorithm. The reliability,failure rate and repair rate presented by service provider are not enough to be convincing. So, we reform it by collecting failure and repair information to improve accuracy. In our ESOACM, the server manager use log file to record services behavior information. For parameter reliability r_i, we assume that:

1) an initial value $r_{i,1}$ presented by service provider ;
2) service invoked times n and failure occurred times f in an interval $(0, t)$;
3) tested times N provided by service provider;
4) reliability estimated from log files $r_{i,2}$.

then the revised reliability is calculated by

$$r_i = \frac{N}{N+n} r_{i,1} + \frac{n}{N+n} r_{i,2} \tag{1}$$

where $r_{i,2} = 1 - \frac{f}{n}$. When the service is never called, the invoked times $n = 0$, the reliability $r_i = r_{i,1}$. If the service provider doesn't present the initial reliability $r_{i,1}$, the reliability $r_i = r_{i,2}$. So, the revised reliability represents the static reliability information and the dynamic reliability information. Similar methods can be used for the estimation of λ_i and μ_i which can be expressed by

$$\lambda_i = \frac{N}{N+n} \lambda_{i,1} + \frac{n}{N+n} \lambda_{i,2}. \tag{2}$$

where $\lambda_2 = \frac{f}{t}$. and

$$\mu = \frac{M}{M+k}\mu_{i,1} + \frac{k}{M+k}\mu_{i,2} \quad (3)$$

where $\mu_{i,2} = \frac{k}{M}$ and k is the repaired times in an interval $(0, t)$, M is total repaired times.

IV. Experiments

A. Experiment 1

For algorithm III-A, we set the reliability of services $r = [0.5, 0.5, 0.6, 0.3, 0.6], n = 5$. The run times run_count varies from 100 to 1000 step by 100. Here,we set the time spent on a run is one time unit. So, the number of total run is identify to the times of total run. The results of our experiment are shown in Table II. Column 'Exp1' is the reliability obtained from algorithm III-A and column 'Zheng' is reliability according to Zheng's[3] method. From the table, we can discover that the reliability is very close to Zheng's result.

TABLE II. Results of Experiment 1

Run times	Exp1	Zheng	Run times	Exp1	Zheng
100	0.970	0.972	600	0.973	0.972
200	0.980	0.972	700	0.970	0.972

B. Experiment 2

For algorithm III-B, we randomly set failure rate $\lambda = [0.0025, 0.003, 0.02, 0.02, 0.02], n = 5$. The run_count is set to 1000 at every specified $total\_time$. We also present the reliability of web services without redundancy. The reliability of single service is calculated by expression $r_i = e^{-\lambda_i t_i}, i = 1, 2, \ldots, n$ λ_i is the failure rate of service i and the t_i is the execution time spent in service i during a run[6]. The reliability with fault-tolerant and the max reliability of single services(MRSS) without fault-tolerant is shown in table III. From the table we can say that the reliability of services by redundancy is higher than a single service and the reliability will approach to zero with the time increased.

C. Experiment 3

To verify the validity of our model and to analyze simply in math, for algorithm III-C, we consider two services with same failure rate and repair rate, the parameter

TABLE III. Results of Experiment 2

Run times	Exp2	MRSS	Run times	Exp2	MRSS
100	0.997	0.779	600	0.654	0.223

V. Conclusions

An extended SOA conceptual model for reliability enhancement by redundancy is presented in this paper and a birth-death process to estimate the reliability of our model is proposed. The birth-death process model is more precision because the information from service provider and log files are both considered. But, there are some details that we have not taken into account. So, our future work will consider other factors that cause composite services failure based on other architecture.

Abstract

Architecture-based reliability analysis has gained prominence in the recent years as a way to predict the reliability of a software application during the design phase, before an investment is made in any implementation. To apply this analysis, the parameters comprising the architectural model must be estimated using the limited data and knowledge available during the design phase. These estimates, as a result, are inherently uncertain. Contemporary approaches, however, do not consider these uncertainties, and hence, may produce inaccurate reliability results. This paper presents a Bayesian approach to systematically consider parametric uncertainties in architecture-based analysis. The novelty of this approach lies in determining credible intervals for the model parameters as a function of their posterior distributions. By leveraging these intervals, we illustrate how to: (i) quantify the impact of uncertainty in a specific parameter on the system reliability estimate; (ii) evaluate when a sufficient amount of data has been collected to reduce the uncertainty to an acceptable level; and (iii) assess the impact of prior knowledge regarding the parameters in improving the system reliability estimate.

1 Introduction

Architecture-based analysis [8, 9] is a powerful approach to assess the reliability of a software application[1] earlier in its lifecycle, and to offer guidance for cost-effective reliability improvement. Such guidance often consists of identifying critical components from the perspective of application reliability, so that additional resources can be allocated to these components to improve their reliability. Architecture-based analysis is thus especially useful in the context of modern, complex software systems which are composed from a variety of components; picked off-the-shelf, built contractually, and developed in-house [13].

In the architecture-based approach, application reliability is expressed in terms of the failure characteristics of the components and the application architecture. The parameters comprising the architectural model thus include the transition probabilities among the components and the reliabilities of the components comprising the application. Thus, the number of parameters (transition probabilities and component reliabilities) that need to be estimated increases with the size of the application. Additionally, these parameters must be estimated based on the limited data or scant knowledge that may be available earlier in the lifecycle before the application is implemented and can be tested extensively. Because of such limited available information, architecture-based analysis must be performed with uncertain parameters. These parametric uncertainties then propagate to the system-level reliability results, which include the reliability estimate and the ranks of the components based on their criticality. Most of the contemporary architecture-based analysis approaches, however, do not consider these parametric uncertainties [2]. Thus, in the best case, the system reliability estimate that these approaches produce underestimate the true reliability, which may result in dedicating more than necessary resources for the system to reach its reliability target. In the worst case, however, the system will be deployed with an optimistic expectation of its reliability [3]. To avoid the pitfalls associated with over and under-estimation, it is necessary to systematically and quantitatively incorporate the impact of uncertain parameters into architecture-based reliability analysis.

In this paper, we present a Bayesian approach to incorporate parametric uncertainties into architecture-based software reliability analysis. The proposed approach constructs joint credible intervals using the posterior distributions of the model parameters as a function of limited information. We illustrate how these credible intervals could be used to explore the influence of uncertain parameters on application reliability. We also demonstrate how the Bayesian approach could be used to quantify the impact of additional data or prior knowledge in reducing the uncertainty in the system-level reliability results.

The paper is organized as follows: Section 2 presents the Bayesian approach. Section 3 illustrates the approach. Section 4 summarizes related research. Section 5 offers concluding remarks and directions for future research.

[1] The terms application, software, and system are used interchangeably throughout this paper.

2 Bayesian analysis methodology

In this section, we introduce a preliminary model for architecture-based reliability analysis that ignores uncertainties in the model parameters. We then describe how this preliminary model can be extended to incorporate parametric uncertainties using the Bayesian approach.

2.1 Preliminary model

We consider a terminating application with n components. We assume that the transfer of control between components is independent and that the failure of a single component causes the entire application to fail. The architecture of the application is represented as a probabilistic control flow graph. This graph is mapped to a discrete time Markov chain (DTMC) which is represented by an $n \times n$ matrix $\mathbf{P}$. The $(i,j)^{th}$ element of $\mathbf{P}$ is the expected value of the random variable $\mathcal{P}_{i,j}$, denoted $p_{i,j}$, and represents the expected probability that control is transferred from component i to component j. Thus, there exists a one-to-one mapping between the application components and the states of the DTMC. Without loss of generality, we assume that the application starts execution with component one and terminates after component n executes, so the n^{th} row of $\mathbf{P}$ contains all zeros.

We let R_i denote the expected reliability of component i. Component reliability is binary, that is, when control transitions to component i, the probability that it executes successfully is represented by the random variable Λ_i whose expected value is R_i. If a component does not execute successfully, the entire system fails. The expected application reliability can be computed using the following algorithm:

1. Define $\mathbf{D}$ as a diagonal matrix where $\mathbf{D}_{i,i} = R_i$
2. Let $\mathbf{Q} = \mathbf{D} \times \mathbf{P}$
3. Solve $\mathbf{S} = \sum_{k=0}^{\infty} \mathbf{Q}^k = (\mathbf{I} - \mathbf{Q})^{-1}$
4. System reliability is given as $\mathbf{S}_{1,n} \cdot R_n$

The matrix $\mathbf{Q}$ is a sub-stochastic matrix where $q_{i,j}$ is the transition probability among components i and j, weighted by the reliability of component i. This captures the notion that a transition from component i to component j occurs conditional to the successful execution of component i, else component i fails causing the application to fail. Using $\mathbf{S}$ to obtain the expected number of times the application reaches the end state n starting from state 1, the system reliability is thus given by $\mathbf{S}_{1,n} \cdot R_n$.

2.2 Incorporating parametric uncertainties

In this section, we discuss our approach to incorporate parametric uncertainties into the preliminary model presented above. Towards this end, we use Bayesian techniques to construct credible intervals for each parameter, such that the true value of the parameter lies within that credible interval at a specified confidence level. The credible interval will provide the range over which each parameter must be varied in order to systematically explore the impact of its uncertainty on the application-level reliability results.

2.2.1 Posterior distribution

The parameters of the architecture-based model include the intercomponent transition probabilities, and the component reliabilities. To construct a credible interval for each parameter, it is first necessary to determine its posterior distribution. A point estimate for the expectation of Λ_i is given by $R_i = x_i/n_i$, where x_i is the number of successful executions of the component across n_i trials. Each x_i then follows a Binomial distribution:

$$Bin(x_i, R_i) = \binom{n_i}{x_i} R_i^{x_i} (1 - R_i)^{n_i - x_i}.$$

We can define a *posterior* distribution $G(\Lambda_i|x_i)$ of the random variable representing component reliability, incorporating any prior knowledge we have about this distribution with additional data we have obtained since then, as follows. Let $g(\Lambda_i)$ be the *prior* distribution of Λ_i, incorporating any *a priori* knowledge about Λ_i, and $f(x_i|\Lambda_i)$ be the likelihood function that provides the probability of observing x_i given Λ_i. From Bayes theorem [1], it follows that:

$$G(\Lambda_i|X) = \frac{g(\Lambda_i) f(X|\Lambda_i)}{\int_0^1 g(\Lambda_i) f(X|R_i) d\Lambda_i}.$$

Since the expected value of Λ_i is used as the parameter of a Binomial distribution, we know that Λ_i has a prior and a posterior that follows a Beta distribution, given as:

$$Beta(\Lambda_i|a_i, b_i) = \frac{\Gamma(a_i + b_i)}{\Gamma(a_i)\Gamma(b_i)} \Lambda_i^{a_i - 1} (1 - \Lambda_i)^{b_i - 1}.$$

The parameters of the posterior can be expressed in terms of the parameters of the prior. If $g(\Lambda_i) \sim Beta(\Lambda_i|\alpha, \gamma)$, then $G(\Lambda_i|x_i) \sim Beta(\alpha + x_i, \gamma + (n_i - x_i))$ [4].

Next, we determine the posterior distribution for each random variable $\mathcal{P}_{i,j}$ representing the transition probabilities in the architecture. The expectation $p_{i,j}$ of this random variable represents the average probability of transitioning from component i to component j. This average transition probability can be estimated as $p_{i,j} = x_{i,j}/n_i$ where $x_{i,j}$ is the number of times control is transferred from component i to component j and $n_i = \sum_j x_{i,j}$ is the total number of times control is transferred out of component i. The number of times control is transferred to various components from component i thus follows a Multinomial distribution [12]:

$$Multinomial(X_i, k_i) = \binom{k_i}{x_{i,1} x_{i,2} \ldots x_{i,k}} p_{i,1}^{x_{i,1}} p_{i,2}^{x_{i,2}} \ldots p_{i,k}^{x_{i,k}}$$

App. Reliability	0.7200	0.6756	6.57%

Table 1. Parameter estimates based on limited data

where k_i is the number downstream components that control can be transferred to, $X_i = (x_{i,1}, x_{i,2}, ...x_{i,k_i})$, and $\sum_{j=1}^{k_i} x_{i,j} = n_i$. Let $P_i = (\mathcal{P}_{i,1}, \mathcal{P}_{i,2}, ...\mathcal{P}_{i,k_i})$ be the vector whose elements are the random variables that represent the transition probabilities associated with state i. These random variables have an expectation of $p_{i,1}, p_{1,2}, ..., p_{i,k_i}$. It is important to note that $k_i \leq n$, that is, the number of downstream components that component i can transfer control to, in general, may be less than the total number of components in the application. When the draws from the Multinomial distribution are independent, the posterior and prior distribution for P_i follows a Dirichlet distribution, given by:

$$Dir(P_i|\Psi_i) = \frac{\Gamma(\psi_{i,1} + \psi_{i,2} + ... + \psi_{i,k_i})}{\Gamma(\psi_{i,1})\Gamma(\psi_{i,2})...\Gamma(\psi_{i,k_i})} \prod_{j=1}^{k_i} p_{i,j}^{\psi_{i,j}-1}.$$

Here, $\Psi_i = (\psi_{i,1}, \psi_{i,2}, ..., \psi_{i,k_i}), \psi_{i,j} > 0 \ \forall j$ is the set of parameters representing the number of times each transition was followed, $p_{i,j} \geq 0$, and $\sum_{j=1}^{k_i} p_{i,j} = 1$. Since the marginals of the $Dir(P_i|\Psi_i)$ are $Beta(\psi_{i,j}, \psi - \psi_{i,j})$ distributed, where $\psi = \sum_{j=1}^{k_i} \psi_{i,j}$, it follows that the prior and posterior of each $\mathcal{P}_{i,j}$ are Beta distributed. Letting $\sum_{j=1}^{k_i} x_{i,j} = n_i$, if $g(\mathcal{P}_{i,j}) \sim Beta(\alpha, \gamma)$, then its posterior follows a $Beta(\alpha + x_{i,j}, \gamma + n_i - x_{i,j})$ distribution [4].

2.2.2 Bayesian credible intervals

With the posterior distribution derived for each model parameter, a Bayesian credible interval can be established that provides a confidence level within which the true value of the parameter lies. For model parameter π_i (either a component reliability or a transition probability) that has a posterior distribution $G(\pi_i|X)$, the bounds of the $(1-\alpha)\%$ Bayesian credible interval is the value y_i for which:

$$\int_0^{y_i} G(\pi_i|X)d\pi_i = \epsilon$$

where $\epsilon = \alpha/2$ defines the lower and $\epsilon = 1 - \alpha/2$ defines the upper bound of the interval. These bounds for all the parameters can be computed using the inverse CDF function of the Beta distribution because the posterior of all the model parameters follows this distribution. This inverse CDF is available in software packages such as MATLAB and Excel [11].

3 Illustrations

This section illustrates the Bayesian approach to incorporate parametric uncertainties using an application from the European Space Agency (ESA) to configure an array of antennas. The architecture of the ESA application, along with the true intercomponent transition probabilities, are shown in Figure 1. The application consists of four components: the $Parser$ component, the $Computational$ component, the $Formatting$ component, and the End component, assigned as components 1, 2, 3, and 4, respectively. For the sake of illustration, we set the reliability of the $Parser$ to 0.84, the $Computational$ component to 0.83, and the $Formatting$ component to 0.95, resulting in a true system reliability of 0.6756. Based on these true values, in this section, we first illustrate the impact of uncertain parameters on the system-level reliability results. Subsequently, we illustrate how the Bayesian approach can be used to systematically assess the impact of parametric uncertainties on system reliability and to provide guidance on reducing the uncertainty in system-level reliability.

3.1 Reliability estimation

To demonstrate how limited data leads to parametric uncertainties, we simulated the operation of the ESA application 50 times. During these 50 runs, we recorded the number of times control transfers among a pair of components, the number of times control transfers out of each component, and the number of failures of each component. Based on these observations, we estimate the component reliabilities and intercomponent transition probabilities. These estimates, along with their true values, are recorded in Table 1.

Parameter	IP (Rank), Est.	IP (Rank), Actual
$Parser$	.0626 (2)	.1484 (1)
$Computational$	.1701 (1)	.1201 (2)
$Formatting$	.0200 (3)	.0157 (3)

Table 2. Component ranks with and without uncertainty

These estimates of the model parameters lead to a system reliability estimate of 0.7200, which is off by 6.17% from its true value. Comparing the reliability estimate obtained from limited data with its true value highlights how the uncertainties in the parameters can propagate to system reliability.

3.2 Component ranks

The architecture-based approach allows us to rank the application components according to their importance measures [3] or significance from the point of view of system reliability. In this section, we demonstrate how uncertainties in the parameter estimates can lead to incorrect ranks. For the sake of illustration, we rank each component i based on its Improvement Potential (IP) measure [3], which is defined as the difference between the system reliability estimate when R_i is 1 and the estimate when R_i is assigned its true or estimated value. This expresses the maximum gain in system reliability that can be attained by devoting resources toward perfecting component i. Table 2 shows the IP of each component when using its true and estimated values. While the true IP ranking reveals the $Parser$ as having the highest improvement potential, using estimated parameters causes the $Computational$ component to be ranked higher than the $Parser$. Parametric uncertainties can thus result in a mis-allocation of resources towards prioritizing the $Computational$ component, when in reality improvements to the $Parser$ component will deliver the largest gain in application reliability.

In order to alleviate the impact of making such wrong decisions, it is necessary to perform a sensitivity analysis for each component across a range of parameter values, and use the insights gained from that analysis to evaluate the validity of the component ranks. The more sensitive the system-level reliability is to the reliability of component i, it is more likely that its estimated component rank is incorrect.

3.3 Sensitivity analysis

In order to explore the sensitivity of the reliability estimate to the individual model parameters, we present a study where we set a single model parameter to each bound of its 95% credible interval and then estimate the application reliability. The reliability value evaluated at each bound represents the 95% credible interval for system reliability with respect to the uncertainty in that single parameter. We define the *reliability uncertainty* (RU) metric as the effect of a parameter's uncertainty on application reliability. This metric is given as the size of the credible interval of the application reliability, found by computing the system reliability at the two extreme values of the parameter's credible interval. If the RU for a parameter is very small, we will have a high level of certainty in the reliability estimate, but as RU increases we can only be certain that the system reliability estimate is off by an increasingly higher percentage. The study makes a worse-case assessment by assuming no prior knowledge about any of the parameters, and hence, uses the uniform priors [4] $g(\Lambda_i) \sim Beta(1,1)$ and $g(\mathcal{P}_i) \sim Dir(1,1,...1)$ for all of the parameters.

Param	Credible Interval	RU Value	Rank
R_1	(0.8380 , 0.9724)	0.1212	7
R_2	(0.6609 , 0.8905)	0.1846	4
R_3	(0.6977 , 0.9845)	0.0860	8
$p_{1,2}$	(0.6960 , 0.8977)	0.1587	6
$p_{1,4}$	(0.1023 , 0.3040)	0.2218	3
$p_{2,1}$	(0.1295 , 0.4259)	0.1619	5
$p_{2,3}$	(0.2595 , 0.5923)	0.2237	2
$p_{2,4}$	(0.1920 , 0.5116)	0.2301	1
$p_{3,4}$	(1.0000 , 1.0000)	0.0000	9

Table 3. Credible intervals of the parameters and their impact on application reliability

Table 3 presents the credible interval for each parameter and its resulting RU. The table illustrates how uncertainties in the parameters reduce the confidence in the application reliability. For example, when parameter $p_{2,3}$ is off by approximately by 20%, there is a 95% chance that it causes an uncertainty of up to 24% in the application reliability. Similarly, uncertainty in the parameters $p_{2,4}, p_{2,3}$, and R_2 results in up to 25.57% uncertainty in the application reliability. Furthermore, R_2 has the highest RU value among all components, and corresponds to the component that was incorrectly ranked as having the highest IP. This illustrates how sensitivity analysis can be used to decide on the accuracy of the derived importance ranks of the components.

We also observe that the level of uncertainty in a parameter seems unrelated to the resulting degree of uncertainty in the application-level reliability. For example, parameter $p_{1,4}$ has the smallest non-zero credible interval among all the transition probabilities, but is ranked as having the 3^{rd} most significant impact on the system reliability. This means that the level of uncertainty in a parameter is not the only factor that determines its impact on the level of uncertainty in the application reliability. Another factor may include the frequency with which a transition is taken or a component is executed during a typical run of the application. This frequency indicates the significance of a given transition or a component to the application reliability. Although these significant transitions and components will have smaller credible intervals (because these will be

estimated using a larger number of observations), the uncertainties in them will still have a disproportionate influence on the uncertainty in application-level reliability.

3.4 Reducing parametric uncertainties

The previous sections highlighted the impact of parametric uncertainties on the system-level reliability results. The uncertainties in the parameters arise because of the limited data used in the estimation process. Thus, to reduce these uncertainties, it is necessary to either use a large amount of data or to incorporate prior knowledge while estimating the parameters. In the following illustrations, we show the impact of either approach on reducing the uncertainty.

3.4.1 Increasing data

Increasing the amount of data used in the estimation process can improve the estimates of the parameters. In the limit, however, for these parameters to approach their true values, an infinite amount of data is required. This is not feasible, and hence, a trade-off between the level of uncertainty that can be tolerated and the amount of data used in the estimation process must be reached.

In Figure 2, the level of uncertainty in the application reliability versus the number of simulation trials used to collect data for parameter estimation is plotted. The figure shows that the degree of uncertainty in system reliability decreases at an exponential rate as the number of simulation runs increases. In this illustration, all of the data used to estimate the parameters is collected from the simulation. In practice, however, this data may come from a variety of sources. Thus, the figure more generally illustrates that devoting a small cost towards improving our pre-existing knowledge can lead to a measurable increase in the accuracy of the system reliability estimate. Devoting too much cost towards gathering this knowledge, however, may be wasteful because the level of uncertainty in the system reliability will not appreciably decrease beyond a certain threshold.

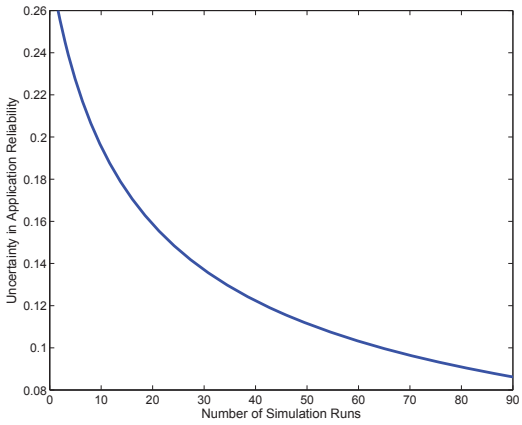

Figure 2. Relationship between reliability uncertainty and available data

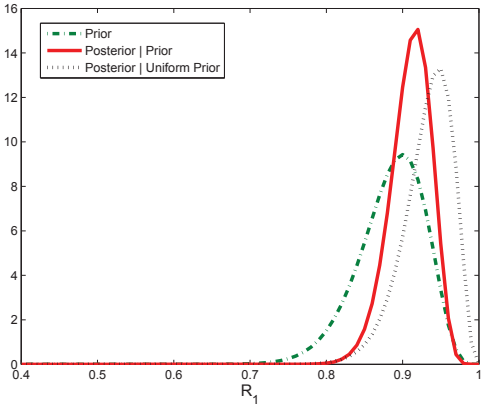

Figure 3. Prior and posterior distributions for the reliability of the *Parser* component

3.4.2 Incorporating prior knowledge

An alternative way to reduce uncertainty is to incorporate prior knowledge in the parameter estimation process. We illustrate this by introducing a non-uniform prior for the reliability of the *Parser* component. This non-uniform prior may be derived based on: (i) how this component operated in a different system; (ii) data provided by the manufacturer; or (iii) our prior experience in its use. We say that the *Parser* component is being reused from a previous system, where it exhibited a reliability of 0.9 across 50 uses.

Figure 3 shows the shape of the resulting prior distribution, the posterior distribution derived with a uniform prior, and the posterior distribution that incorporates this non-uniform prior for the $Parser$ component. Under a uniform prior, the posterior distribution has a wide body whose mean value is below its true reliability. The prior distribution, however, overstates the true reliability of the component and exhibits a similarly wide body as the posterior under the uniform prior.

In incorporating this prior knowledge, we get a new posterior distribution with a mean value of 0.9099. This mean is closer to the true component reliability of 0.84 when compared to the estimate found under a uniform prior (0.932). This new component reliability estimate results in a new system reliability estimate of 0.6998, which is inaccurate by only 3.52%, compared to 6.57% in the case of using a uniform prior for the $Parser$ reliability. Furthermore, the sharper peak of this new posterior reduces the size of the 95% credible interval for the component from 0.1212 to 0.1051, resulting in a reduction in the impact of its uncertainty on the application reliability from 0.1846 to 0.0947.

4 Related research

In this section, we summarize and compare our work to related efforts. Goseva *et al.* [6] model component reliabilities and transitions with Binomial and Multinomial distributions respectively. However, they only estimate the model parameters based on the Beta and Dirichlet distributions. A more recent study [5] applies their Bayesian approach to an empirical case study of the GCC compiler. Uncertainty analysis based on perturbation theory has also been proposed in the context of architecture-based analysis [10, 7].

Unlike previous approaches, this research employs Bayesian techniques to compute credible intervals for all the model parameters and proposes an approach to quantify the impact of uncertainty in the parameters on the uncertainty in the system reliability. This approach thus provides a practical tool for test planners who must identify where to target limited resources to improve the confidence in the reliability of their software application.

5 Conclusions and future research

This paper introduced a Bayesian approach to incorporate parametric uncertainties in the assessment of software application reliability based on its architecture. We illustrated how the approach could be used to systematically assess the impact of uncertainties in the parameters on system-level reliability in a systematic, quantitative manner. The case study suggests that there exist additional factors besides uncertainty in the parameter itself that can affect its impact on system-level reliability. We also explored how the level of uncertainty in the application reliability reduces as a function of increasing data or prior knowledge used in the estimation process.

Our future research seeks to extend the uncertainty quantification procedures to importance assessment and optimization. In addition, understanding how uncertainty across multiple model parameters affects the uncertainty in the application reliability needs to be investigated.

***Abstract*—Architecture-based reliability analysis of software applications has been the focus of several recent research efforts, as these applications continue to grow in size and complexity. Prevalent research in the area of architecture-based analysis predominantly focuses on sequential applications; with a few exceptions that address concurrency. Concurrency, however, is very common in modern software applications that are developed using the object-oriented or the component-based software development paradigms. Reliability analysis considering concurrency within the context of the application architecture is thus necessary for modern software applications. Our preliminary approach to analyze the reliability of a concurrent software application suffers from state-space explosion; due to which it cannot be applied to practical software applications. In this paper, we offer a methodology based on the Stochastic Reward Net (SRN) modeling paradigm to alleviate the model specification challenge associated with the state-space explosion issue. Our method uses SRNs to intuitively and concisely specify the architecture of a concurrent software application. We demonstrate how the expressive power of SRNs can be used to specify execution constraints, further reducing the state space. Finally, we illustrate how SRN-based specification can facilitate sensitivity analysis through an example.**

I. INTRODUCTION

Software applications provide a number of critical functions in many domains including telecommunications, healthcare, and finance. Ensuring that these applications meet or exceed their reliability requirements is therefore necessary for their widespread adoption. As the size and complexity of software applications continues to grow, analytical evaluation of their reliability is becoming an important part of the application design process. Analytical methods incorporate the application architecture in order to identify those application components that are critical from the perspective of its reliability. Identifying such critical components in the early phases can guide the allocation of resources to these components, so that the application reliability can be improved in a cost-effective manner.

Prevalent research in the area of architecture-based software reliability analysis [1-5] has predominantly focused on sequential applications, where control resides in one component at a time. The assumption of sequential execution was valid for applications that were developed using the procedural programming paradigm. Many modern software applications, however, are built using the object-oriented and component-based software development paradigms, and concurrent execution of components is very common in these applications [6]. Reliability analysis of a software application considering concurrency within the context of the application architecture is thus essential for contemporary, concurrent software applications.

In this paper, we present an efficient approach for architecture-based reliability analysis of a software application considering concurrent component execution. We build upon our preliminary Markov model to represent component-level concurrency in the application architecture [7, 8]. A major shortcoming of this preliminary approach is state-space explosion; where the number of states in the model grows exponentially as a function of the number of components in the application. State-space explosion poses two challenges in applying this approach to large, practical applications. First, the process of specifying large models necessary to represent applications with even a moderate number of components is cumbersome and error prone. Second, the solution of these large models can be computationally intractable. These specification and solution challenges intrinsic to the preliminary approach must be mitigated in order to apply this approach to practical applications.

This paper addresses the specification challenge through the use of Stochastic Reward Nets (SRNs) [9]. We choose SRNs to concisely represent the architecture of a concurrent software application for several reasons. First, SRNs offer an intuitive way to represent concurrent behavior. Additionally, they provide a high-level interface for automatically generating the underlying Markov model. Finally, SRNs provide powerful support for modeling execution constraints within the architecture, and such constraints may further reduce the state space of the Markov model, thereby indirectly alleviating the model solution challenge. We illustrate how the SRN-based specification of a concurrent application can facilitate sensitivity analysis and identification of bottlenecks.

This paper is organized as follows: Section 2 presents an overview of our preliminary model. Section 3 describes how large models can be specified using SRNs. Section 4 illustrates the use of SRNs to represent constraints. Section 5 summarizes related research. Section 6 offers concluding remarks and directions for future research.

II. PRELIMINARY MODEL

In this section, we present our preliminary model, and discuss the associated state-space explosion issue. We consider a continuously running application [8] which runs forever unless it fails or is stopped on purpose. We assume that at any given time the application state may be represented by the list of components under execution. The application state thus evolves as components begin and suspend execution, and this evolution can be represented using a state-space model.

We illustrate the architectural representation using an example of application consisting of three components. Let C_i denote component i. Figure 1 shows the complete state-space model of the application architecture. If exactly one application component is executing, then the application could be in states $<C_1>$, $<C_2>$ *or* $<C_3>$. In state $<C_1>$, either C_2 and C_3 can begin execution, or C_1 can terminate. If C_2 begins, then the application transitions to state $<C_1,C_2>$, if C_3 begins then the application transitions to state $<C_1,C_3>$, and if C_1 terminates then the application transitions to state $<SUSP>$, where all the components are in a suspended state. Depending upon which component begins execution from the state $<SUSP>$, the application transitions back to either state $<C_1>$, $<C_2>$ or $<C_3>$. The states and state transitions starting from states $<C_2>$ and $<C_3>$ to $<SUSP>$ can be generated using similar reasoning.

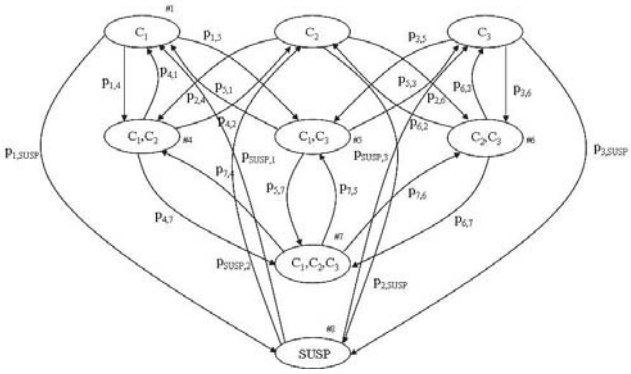

Figure 1 State-space model of the architecture

Next, we describe how expressions for the application reliability can be obtained based on the above representation of the architecture. For this purpose, we let k denote the number of states in which at least one component is executing. We exclude the $<SUSP>$ state in the count, since in this state no component is active, due to which, we assume that the application cannot fail. We let n denote the total number of components. We assume that component C_i fails according to an exponential distribution with failure rate λ_i. We let π_j denote the steady-state probability of state j. π_j is obtained by mapping the state-space representation of the architecture to a Continuous Time Markov Chain (CTMC) model and solving the CTMC model using the numerical methods built into tools such as MATLAB [10].

We assume that a component failure causes the application to fail and is the result of an internal error. As a result, component failure will depend on its total execution time, cumulative over cycles or service requests, which is obtained as follows. For a given execution time t, the average execution time in state j denoted t_j is $t\pi_j$. The execution time of each active component in the state is t_j/c_j, where c_j is the number of active components in state j. Thus, the cumulative execution time spent in a component, as a function of the total execution time is given by:

$$\omega_i(t) = \sum_{j=1}^{k} \pi_j \frac{t}{c_j} I_{i,j} \qquad (1)$$

where $I_{i,j} = 1.0, 1 \le i \le n, 1 \le j \le k$, if component j is active in state i and 0 otherwise.

R_i, the expected reliability of component i, is given by:

$$R_i = e^{-\lambda_i \sum_{j=1}^{k} \pi_j \frac{t}{c_j} I_{i,j}} \qquad (2)$$

Based on Equation (2), the expected application reliability, denoted $R(t)$, is given by:

$$R(t) = \prod_{i=1}^{n} R_i = \prod_{i=1}^{n} e^{-\lambda_i \omega_i(t)} = e^{-\sum_{i=1}^{n} \lambda_i \sum_{j=1}^{k} \pi_j \frac{t}{c_i} I_{i,j}} \qquad (3)$$

Figure 1 shows that an application, where its three components can execute simultaneously, has 8 states in the state-space representation of its architecture. Extending the reasoning, an application with n components will have 2^n states in its representation. Thus, the state-space representation will grow exponentially as a function of n, making it infeasible to both specify and solve the model.

III. SRN SPECIFICATION

The previous section highlights how the representation of the architecture results in state-space explosion. State-space explosion raises model specification and solution challenges, which must be mitigated in order to apply this model to real-life applications. In this paper, we assume that a *tolerance strategy* [8] exists, that is, the large model can be solved using the built-in capabilities in many tools. Matlab for example, can solve the model for an application with 15 components with a state space of 2^{15} x 2^{15}. To represent this model, however, a user has to manually create a 2^{15} x 2^{15} matrix and set the values of 163,840 (2^{15}.15) transitions, which is time consuming and error prone. Therefore, we demonstrate how the model can be specified using a high-level specification mechanism of Stochastic Reward Nets (SRNs). In this section, we first provide an overview of SRNs, and then illustrate how SRNs can intuitively represent the architecture.

a. Overview of SRNs

Stochastic Reward Nets (SRNs) are a descendant of Petri Nets (PNs) in which a reward function could be associated with the markings [6]. PNs have been further extended to

Generalized stochastic Petri nets (GSPNs) by allowing transitions to have zero and exponentially distributed firing times [11]. SRNs are considered to be a superset of GSPNs [6]. SRNs are a richer modeling paradigm due to additional constructs such as guard functions, marking-dependent arc multiplicities and reward rates at the net level. We choose SRNs because of: (i) their expressive power which allows intuitive specification of real-life constrains; and (ii) the ability to solve a SRN model using numerical techniques incorporated in the Stochastic Petri Net Package (SPNP) [9].

A SRN is a directed graph, which contains two types of nodes: places and transitions. A directed arc connecting a place (transition) to a transition (place) is called an *input (output) arc*. Arcs are associated with a positive integer called *multiplicity*. Places can contain *tokens* that move from one place to another through transitions. A transition is enabled when each of the places connected to it by its input arc has at least the number of tokens equal to the multiplicity of those arcs. When an enabled transition fires, a number of tokens equal to the input arc multiplicity is removed from each of the corresponding input places, and a number of tokens equal to the output arc multiplicity is deposited in each of the corresponding output places. A SRN may also include an *inhibitor arc*, which can also have a multiplicity associated with it. An inhibitor arc inhibits the transition it is connected to if the place it is connected to at its other end has a number of tokens equal to at least its multiplicity. The state of a SRN with P places, represented by a vector $(m_1,m_2, \cdots ,m_p)$, is called as a marking of the SRN, where m_i is the number of tokens in place i. The finite set of all possible markings is called the *reachability set*. The markings of a SRN and transition rates among them are equivalent to the corresponding states and state transitions of a continuous time Markov chain (CTMC) [9].

To extend the power of specification, a SRN may also specify enabling (or guard) functions for each transition. SRNs substantially extend the modeling power of Generalized Stochastic Petri Nets (GSPNs) [15], which are an extension of Petri nets [24]. SRNs represent a powerful modeling technique with concise specification and form closer to designer's intuition. This makes it easier to transfer the results obtained from solving the model and interpret them in terms of the entities in the system being modeled.

b. SRN model

We describe the process of specifying the architecture of a concurrent application using SRNs using the three-component example. We represent the working and idle states of each component using places and the sojourn time in each state using transitions. Thus, places C_i_wrk, and C_i_idl, represent the idle and working states of component C_i. Transitions *Tiwak* and *Tislp*, represent the transitions from working to idle and from idle to working states for C_i. Tokens (or a lack thereof) in each place represent the state of the system. In this problem, each component has only one token, which can either be in the place C_i_wrk or C_i_idl indicating that the component could either be in the working or in the idle states but not both. Figure 2 shows the SRN model of the architecture. The notation representing the component parameters is in Table 1.

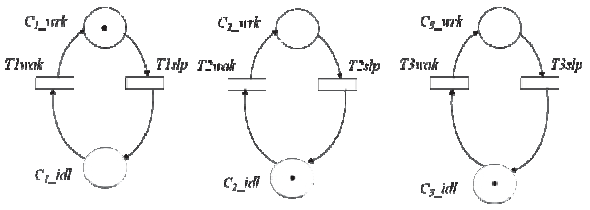

Figure 2 SRN model of three-component concurrent application

TABLE 1 EXECUTION AND FAILURE RATES OF COMPONENTS

Comp #	Transition rates (/min)		Failure rate (λ_i)
	Working to Idle (ρ_i)	Idle to Working (γ_i)	
C_1	0.3	0.5	0.0001
C_2	0.5	0.1	0.0001
C_3	0.2	0.4	0.0001

The reachability set, which is the state space of the underlying CTMC, is automatically generated from the SRN model using SPNP and is shown in Table 2. The second column shows the active components in each marking. The Markov chain corresponding to the reachability set is shown in Figure 3. SPNP also computes the steady-state probabilities as shown in Table 4.

TABLE 2 REACHABILITY SET GENERATED FROM THE SRN MODEL

	Active comp.	C1_ idl	C1_ wrk	C3_ wrk	C2_ wrk	C3_ idl	C2_ idl
M_0	All idle	1	0	0	0	1	1
M_1	C_1	0	1	0	0	1	1
M_2	C_2	1	0	0	1	1	0
M_3	C_3	1	0	1	0	0	1
M_4	C_1,C_2	0	1	0	1	1	0
M_5	C_1,C_3	0	1	1	0	0	1
M_6	C_2,C_3	1	0	1	1	0	0
M_7	C_1,C_2,C_3	0	1	1	1	0	0

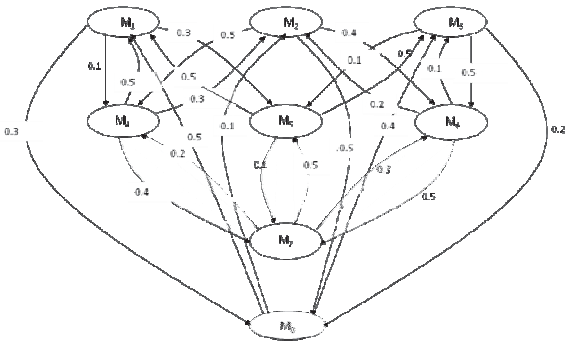

Figure 3 Markov chain generated from the SRN specification

TABLE 3 STEADY STATE PROBABILITIES

State	Steady Probability	State	Steady Probability
M_0	0.1042	M_4	0.03472
M_1	0.1736	M_5	0.347
M_2	0.0208	M_6	0.0417
M_3	0.2083	M_7	0.0594

We assume that the execution time of the application is 100 minutes. Using the failure rates of the components from Table 1, along with the steady-state probabilities from Table 4, the system reliability is computed to be 0.964. This indicates that the execution is successful in 96% of the runs.

c. Sensitivity anlaysis

In addition to reliability estimation, at design time, it is also useful to assess the sensitivity of the application reliability with respect to component parameters. Such sensitivity analysis can identify critical components, and these components can then be allocated additional resources to improve their reliability. Compared to our preliminary approach, the SRN model has fewer parameters; and these are defined at the level of components, rather than at the level of the architectural states. Therefore, the SRN model facilitates sensitivity analysis in a concise and intuitive manner. In this section, we demonstrate how the SRN model could be used for sensitivity analysis.

The reliability of a component is a function of its expected execution time, which in turn is a function of its transition rates from the working to the idle, and from the idle to the working states. Therefore, to assess the relative impacts of the components on the application reliability, we vary their transition rates out of the working states by ±20% in steps of 5% around the initial values, one at a time, while holding all the other parameters constant. We solve the SRN model for each transition rate, and use the resulting steady state probabilities to compute the application reliability.

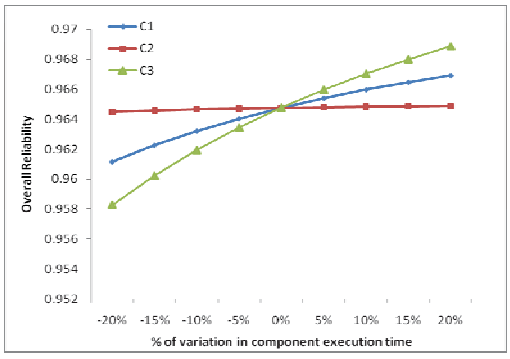

Figure 4 Application reliability as a function of component parameters

Figure 4 shows the application reliability as a function of the expected execution times of the components. The figure indicates that C_3 has the strongest impact on the application reliability, followed by C_1. C_2 has the least impact. This can be explained by considering the initial values of the transition rates listed in Table 1. The table suggests that the transition rate from the working to the idle state is higher in the case of C_1 than in the case of C_3. However, the transition rate from the idle to the working state is lower for C_3 than that of C_1. These transition rates suggest that C_1 and C_3 will have comparable execution times, making it difficult to determine intuitively which one of these will have a higher impact on the application reliability. Our quantitative sensitivity analysis, however, definitively ranks C_3 over C_1, providing solid guidance on devoting resources to reducing the expected execution time of C_3 in order to improve its reliability. Finally, C_2 transitions from the working to the idle states comparatively frequently, and spends a significant portion of the time in the idle state, due to which it is expected to have the least impact on the application reliability. Our analysis results confirm this intuition.

IV. MODELING EXECUTION CONSTRAINTS

SRNs provide powerful constructs such as inhibitor arcs and guard functions to represent execution constraints. Such constraints may also reduce the state space, and hence, alleviate the model solution challenge. We illustrate the modeling and expressive power of SRNs using an application with four components C_1, C_2, C_3, C_4, with the following constraints: i) C_1 can only execute with C_2; and (ii) C_3 cannot execute when C_4 is executing.

Similar to the previous example, the behavior of each component is represented using places and transitions. All constraints on the execution of the components are represented using inhibitor arcs. The inhibitor arcs from place C_2_*idl* to *T1wak* and from place C_1_*wrk* to *T2slp* represent the first constraint. *T1wak* is disabled as long as there is a token in place C_2_*idl* (indicating that C_2 is idle) and C_2 cannot be idle as long as there is a token in place C_1_*wrk* (indicating that C_1 is working). The second constraint is satisfied through the use of two more inhibitor arcs: from place C_4_*wrk* to the *T3wak* transition and from C_3_*wrk* to *T4wak*. The first inhibitor arc causes *T3wak* to be disabled if there is a token in place C_4_*wrk* indicating that C_4 is working. Meanwhile C_4 cannot run if C_3 is working. The resulting reachability graph has fewer states, from a maximum of 16 to 8. The state space, automatically generated using SPNP, is shown graphically in Figure 6.

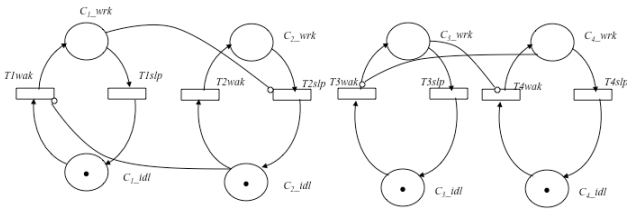

Figure 5 SRN model with execution constraints

V. RELATED RESEARCH

Prevalent research in the area of architecture-based reliability analysis is predominantly focused on sequential applications [1]. A few efforts that consider concurrent applications map the application architecture to a state-space model. Wang et al. [12] presented an approach similar to ours to assess the reliability of an application which follows

the parallel/pipe filter architecture style. Kanoun et al. [13] present a hierarchical approach for a continuously running application. Rodrigues et al. [14] develop a composite solution approach for a terminating application. The analysis methodology described in this paper provides a hierarchical approach for a concurrent, terminating application. Due to its hierarchical nature, the methodology facilitates different types of analyses, which is a significant advantage of this research over the work described by Rodriguez *et al*.[14]. The work closest to ours is by Pettit and Gomaa [15] where a methodology for translating concurrent UML software architectures into an underlying Colored Petri Net (CPN) model is presented. Their work, however, focuses on the performance aspects, unlike ours which focuses on the reliability characteristics.

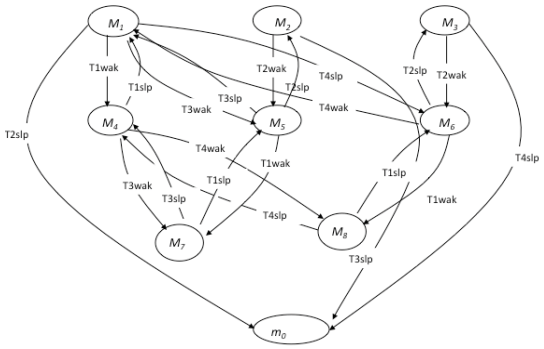

Figure 6 State-space model of architecture with constraints

VI. Conclusions and Future Research

In this paper, we present an efficient approach to analyze the reliability of a software application considering concurrent component execution within the context of its architecture. We demonstrate how Stochastic Reward Nets (SRNs) can be used to effectively and intuitively specify architectural models of large applications, making it possible to apply the approach in practice. We also describe how the expressive power of SRNs could be used to represent constraints on the execution of the application. Through an example, we present how the SRN specification can be used to facilitate sensitivity analysis and identification of bottlenecks. Our future work consists of extending the SRN-based approach to model terminating, concurrent software applications

VII. Acknowlegments

***Abstract* — Automated In-process Software Engineering Measurement and Analysis (AISEMA) systems are powerful tools to monitor and improve the software development process. However, to be useful, it is required that such tools never stop working. Therefore, they need the support of advanced monitoring systems able to detect and locate malfunctions and inform automatically human operators providing all the information required to solve the problem. This paper describe the approach and the tools developed to support a specific AISEMA system developed to support both managers and developers in implementing continuous process improvement initiatives.**

AISEMA; development process; monitoring.

I. INTRODUCTION

The success of software measurement programs is strongly dependant on the automation of the related data collection (Pfleeger, 1993; Daskalantonakis, 1992; Offen and Jeffery, 1997; Hall and Fenton, 1997; Iversen and Mathiassen, 2000). Manual data collection suffers of several limitations including: it is time consuming, tedious, error prone, and often biased or delayed (Johnson and Disney, 1999). Semi-automated data collection is better (tools such as LEAP (Moore, 1999)) but there are still context switching problem (Johnson *et al.*, 2003) with a negative impact on the performance of the developers since it requires to switch continuously between working activities and data collection.

A new generation of tools (such as PROM (Sillitti *et al.*, 2003) and Hackystat (Johnson *et al.*, 2003)) has been developed to overcome such limitations providing a fully automated, non-invasive data collection. Such tools allow data collected from on-going projects to be used for improvement of the same project, therefore they are also called Automated In-process Software Engineering Measurement and Analysis (AISEMA) systems.

AISEMA systems aim at automatically collecting the data, but also at providing tailored analyses for decision support. They reduce the cost of data collection, as they run in the background and let people focus on their work without any additional workload or distractions. They can collect a large variety of data. Based on these data, they propose: support for process management (Remencius *et al.*, 2009; Danovaro *et al.*, 2008), assessment of low-level processes (Coman and Sillitti, 2009), etc.

Ensuring continuous data accuracy is one of the main challenges during the usage of an AISEMA system (Coman *et al.*, 2009). The changes in the environment (such as software updates, software crashes, hardware failures, changes in security policies, etc.) affected sometimes the accuracy of data, mainly by disabling some of the data collection components, hindering data transfer or causing data loss. Not all such events are avoidable. Consequently, small amounts of data might be lost from time to time. However, it is very important to limit as much as possible these missing data and to have detailed information on the cause why they are missing and on their type. Such information helps to assess whether the missing data invalidate or not a specific analysis, thus ensuring reliable results of data analyses.

In most of the cases, existing systems have already error prevention mechanisms located at each of theirs components. This is the case of the PROM system (Sillitti *et al.*, 2003). Such mechanisms ensure a good functioning of the components. However, they cannot prevent, for instance, a silent disable of the components as result of repeated crashes of the host system. Moreover, in some cases, the disabling of the components is perfectly acceptable (for instance, when a developer chooses not to collect some specific data). Thus, to assess whether the disabled status of a component represents a failure of the system or not, additional context information is needed.

In PROM, as the components interact with the server over the network medium, the correct functioning of the system as a whole does not depend only on the correct functioning of each individual component. Because the client components are not aware of their broader context (and are not meant to be aware), there is a need for a separate component that monitors the functioning of the system as a whole. Such component should identify potential problems and use local information from specific components to localize the actual cause of the problem. Additionally, such component should log the occurrence of the problem and, if the solution is known, to proceed with solving the problem. If the solution is unknown, the component should notify the maintainers of the system.

The initial solution used during most of the case-study was to have a human performing such monitoring. However, this is

extremely time consuming and costly. Moreover, ideally, the monitoring should be continuous and thus requires an automated solution. The solution developed was to enhance the existing AISEMA system with characteristics of autonomic computing (Horn, 2001; Kephart and Chess, 2003) such as self-monitoring and self-healing. This paper presents in detail the concrete approach and its implementation. It is organized as follows: Section 2 presents the related work; Section 3 introduces our approach; Section 4 describes the proposed implementation; Section 5 summarizes the results obtained; finally, Section 6 draws the conclusions and presents future work.

II. Related Work

The initial manifesto of autonomic computing (Horn, 2001) proposed it as the single approach able to mitigate the effects of an increasingly acute software complexity crisis. The manifesto pointed out that the complexity of the IT infrastructure grows constantly and threatens to get beyond human ability to manage it. Continuously increasing number of connections, dependencies and interactions between software components make the maintenance and management of the software systems increasingly complex, up to the point of surpassing human ability of managing these tasks. Thus, the only solution resides in building software systems that are able to configure and manage themselves, adapting to changing environments and adjusting their behavior for most efficient use of their resources to solve the required tasks.

Autonomic computing identifies four key aspects that self-managing software should possess: self-configuration, self-optimization, self-healing, and self-protection. Of these four, the self-healing is the main aspect that AISEMA systems should have to ensure continuous data accuracy.

Self-healing is defined as the capability of a software system to automatically detect, diagnose, and repair localized problems resulting from bugs or failures in software and hardware (Kephart and Chess, 2003). Koopman (2003) proposes a taxonomy that identifies four main aspects of a self-healing strategy: fault model, system response, system completeness, and design context.

The fault model (also called a fault hypothesis) identifies the faults that the system should be able to tolerate. The system response represents the strategy of the system to detect and treat faults. The system completeness and design context include the factors that influence the scope of self-healing capabilities.

Each of these aspects can be further described by a set of properties. Table I gives an overview of the characteristics of our approach (PROM) in terms of the aspects and properties defined in the taxonomy of Koopman.

TABLE I. Characteristics of the approach in terms of a taxonomy for self-healing problem spaces

Aspect	Property	PROM
Fault model	Fault duration	Permanent
	Fault manifestation	Corrupted or missing data
	Fault source	Changes in the environment, non-malicious
	Granularity	Component
	Fault profile expectations	Expected and likely faults
System response	Fault detection	Anomaly detection via supervisory checks and nonintrusive testing of results
	Degradation	Degraded performance
	Fault response	Reactive
	Recovery	Warm or cold component reboot, recovery of corrupted settings
	Time constants	Valid data occur much more often than anomalies
	Assurance	"Good enough" data quality
System completeness	Architecture completeness	Closed, complete system
	Designer Knowledge	Complete
	System Self-knowledge	Partial knowledge on component presence
	System evolution	Upgrades and extensions
Design context	Abstraction level	Software component within distributed system
	Component homogeneity	Heterogeneous components and resources
	Behavioral predetermination	Predetermined data type
	User involvement	Fully automatic
	System linearity	N/A
	System scope	Multiple computers and users on Internet or closed network system

Shehory (2006) identifies three main types of problems that self-healing approaches usually address: concurrency problems, functional problems, and performance problems. The approach proposed here addresses functional problems.

There are already many projects exploring various self-healing strategies (Hoover *et al.*, 2001; Raz *et al.*, 2002a; Shelton *et al.*, 2003; Shehory, 2006; Mikic-Rakic *et al.*, 2002). The proposed approaches focus on reconfigurable architecture (Shehory, 2006; Mikic-Rakic *et al.*, 2002), graceful degradation (Shelton *et al.*, 2003), optimized usage of resources (Hoover *et al.*, 2001), or inferring specifications from underspecified components (Raz *et al.*, 2002a). Most of the proposed approaches focus on distributed systems and address software failures in one or more of the components. By contrast, the approach proposed here focuses on failures due to environment factors such as disable of components or loss of connectivity. The proposed approach makes also use of the specificities of the domain, namely the characteristics of the automatically collected data.

Among the existing self-healing approaches, one that is very similar to the approach presented here is that of Raz *et al.* (2002a). They focus also on detecting failures by searching for semantic anomalies in the data. In their case, the data are dynamic data feeds that change outside user control and are usually under-specified. Their approach has two phases: *setup*

and *usage*. During *setup*, the approach aims at inferring invariants from data presented as input. These invariants are used during the *usage* phase to detect anomalies in the data. During the *setup* phase, human intervention is required to find a training set size, establish parameter values, select attributes to take into account, and select from the proposed invariants. During the *usage* phase, human intervention is also desired to eliminate from the results the false positives (normal data falsely declared as anomalous).

Similarly to the approach of Raz *et al.,* the approach proposed here also detects failures by searching for anomalies in the data. However, the domain is very different and it allows to take one step further by taking action to correct faults based on the detected anomalies.

By contrast to the approach of Raz *et al.*, the specifications of the data are very well known as the data come from the components of the system itself. Thus, data invariants can be defined by the administrators of the system, together with the possible causes and steps to take for restoring proper functioning. Moreover, the definition of data invariants can also take advantage of overlapping data coming from different sources. Once the invariants have been defined, the system can perform fully automatically the cycle of fault detection, cause identification, and fault resolution. Human intervention might be required again only in cases when none of the proposed solutions solve the problem.

Another contribution of the approach proposed here is a model for defining data invariants together with potential causes of violation and actions to take for resolution of the violation. The model also allows the combination of basic invariants to easily specify more complex ones while hiding the complexity of the definition. While the current implementation expects predefined data invariants, the approach can be easily extended with automated inference of data invariants.

III. THE APPROACH

The main goal is to ensure continuous high accuracy of automatically collected data. The approach proposed here is to perform regularly a set of checks on the collected data to detect anomalies and then to take action to prevent further anomalous data. Anomalies in the data indicate a problem in the functioning of the system. When anomalous data are detected, the system investigates several possible causes to localize the actual problem. To do so, it performs a set of tests regarding the status of the network and of the components installed on the client machine from which data originated. After identifying the cause(s), the system proceeds to heal itself. Depending on the actual cause, the actions taken can consist in warm or cold reboot of components on the client machine, restoring corrupted files or notifying the user that user action is needed. Moreover, the system logs all checks and tests performed and their results to provide a complete view on the status of the data at any given time.

An anomaly is defined as a violation of one or more data invariants. A data invariant expresses a condition that all accurate data should satisfy. The definition of data invariants is based on domain knowledge. As the collected data are well defined and the system specifications are known, the easiest approach is to use such knowledge for data invariant definition.

Thus, simple data invariants can define the domain of values for each type of data collected (for instance, the time spent in some activity should be positive, and below 24 hours during a single day), the required fields (according to the known data structure), or the frequency with which they are collected (according to the specifications of the system).

The above type of invariants describes mainly the structural properties of data, rather than the semantic ones. The violation of such an invariant can help identify severe problems (such as no network connection or hardware failure) but do not reveal more subtle issues (such as data from one component with legal but incorrect values). Additional data invariants that define relations in the data can help detect also semantic anomalies. Such invariants are usually called adaptive invariants to distinguish them from invariants that impose certain specific values rather than relations.

The automatically collected data come from various components. As such, the data usually overlap to some degree. Data invariants that make use of these overlaps are used to identify anomalies in data coming from one component. Moreover, as different data represent different views on the same artifact, there are some relations in the data that should be respected. Such relations that should hold at any time are usually called *adaptive invariants*. The violation of an adaptive invariant means that the data are not semantically consistent.

A. The Data Invariant Model

The definition of an invariant contains the data property or the data relation that has to be ensured, a description of the problem to be reported if the invariant is violated, and a list of the potential causes of the identified problem. The actual computation of a data invariant can be a direct check of a data property, or it can build on the results obtained on checking several other data invariants. This gives particular strength to the model as it allows the definition of extremely complex invariants while making their definition easy by hiding their computational complexity from the user.

The self-healing ability requires not only that anomalous data are detected, but also that the cause of anomaly is removed. There is not a one-to-one relation between anomalies and causes. The violation of a data invariant can be due to one or more of the causes listed for that invariant, or even to a new cause, not yet identified. Thus, each cause is defined together with a set of tests that should fail only when the cause is present. Such tests usually concern local conditions on the machine which generated anomalous data. However, the only limits to what such tests check depend only on the possibility of actually performing the test.

The various tests associated with a potential cause is useful not only to identify the presence of a cause, but also to distinguish between malign and benign manifestations of the same cause. The benign manifestation of a cause means a false-positive in the sense that the violation of the adaptive invariant is not due to a problem in the functioning of the system, but rather to special circumstances (for instance no upload of data

due to user being on a sick leave). The malign manifestation of a cause represents a real failure of the system, one of its components or the network medium.

Finally, each test has to define also a list of actions to take if the test fails. Such actions should remove the cause of anomalous data and should restore the proper functioning of the system.

Thus, an invariant's definition should contain such information as shown in Table II. Table III shows an example of a simple data invariant and Table IV provides an example of the definition of one of the possible causes of violation of such an invariant.

TABLE II. STRUCTURE OF A DATA INVARIANT

Field	Meaning	Intended user
Name	Short, descriptive name for the data invariant. Helps in reports for administrators.	Human
Description	A more detailed description of the invariant and, if needed, the reasons justifying it.	Human
Computation	The actual function or formula that returns true is the invariant is satisfied and false if it is violated.	System
Problem reported if the invariant is violated	A description of the problem identified by a violation of the invariant.	Human
List of possible cause(s)	A list with the possible causes of the invariant's violation	System

TABLE III. EXAMPLE OF A DATA INVARIANT'S DEFINITION

Name	Data upload
Description	For each user, there should be at least one upload of data each day.
Computation	AnyUploadCheck (method)
Problem	NO uploads during the day.
Possible causes	1. AISEMA system inactive on user's machine. 2. Transfer scheduler NOT running. 3. Corrupted configuration of connection on user's machine. 4. Server component down. 5. Server unreachable from client machine.

TABLE IV. EXAMPLE OF A POSSIBLE CAUSE'S DEFINITION

Cause	Test	Type	Action to take if test fails
AISEMA system inactive on user's machine	Check flag of system activity to be set to active.	Benign	Just annotate that the user has deactivated the system on his/her machine.
	Check that data are collected on user's machine (there are files stored).	Malign	Warm reboot of the client components.

IV. IMPLEMENTATION

The approach is implemented in two components: PROM Data Inspector (server-side component) and PROM Console (client-side component). Both components are written in Java. PROM Data Inspector implements the actual problem detection and takes steps to solve the identified issues. PROM Console provides additional information on the status of the clients when needed and it propagates to the client the actions recommended by PROM Data Inspector to solve the identified problems. Figure 1 shows the relations between the existing architecture of PROM and these two components.

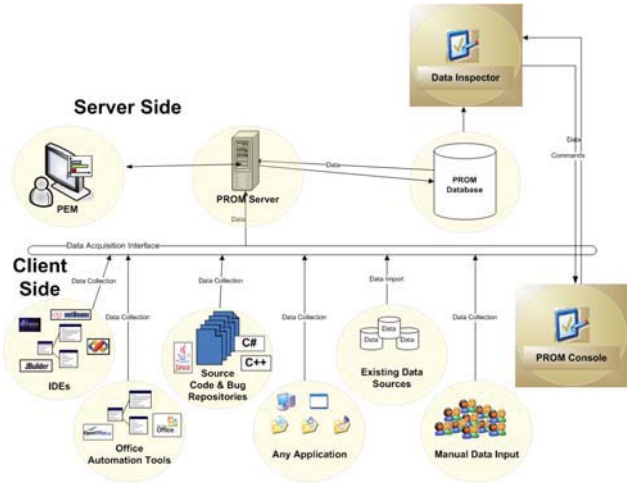

Figure 1. PROM Architecture and the relationship with PROM Data Inspector and PROM Console

The definitions of data invariants are stored in the PROM database. At present, the implementation of the formula of the invariant is in a separate module of the Data Inspector. However, PROM Data Inspector can be easily extended to use formulas implemented in external modules. This makes the actual structure of the data storage transparent to the Data Inspector, ensuring that the self-healing mechanism is independent from the way in which data are stored.

Data invariants can be of two types: basic and summary invariants. The basic invariants have a simple, single data property to check. They are usually meant for testing fixed data invariants rather than adaptive invariants that require more complex checks of data relations. For such checks, the summary invariants are more appropriate. A summary invariant has a computation formula that usually involves other basic invariants. This allows to check for complex data relations. Moreover, if desired, several distinct invariants can be defined to allow a more precise identification of the actual cause of violation.

PROM Data Inspector runs at regular intervals, loads the invariants from the database and performs a check of all defined data invariants. For any invariant that is violated, the component goes through the list of possible causes and runs the associated tests. For every failed test, the corresponding action is taken and its result is stored. If the execution of the action fails, an error notification is sent to the administrators of the system. After successful execution of an action, the system performs again the test that had previously failed. However, the system has to wait until the next round of overall check of data invariants to be sure that it solved the problem that was actually causing anomalous data. Thus, the overall algorithm has the following steps:

1. Check all data invariants and store results.

2. For each data invariant that was violated:
    a. For each possible cause:
        i. Perform all associated tests
            1. If a test fails, run the corresponding action;
            2. If the action completed successfully, perform again the test;
            3. If the action could not be run or the test failed again after action has been taken report to the administrators.
    b. If all tests of all possible causes passed from the first run (i.e., no cause has been identified as responsible for the observed violation), notify the administrators.

The PROM Data Inspector stores all the results of the check of invariants in the database for future reference, together with a timestamp. Optionally, it can also generate a report and send it by email to the administrators. The detailed results of the checks performed can be used for having a clear view on the status of the data at any given time. The Data Inspector ensures the compatibility with the graphical interface PEM (PROM Experience Manager), so that the status and results of all tests can be displayed in a chart allowing for fast identification of days and users with problematic data.

The PROM Console resides on the client machine and communicates with the Data Inspector on the server. It gathers information about the local context, such as the PROM components installed, the state of their configuration files and the data that are collected. It sends such data to the Data Inspector which uses them to perform the tests for cause identification. Upon request from the Data Inspector, PROM Console notifies the user that some specific action needs to be taken, or it implements directly non-invasive actions such as restoring of corrupted configuration files.

V. Results

PROM Data Inspector and PROM Console were in usage during the last 2 months of data collection in the an experiment in a company (Coman *et al.*, 2009). In a first step, Data Inspector represented mainly an automation of the data checks that were previously performed manually. However, it soon became obvious that it can also perform more complex checks that are very tedious to be performed manually. Thus, the summary invariants were introduced, allowing the combination of many basic invariants.

The initial reports of the PROM Data Inspector were just listing all the tests performed together with the results obtained. However, such reports were hard to read without knowing the inner functioning of Data Inspector. The current version addressed this problem by providing at the beginning summaries of the identified problems, together with the possible causes. This new form of reports proved to be understandable also by people that were not directly involved in the definition of data invariants or in the development of the Data Inspector. Figure 2 shows an example of the contents of a report generated for a single user showing an identified problem and listing the possible causes. In the report, each test represents in fact a data invariant. This change of name makes the report more intuitive to people and does not require users to know what a data invariant is.

VI. Conclusions and Future Work

This paper reported on the first step towards transforming AISEMA systems into autonomous systems, by ensuring self-healing capabilities. The proposed approach is to detect data anomalies and to trace them back to the software or hardware failure that caused them. The data anomalies are modeled as violations of data invariants. The data invariants are based on the knowledge of the system and of the data collected. They can be very simple (e.g., time recorded should always be positive) or more complex, combining several basic invariants for testing of relations into the data.

To solve the issues that cause data anomalies, each data invariant contains also a list of possible causes. Each cause has a list of tests that help identify the exact problem and whether it is benign (not a failure but special circumstances) or malign (a failure that has to be solved). For each test there is also a list of actions to be taken when the test fails. This model ensures flexibility (new invariants can be added at any time), simplicity (the complexity of invariants can be hidden from the user by building on underlying levels of invariants), and traceability of issues that affected the collected data (all actions are clearly defined and the results are always stored).

The current implementation uses only user-defined invariants. As future work, it would be valuable to explore the possibilities of automatically extracting invariants from previously collected data. Techniques such as the one used in Daikon (Ernst *et al.*, 2001) or Mean (Raz *et al.*, 2002b) have already been applied to automated detection of data invariants in online data feeds. However, applying such techniques is not

straight forward, as the characteristics of the AISEMA data are quite different from those of online data feeds (i.e., most of the data are not normally distributed, the volume of data is bigger, complex relations between various types of data have to be taken into account).

To preserve the character of self-healing of the proposed approach, an automated detection of data invariants should also be complemented by an automated detection of possible causes and of appropriate measures to be taken for each identified cause. However, this is still an open issue.

Specification and Implementation of SPEM4MDE, a metamodel for MDE software processes

Samba Diaw, Redouane Lbath, Bernard Coulette
University of Toulouse,
Laboratory of IRIT
Toulouse, France
{diaw, lbath, coulette}@irit.fr

Abstract— It is widely accepted that MDE is a novel and important approach for building complex systems. This fact forces many organizations to transform their software development processes into model-driven ones. While model-driven development processes – called MDE processes – have started to appear, a tool-supported Process Modeling Language (PML) for describing, enacting and evolving such processes is still lacking. In this article, we propose a PML that combines SPEM 2.0, UML 2.2 and MOF 2.0 QVT concepts. We extend these concepts for the MDE domain and define the behavior of MDE process models in terms of UML state-machines. The result is a language that can be used to define a MDE process, and thanks to its behavioral semantics, to guide the execution of projects based on such a process. To evaluate and validate our approach, we have developed a prototype under the TOPCASED environment.

Keywords: Model-Driven Engineering (MDE), Model-Driven Architecture (MDA), Model Transformations, Process Modeling Language (PML), Model-Driven Development (MDD), MDE Software Process, TOPCASED environment

I. INTRODUCTION

MDE (Model-Driven Engineering) ([1], [2], [21]) is a recent software engineering discipline that advocates the use of models within the software development rather than code. The term MDE was proposed first by Kent in [19] and is derived from the OMG's Model Driven Architecture (MDA) initiative [3], [15]. MDE aims at improving significantly the development of complex software systems by providing the means to switch from one abstraction level to another or from one modeling space to another [2], [21]. The finality is to describe both the problem and its solution by using models, and by clearly establishing a methodology to show how to switch from a problem to its solution by using model transformations [2]. MDE is then a form of generative engineering in the sense that the whole or part of an application is generated from models. In this new perspective, models take an important place among software development artifacts and must be formal in order to be understood or transformed by tools. In [5], Kleppe and al. define a model-driven software development as "*a process of developing software using different models on different levels of abstraction with (automated) transformations between these models*". Therefore, the model-driven software development process [7], [25], [26], [28] – called MDE software process – may be seen as a transformation chain, each transformation consuming one or several source models and producing one or several target models. The description of a software process is called *process model*. It can be expressed through any specific language or notation which is called Process Modeling Language (PML). A process model can be enacted when a development team follows the process model during the development life cycle. One of the major advantages of software process modeling is to help developers using a unified and consistent terminology in order to communicate around the process. Software process modeling should also make possible understanding, reuse, evolution, management, and standardization of processes [27].

Our general research goal is to propose a tool-supported PML to model and enact MDE software processes. However, as stated in related work (section V), there is no PML meeting this goal so far.

The work presented in this paper focuses on modeling and enactment of MDE software processes. More precisely, our goal is to specify and implement a metamodel called SPEM4MDE [22] which is a generic and flexible language that combines SPEM 2.0 [12], UML 2.2 [13] and MOF 2.0 QVT [14] concepts. A first version of the SPEM4MDE metamodel was described in [22]. Since this first work, we have been enriching our metamodel by taking into account the QVT standard for transformations execution and the UML 2.2 BehaviorStateMachines package for describing MDE processes behavior. In addition, we have developed a prototype called SPEM4MDE-PSEE which is a CASE tool supporting MDE process models edition and enactment.

The paper is organized as follows: section II introduces the motivation and objectives of this work. Section III presents the specification of the SPEM4MDE metamodel. Section IV presents the validation of SPEM4MDE through a prototype and a MDE process example which we modeled and enacted using this prototype. Section V discusses related works, while section VI concludes and introduces perspectives.

II. MOTIVATION AND OBJECTIVES

With the emergence of MDE, many organizations have been starting to transform their traditional software development processes into model-driven processes [28]. The underlying objective is to reduce time of development, and to increase software productivity and quality. As established in

[27] for traditional software development, the specification of MDE processes should guide developers in the elaboration and the transformation of models.

Our main objective is to provide the MDE community with a metamodel to define and enact MDE software processes. As defined in [5], a MDE process is a process of developing software using different models and transformations between these models.

The concepts of SPEM 2.0 are quite generic since they are supposed to be able to describe any kind of software (and even system) process including MDE ones. However, SPEM 2.0 concepts are not able to capture the exact nature of most activities and artifacts of a model-driven development. Indeed, most of model-driven development activities are model transformations, and most of model-driven development artifacts are models.

We claim that reification of MDE concepts allows process designers to explicitly describe specific aspects of MDE development. For instance, to make it possible to check the conformance relationship, it is important to specify models and metamodels as input/output parameters of transformations. So we advocate promoting MDE concepts as first-class citizens in MDE process technology.

Therefore, we have decided *to extend the SPEM 2.0 metamodel for MDE domain*. In addition, SPEM 2.0 does not fulfill executability. To overcome this limitation, we reuse the UML state-machines for describing behavior of MDE processes. We also allow the specification of transformations' behavior with QVT in order to benefit from existing tools that implement this standard.

III. SPECIFICATION OF THE SPEM4MDE METAMODEL

SPEM4MDE is formally specified as a metamodel that reuses subsets of the concepts defined by the OMG's standards SPEM 2.0 [12], UML 2.2 [13], and QVT [14]. A first version of SPEM4MDE was published in [22]. Since this publication, we have reorganized and enriched the metamodel, and developed an operational prototype for MDE process modeling and enactment. More precisely, the metamodel has been enriched by adding a new package for describing model relationships and traceability at enactment time, and integrating the QVT concepts in the behavioral package. In the following, we describe the new version of SPEM4MDE. The prototype is presented in section IV.

As shown by Fig. 1, SPEM4MDE is structured in the form of three packages: *MDE Process Structure, Model Relationship,* and *MDE Process Behavior*.

The *MDE Process Structure* package outlines concepts that describe SPEM activities and transformations. It merges the SPEM 2.0 *Process structure* package in order to describe a transformation as a specialization of SPEM *Activity*. The *SPEM 2.0 Process structure* package describes a process in terms of breakdown elements, which are activities, input and output products, and roles that perform activities.

The *Model Relationship* package describes relationships between models. It imports some concepts from *MDE Process Structure*.

The *MDE Process Behavior* package reuses the *UML 2.2 BehaviorStateMachines* package and merges the *MDE Process Structure* package in order to describe the behavior of MDE process elements by means of UML state-machines. In addition, it merges the *QVTBase* package in order to describe the execution semantics of transformations. The *QVTBase* package contains a set of basic concepts that describe transformations, their rules, and their input and output models.

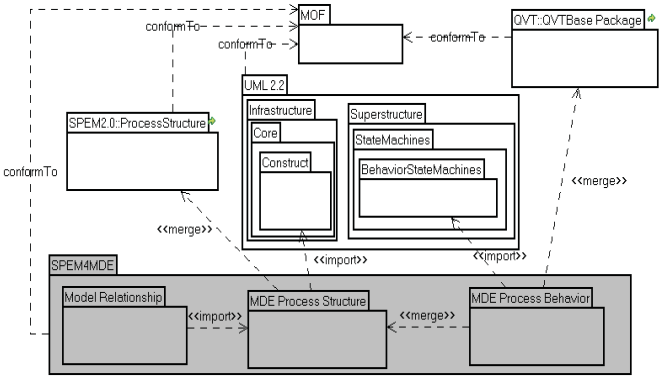

Figure 1. SPEM4MDE packages hierarchy

A. MDE Process Structure Package

Fig. 2 shows the MDE Process Structure package. The objective of this package is to describe the structure of a MDE process that encompasses traditional activities (e.g. edit a model) and model transformations. Activities are described by their input and output products, roles that perform activities, and constraints that specify their precondition, invariant, and postcondition. *InitialActivity* is a pseudo-activity that starts the process while *FinalActivity* is a pseudo-activity that stops the process.

A *Model* is a description of (part of) a system written in a well-defined language (i.e. a model must conform to a metamodel) [5]. The rules WF01, WF02, and WF03 described below, introduce restriction between a model and its compliance model. A model at the *M1* level should conform only to a metamodel (i.e. a model at the *M2* level); a metamodel should conform only to a meta-metamodel (i.e. a model at the *M3* level); and a meta-metamodel should conform only to itself. A model may not have a level (e.g. UML Infrastructure has not a fixed level).

A *TransformationDefinition* is considered as a particular *SPEM Activity*. It is described by its informal rules, its input and output models, and its source and target metamodels. Informal rules describe relationships between constructs of a source metamodel and constructs of a target metamodel. A *TransformationDefinition* is endogenous (i.e. its source metamodel and its target metamodel are identical) or exogenous (i.e. its source metamodel and its target metamodel are different). As a SPEM Activity, a *TransformationDefinition* is performed by roles, specified by *RoleUse* via *ProcessPerformer*. However, since a transformation in

SPEM4MDE is to be executed automatically, a *TransformationDefinition* should have only one *ProcessPerformer* linked to only one *RoleUse*.

The following constraint rules are used to define the static semantics of the MDE Process Structure package. Due to space limitation, the OCL expression is shown for only the first three rules.

- [WF01]: A *Model* at the *M1* level must conform to a Metamodel (i.e. a model at the *M2* level).

  Context Model inv: (self.level=#M1 and self.complianceModel→notEmpty()) implies (self.complianceModel.level= #M2)

- [WF02]: A *Metamodel* must conform to a *Meta-Metamodel (i.e. a model at the M3 level)*

  Context Model inv: (self.level=#M2 and self.complianceModel→notEmpty()) implies (self.complianceModel.level= #M3)

- [WF03]: A *Meta-Metamodel* must conform to itself.

  Context Model inv: (self.level=#M3 and self.complianceModel→notEmpty()) implies (self.complianceModel=self)

- [WF04]: Input and output models of a *TransformationDefinition* should have the same level; source and target metamodels of a *TransformationDefinition* should have the same level; source and target meta-metamodels of a *TransformationDefinition* should have the same level.

- [WF05]: An *Activity* may be decomposed only into *Activities* or *Transformations.*

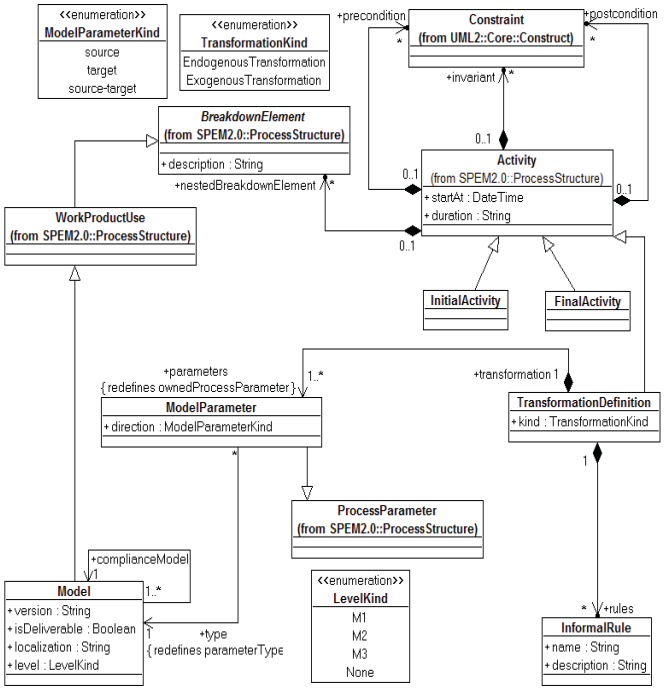

Figure 2. MDE Process Structure Package

B. *Model Relationship Package*

Fig. *3* shows the Model Relationship pac*kage.* The objective of this package is to describe common relationships between models, which are composition, and refinement. A model may be decomposed into other models (e.g. decomposition of UML metamodel into Class Diagram metamodel, Use case metamodel, etc). A model may be the refinement of another model (e.g. PIM to PSM in MDA approach). The concept *Trace* represents a set of trace elements that together describe traceability links between source and target model elements in a *TransformationDefinition*.

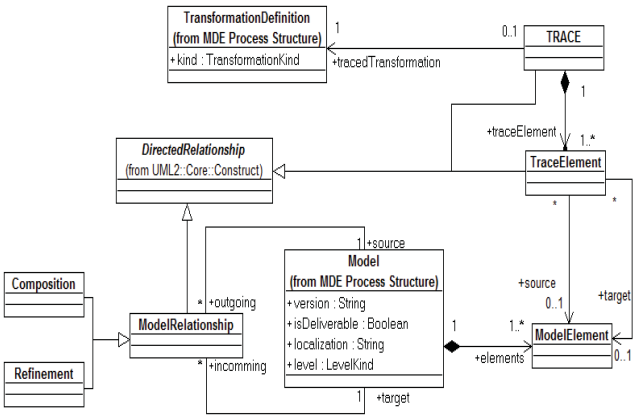

Figure 3. Model Relationship Package

C. *MDE Process Behavior Package*

To allow computer-assisted enactment of MDE processes, it is necessary to be able to model their behavior. The goal of the *MDE Process Behavior* package is to provide concepts for implementing transformations defined in *MDE Process structure* and concepts for defining behavioral models of MDE process elements. Fig. 4 shows the MDE Process behavior package.

The concept *TransformationImpl* describes the implementation of a transformation in a formalism which is either rule-based, program-based, or template-based. A *TransformationImpl* is executed by a required MDE tool. *HumanActor* specifies a person who plays his assigned roles within the process.

Transformation with QVT meaning is a rule-based transformation that extends *TransformationImpl*. To help transformation designers describe transformations with rules, we advocate the use of QVT.

The following constraint rules define the static semantics of the MDE Process Behavior package. The OCL expression is given for only the first rule.

- [WF01]: Input models of *TransformationImpl* must conform to the source metamodels of its associated transformation specification.

Context TransformationImpl inv: (self.parameters→select(i\|i.direction=ParameterKind.in)→ collect(t\|t.model.complianceModel))=

(self.specification.parameters→select(m|m.direction= ModelParameterKind.source) →collect (t| t.type))

- [WF02]: Output models of *TransformationImpl* must conform to the target metamodels of its associated transformation specification.

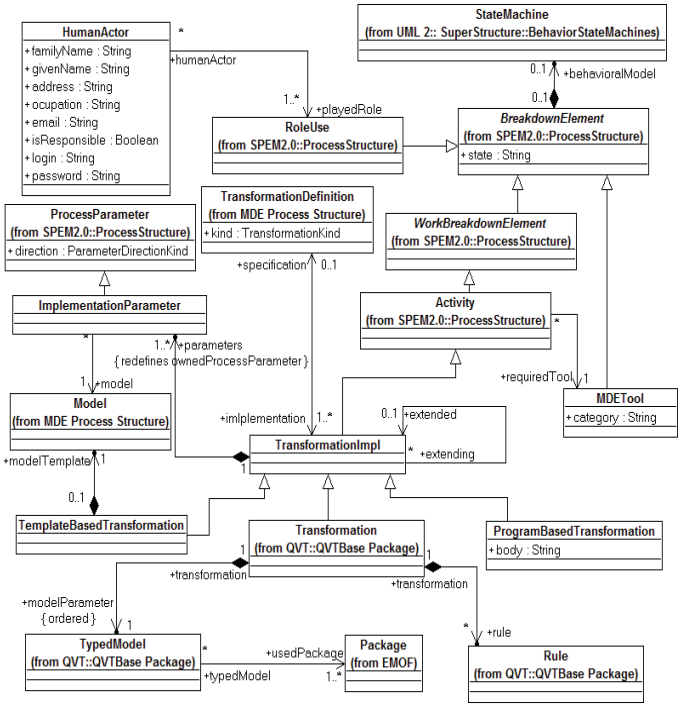

Figure 4. MDE Process Behavior Package

The behavior of a *BreakdownElement* may be described by a UML state-machine. The property *state* in BreakdownElement defines the state of each MDE process element at enactment time.

To illustrate the use of UML state-machines in MDE Process Behavior package, Fig. 5 shows a default behavior of any transformation. This behavior may be reused or adapted when defining a MDE process. We distinguish between three composite states: *Not-Running*, *Running*, and *Finished*. After the process has been instantiated, the transformation is in the state E*xecutable*. The transition from the state *Executable* to the state *Startable* occurs when the function *Startable ()* returns true (i.e. precondition and precedence constraints are fulfilled). The transformation switches from the state *Startable* to the state *Executing* when the required MDE tool is running. A transition to the state *Inconsistent* occurs when the invariant associated to the transformation is no longer fulfilled. From *Executing* state, the transition to the state T*erminated* is triggered when the execution process of the transformation is finished. From *Executing* state, the transition to the state *Aborted* happens when the developer cancels the transformation execution. From the state *Inconsistent*, there are four options: *reconcile* the transformation with the MDE process and then it switches to the state *Executing*, *cancel* the transformation execution and then it switches to the state *Aborted, finish* the transformation execution and then it switches to the state *Invalidated*, or *restart* the required MDE tool and then the transformation switches to the state *Executable*. From the state *Terminated*, if the transformation is validated (i.e. its target models are validated and its postcondition is fulfilled), the transformation switches to the state *Validated*, otherwise it switches to the state *Invalidated*. From the state *Invalidated* the user may restart the required MDE tool and then the transformation switches again to the state *Executable*.

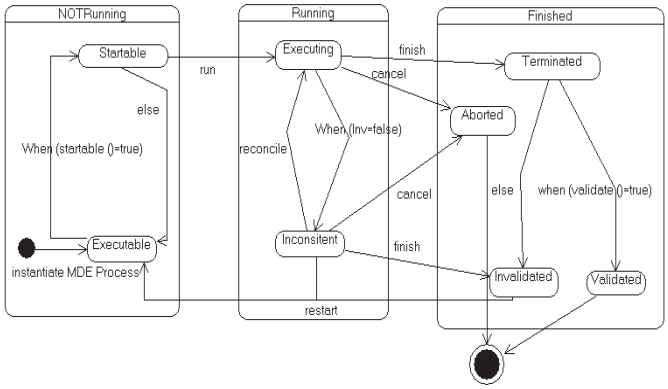

Figure 5. Default Behavior of a Transformation

IV. VALIDATION

A. *The prototype SPEM4MDE-PSEE*

To validate the specification of the SPEM4MDE metamodel, and allow users to define and enact SPEM4MDE process models, we have developed a prototype SPEM4MDE-PSEE under the TOPCASED environment [18]. As shown by Fig. 6, SPEM4MDE-PSEE is divided into two components: *SPEM4MDE Process Editor*, and *SPEM4MDE Process Enactment Engine*.

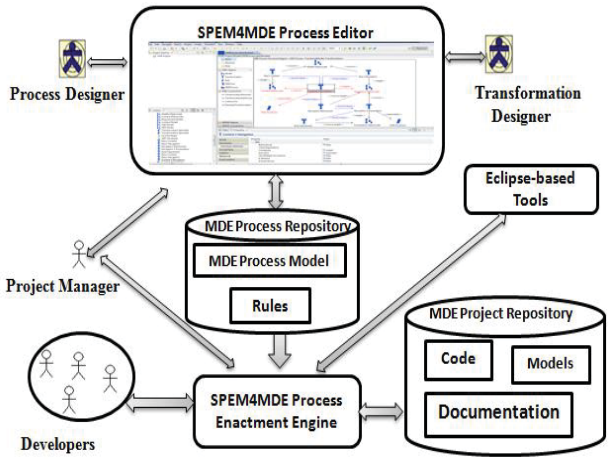

Figure 6. Architecture of SPEM4MDE-PSEE

SPEM4MDE Process Editor allows process designers to describe, and modify MDE process models. Describing a MDE process model includes describing its structure and its behavior. Transformation rules in a MDE process are described by transformation designers. Once the MDE process model is described, the process designer may check it with respect to the

constraints defined in the SPEM4MDE metamodel, or to additional constraints. There are two ways for checking MDE process models: checking on demand (i.e. when the user triggers himself the checking process) or checking during edition (i.e. checking is done automatically by the tool). Outcomes of process editing are stored in a repository called *MDE Process Repository*. This editing component may also be used by a project manager for adapting a MDE process model to a given project.

SPEM4MDE Process Enactment Engine allows developers to enact a project-specific process model by allowing them at each time to execute enactment operators and to know the sate of any MDE process element. It is integrated with other eclipse-based tools (ATL, Smart QVT, etc.) in order to execute transformations. Developers can then keep track of what is the current state of each element of the MDE project, what has been done before and what is left. Outcomes are models, code, documentation, etc. and are stored in a MDE *Project Repository*

B. *Case Study: A process for developing web systems*

In this section we illustrate our approach with a MDE process example: UWE (UML-Based Web Engineering) [8], [9]. We first give an overview of the UWE process. Then, we show the description of an extract of UWE with the *SPEM4MDE Process Editor*. Afterwards, we show the adaptation of another extract of UWE to a very simple MDE development project: a music portal web application. Finally, we show how to use *SPEM4MDE Process Enactment Engine* when enacting the adapted process model.

1) *The UWE Process*

The objective of the UWE process is to give to web developers a systematic and semi-automatic support of web systems development based on models and their transformations. The process covers the whole development life cycle of web systems from the requirements specification to code generation. It is a model-driven development process following the MDA approach. It consists of a set of models and model transformations, specified by metamodels and model transformation languages. The metamodels are the Web Requirements Engineering metamodel (WebRE) [23], the UWE metamodel [9], and the metamodel of the Web Software Architecture approach (WebSA) [8] that contain respectively elements for modeling requirements, structure and behavior, and the architecture of Web systems. The UWE metamodel includes the *Content Metamodel*, the *Navigation Metamodel*, and the *Presentation Metamodel*. The UWE process starts with the definition of a *requirements model* that is a computational independent (CIM) business model. Two sets of platform independent design models (PIM) are derived from these requirements: *functional models* which represent the different concerns of the Web system (content, navigation, business logic, presentation, and adaptation); and *architectural models* which represent the architectural features of the Web system. *Functional models* are afterwards integrated mainly for the purpose of verification into a *big picture model*. A merge of this *big picture model* with the *architectural models* results in an *integrated model* covering functional and architectural aspects. Finally, platform specific models (PSM) are derived from the *integrated model* from which programming code can be generated. The transformation of *requirements model* into *functional models* is a composite *transformation,* each sub-transformation dealing with a separate concern of Web engineering.

2) *Describing UWE's Functional Models Transformation with SPEM4MDE-PSEE*

To illustrate the use of the SPEM4MDE Process Editor, Fig. 7 gives an extract of the UWE process model, related to the "*requirements model to functional models"* transformation. It comes as a set of six sub-transformations: "*Req 2 Content"*, "*Content 2 Navigation"*, "*Req 2 Navigation"*, "*Navigation Refinement"*, "*Navigation 2 Presentation"*, and "*Style Adjustment"*. These transformations are ordered as depicted by the links «*finishToStart*». Source and target metamodels of each transformation are depicted by the links «*source*» and «*target*», respectively. Input and output models of each transformation are depicted by the links «*in*» and «*out*», respectively. However, for readability of Fig. 7, we only give input and output models of the first two transformations. For instance, "*Content 2 Navigation"* has the "*Content Model"* as an input model, "*Content Metamodel*" as a source metamodel, "*Navigation Model"* as an output model, and "*Navigation Metamodel" as a target metamodel. "Navigation Model"* is conformed to "*Navigation Metamodel", while "Content Model"* is conformed to "*Content Metamodel"*. It should not start before "*Req 2 Content"* is finished, and must be finished before "*Req 2 Navigation"* can start. For more details about the UWE process, the reader is referred to [8].

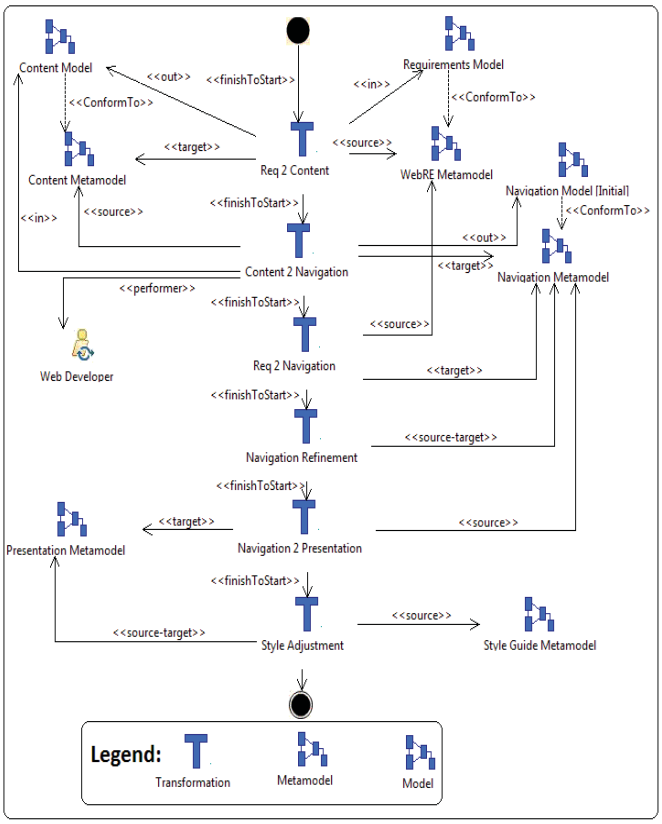

Figure 7. Functional Model Transformations within UWE Process

3) Adapting the UWE Process to a Project Example

Before a process model can be enacted for a given development project, it has to be adapted to the project by the means of *SPEM4MDE Process Editor*. This adaptation consists in specializing it into a project-specific process model, where each transformation is linked to its implementation and assigned resources (human actors, tools, workspaces, and used artifacts), and each activity is associated with its resources.

To illustrate how the UWE process model may be adapted with SPEM4MDE, let us consider a simple project example: a web portal application for vending musical albums, and an extract of the process, limited to the "*Content 2 Navigation"* transformation (shown in Fig. 7). The adaptation of this extract is depicted by Fig. 8. It consists first in specifying the implementation of the transformation ("*Content 2 Navigation Impl"*), and assigning its resources: a human performer (*Bob*) who plays the *Web Developer* role, an input model ("*Music Portal Content Model"*), an output model ("*Music Portal Navigation Model"*), and a tool (Smart QVT) for executing the transformation implementation (rules describing the transformation – not shown in the Fig. – are implemented in QVT). The project-specific UWE process model is linked with the UWE process model through stereotyped associations: «*implements*» for the transformation implementation, «*conformsTo*» for the input/output models, and «*plays*» for the human actor. Moreover, the state of "*Content 2 Navigation Impl*" is set to Executable (see Fig. 5). The adaptation of the other UWE's transformations is done similarly. At this stage, input and output models specify rather references than concrete models, which will be produced once the transformations are performed.

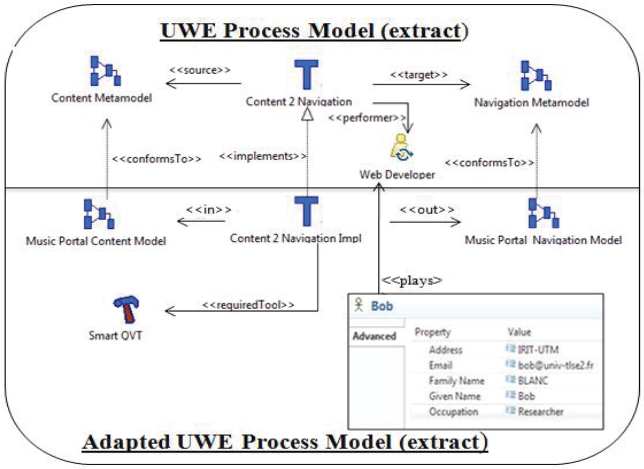

Figure 8. Adaptation of the "Content 2 Navigation" Transformation

4) UWE Process Enactment

Process enactment is based on the behavioral model described by state machines (as discussed in section III (sub-section C)). The *SPEM4MDE Process Enactment Engine* offers to developers entries of menu (i.e. enactment operators) that show for each process element the set of all operations specified by the corresponding state machine. Moreover, it also shows whether these operations are eligible or not. Once an operation is executed by developers, the state of the related process element is updated according to its corresponding state machine, and attached actions (with UML state-machines meaning) are executed, if any. As stated in the precedent section, a process enactment can start only once the process model is adapted to a given project.

To illustrate the enactment of the UWE process, let us consider the extract of the adapted UWE process shown by Fig. 8. Let us suppose that the process is at the stage where the implementation of the "*Req 2 Content*" transformation (shown in Fig. 7) has been performed, producing the "C*ontent Model"* (shown by Fig. 9 below) which is linked to "*Content 2 Navigation Impl"* as an input model.

As shown by Fig. 9, an artist produces albums, each album having one or more songs. A session may be associated to the application's current user. A credit card is used for buying albums, but may have an owner different from the user.

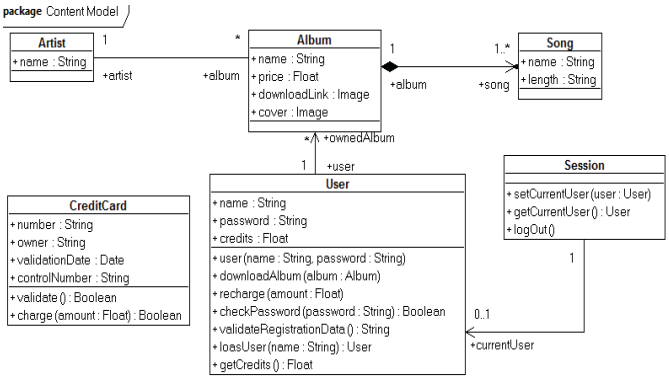

Figure 9. Source Model of "Content 2 Navigation Impl"

Fig. 10 shows the contextual menu displayed by the *SPEM4MDE Process Enactment Engine* for "*Content 2 Navigation Impl*". It indicates all possible operations described by the behavioral model of a transformation (see Fig. 5), and whether each operation is eligible (green mark) or not (red cross).

Initially, "*Content 2 Navigation Impl*" is in the state "*Executable"*. It has switched to the state "*Startable"*, because the "*Req 2 Content*" transformation is already performed (i.e. precedence of "*Content 2 Navigation*" is fulfilled), and the "*Content Model*" is created and validated (i.e. precondition "*Content 2 Navigation Impl*" is fulfilled). Since the current state is "*Startable"*, then the operation "*run*" is eligible. If a non-eligible operation is clicked on, a message displays (not shown in the Fig.) what conditions should be fulfilled in order to make it eligible.

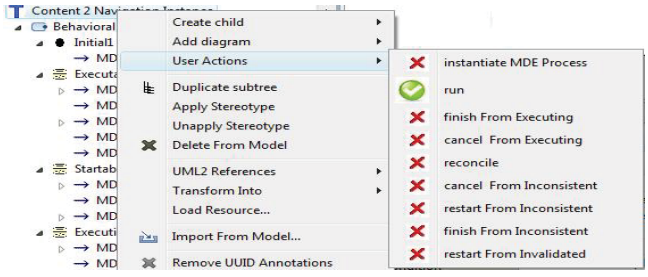

Figure 10. Contextual Menu of "Content 2 Navigation Impl "

When the operation "*run"* is executed, "*Content 2 Navigation Impl*" switches to the state "*Executing"*, its contextual menu is updated consequently (see Fig. 11 below). Moreover, the attached action (i.e. launching the associated tool (*Smart QVT*)) is performed.

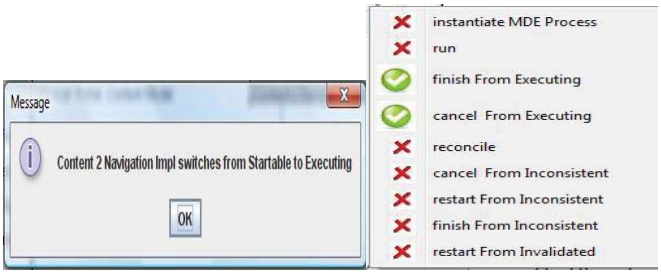

Figure 11. Displayed message (left) and the updated menu (right) after triggering the run action

If the "*finish From Executing*" operation is performed, the current state switches to the state "*Terminated"*, meaning that the output model (i.e. the "*Music Portal Navigation Model*" shown in Fig. 12) is created. At this stage, if this model is validated, "*Content 2 Navigation Impl*" switches to the state "*Validated"*, otherwise it switches to the state "*Invalidated"*. As shown by Fig. 12, the "*Music Portal Navigation Model*" describes the output model of "*Content 2 Navigation Impl*". From the home page, a user may register, recharge his account, or search an album. The result of the search is a list of albums. From this list, the user can view the details of each album and afterwards download it, and may then recharge its account. Before registering, recharging, or downloading an album, the user should log in.

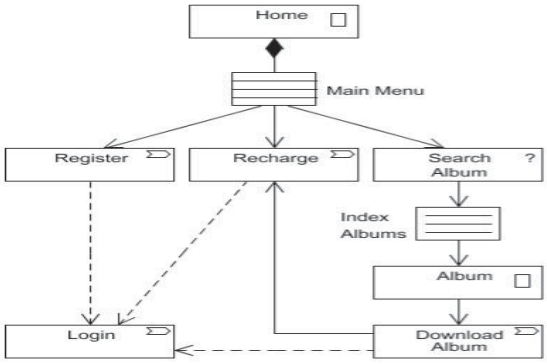

Figure 12. Target Model of "Content 2 Navigation Impl"

V. Related Works

Works related to our domain of interest mainly focus on transformations and MDE processes modeling. In the transformation area, we distinguish between model-to-code and model-to-model transformation approaches. In general, model-to-code can be viewed as a special case of model-to-model transformation; we only need to provide a metamodel for the target programming language. Among model-to-model transformation approaches, we distinguish between rule-based, graph-based, program-based and template-based approaches. Model transformation is the central topic of MDE and is essential to define a MDE process. The first MDE process came with the OMG's MDA initiative [3], [15] which depicted a general purpose process that can be applied to any application domain. Then, starting from the MDA approach, other MDE processes dedicated to middleware service [16], web applications [8], e-learning [17], models composition [20], embedded-systems [10], and a version of the Open Unified Process for MDD [24] have been proposed. However, there is a lack of consistent terminology since there is no unified language to specify MDE processes: each one adopts ad hoc notations and different concepts are used to define the activities and artifacts for software development life cycle.

Many languages and formalisms have been proposed for modeling software processes ([6], [12], and [29]), however only a few of them take into account explicitly MDE concepts [4], [11]. The SPEM 2.0 standard [12] describes a process in terms of activities, input and output products, and roles that perform activities, but fails on describing MDE concepts in a process. Moreover, SPEM does not address the process enactment in its last version. Nevertheless, it clearly suggests two possible ways of enacting SPEM 2.0 process models: mapping the SPEM 2.0 process models into project plans or linking SPEM 2.0 process elements with external behavior formalisms. To overcome the limitations of SPEM regarding enactment, several approaches based on state-machines (eSPEM [29], xSPEM [30], etc.), Petri nets (e.g. Porres' approach [4]), and on workflow (XPDL, BPEL [31], BPEL4PEOPLE, etc.) have been proposed.

The QVT standard [14] is suitable for defining model mappings and executable model transformations, but fails on describing process design aspects.

In [4], an approach that is targeted towards the development of software and systems using MDE methods is presented. The dynamics of this approach is based on Petri Nets. This approach can be integrated with existing approaches for software process modeling, but the metamodel contains only one concept (*transformation Tool*) that is related to MDE.

In [11], an approach to MDA process specification, based on the SPEM 2 standard concepts, is proposed. This approach is supported by a tool called *Transforms* which can be used to instantiate a MDA process for a given domain. Developers can describe steps and associate artifacts to perform MDA modeling and transformations chain. This approach has however some limitations, since it is tightly coupled with MDA concepts. Furthermore, it does not separate the specification of a transformation from its implementation.

VI. Conclusion

So far, MDE concepts are not explicitly supported by existing PML (Process Modeling Language). Reification allows promoting MDE concepts as first-class citizens.

In this paper, we have presented the specification and the implementation of SPEM4MDE, which is a metamodel dedicated to MDE software process modeling and enactment. SPEM4MDE extends SPEM 2.0 by adding concepts and semantics relating to MDE. It also reuses the QVT standard, and UML state-machines for defining the execution behavior of transformations and the behavior of MDE processes. In

addition, SPEM4MDE offers a set of behavioral MDE process models that process designers may reuse or adapt for a particular process. A prototype called SPEM4MDE-PSEE has been implemented under the TOPCASED environment. It helps process designers describe structural and behavioral aspects of SPEM4MDE process models and ensure that such process models are well-formed. SPEM4MDE-PSEE aims also at guiding the execution of projects based on a MDE process. Furthermore, when enacting a MDE process model which is specific to a project, developers can keep track of what is the current state of each element of such a MDE process model, what has been done before and what is left. To demonstrate the capabilities of our prototype, we have used an extract of the UWE process. The structure of this extract and the behavior of transformations that are involved in this extract have been modeled under *SPEM4MDE Process Editor*. *SPEM4MDE Process Enactment Engine* transforms the behavioral model of one transformation in UWE process as entries of menu representing operations that may be triggered at enactment time. Thanks to this menu, developers may know at any time, operations that are eligible or not.

Two important perspectives of this work are under consideration. Firstly, we intend to implement traceability of model transformations. The underlying objective is to replay easily a transformation when change occurs on its input models. Secondly, we envisage extending the SPEM4MDE metamodel for handling model-based collaborative development processes. For instance, the extension of SPEM4MDE for collaborative MDE processes will permit to coordinate developers' activities who work on the same model.

Conformance Checking of Software Development Processes Through Process Mining

Artini M. Lemos, Caio C. Sabino,Ricardo M. F. Lima, César A. L. Oliveira

Abstract

The design and management of software development processes is essential to reduce costs and improve the quality of software products. The execution of such processes is usually monitored to register important information about the dynamic behavior of the software development process. As a result, a huge amount of information is stored in the database and the software managers are deluged by data. Then, it is important to find ways to automatically analyze the process execution logs to discover the actual process model, characterize trends in it, and flag anomalies. Process mining is a well established technique designed to attack this challenge. This paper demonstrates the application of process mining technique and tools to perform a software development process conformance analysis to detect inconsistencies between a process model and its corresponding execution log. The work conducts a case study using an event log database with more than 2,000 process instances gently provided by a Brazilian software house. The paper aims at closing the gap between process mining and software engineering areas. We hope to motivate and guide software managers to adopt process mining technique as a practical tool for the analysis and improvement of software development processes.

1. Introduction

Software development usually follows a sequence of activities designed to capture the best practices from software development projects. Such sequence of activities defines the software development process, which should be constantly revised and improved to embody strategies for accomplishing software evolution. Even when the process is automated, due to personal preferences, previous experiences, or even time and cost pressures, it is common to see project managers adopting their own software development processes. Moreover, usually some process activities are ignored to save time and meet the project deadline. Therefore, the first step of any software process improvement project should be the conformance analysis to determine if the defined process is being actually followed.

In this context, it is important to discover the real software development process to compare it with the company's formal process. Software development process discovery has been an intensive task, either done through exhaustive empirical studies or in an automated fashion.

Software houses usually automate their development processes through a monitoring system. This system is capable of registering valuable information about process execution, such as timestamps, task identification, stakeholders involved in the execution of an activity etc., in the form of execution logs. Such execution logs (also called event logs or audit trails) are the starting point for the process mining technique, which was developed to semi-automatically extract useful information from them [4].

Processing mining has been successfully applied in many different areas, including software engineering. In [1] authors explore process mining techniques for discovering development processes from publicly available open source software development repositories. In [6] authors define a process mining framework to discover software development processes from event logs generated by software configuration management (SCM) systems. Unfortunately, these works are more oriented to the computational intelligence area. They focus on describing the mining techniques, demonstrating their efficiency in discovering software process models. Less attention is devoted to the application and use of such techniques to evaluate the software development process in a real environment.

This work aims at bridging this gap between process mining and software engineering areas by demonstrating how to explore process mining techniques to perform a conformance analysis and evaluate whether the established software development process is being followed. The conformance analysis main goal is detecting inconsistencies

between a process model and its corresponding execution log. Despite some works have explored process mining techniques for the conformance analysis of general business processes [5], it is not of our knowledge any study that applies process mining to conformance checking of software development processes.

In this work we use the process mining ProM tool [9] to mine the event logs of a real company and discover the process model that is actually employed by them. We are particularly interested in the process *control-flow perspective*. In the control-flow conformance analysis, we want to evaluate if process activities are being executed in the correct order and discover which activities are actually being executed in the process instances. For this objective, we employed a feature of the ProM framework that generates a Markov chain from the process logs.

The paper explores a real database with event logs generated in the past five years from the execution of a software development process. The database was gently provided by a Brazilian software house with annual revenue of more than US$ 500 million. The database includes more than 2,000 cases (process instances).

The paper is organized as follows. Section II describes the process mining technique and presents the ProM tool. Section III discusses the conformance checking study conducted in this work. It begins by presenting the formal software development process defined by the company; then describes the event log characteristics and the mining strategy; in the next step it demonstrates how to use ProM to identify problems in the even logs and how these problems were corrected; finally, it discusses the conformance analysis study herein conducted. Conclusions and future works are discussed in Section IV.

2. Process Mining

Business process mining, or just *process mining*, is a "nascent research field at the intersection of data mining and business process modeling" [3] that targets the extraction of non-trivial and useful information based on execution logs [4]. Since many systems record their transactions in log files, process mining techniques can be used for a large class of business processes. By using process mining, many kinds of information can be collected about the process, such as control-flow, performance, organizational information and decision patterns.

It is important to note that most process mining techniques do not generate a model for only reproducing all log entries, but collects general information about the process real execution, considering that exceptional behavior or some minor errors may occur in the log file that should not be part of the process.

Once the process model is obtained and possibly validated, it can be analyzed in order to better understand how it actually works. In the analysis of the process model, some changes can be proposed and their effects can be estimated and measured. That means that the impact of some changes can be calculated without having to change and verify the real process. Therefore, process mining techniques can be used to gain insight on how to improve the process quality.

Many process mining algorithms have been proposed. The ProM Framework [9] is a tool that features many mining and analysis plug-ins implementing several of these algorithms.

ProM is an extensible open source framework implemented in Java with a user-friendly graphical interface that provides a wide variety of plug-ins that support, implement, and use process mining techniques. There are currently more than 230 plug-ins, distributed on functionalities like filtering, mining, analysis, exporting and conversion.

The input log files for ProM are in a common log format: Mining XML (MXML). ProM can also take as input process model files, such as PNML and many others. When the log file is opened, ProM collects some statistical data about it and present them in the main window. Also, many plug-ins become available to operate on the log.

The mining plug-ins aim at discovering multiple perspectives of the process, such as the control-flow, the organizational structure, the data perspectives and some other information. Details about these perspectives are given in [9]. The analysis plug-ins deal with verification of process models, conformance checking between the log and the model, performance analysis, among other things.

ProM also provides filters for cleaning the log from undesired elements. Filtering "is usually a projection of the log to consider only the data you are interested in" [9]. Also, some mining plug-ins have configurable settings in order to obtain better results depending on the user's purposes.

ProM allows multiple combinations of plug-ins, making it possible to analyze the results of a mining algorithm or merge the contents of multiple perspectives to obtain a more complete model for the process.

With an extensible framework, new algorithms can be easily added as new plug-ins and this makes ProM a very powerful tool. ProM works with several modeling languages, such as Petri Nets [2], EPCs [7], YAWL [8], and supports the conversion between most of them, being a very versatile tool.

3. Discovering a Software Development Process

In this section, we explore the case of a Brazilian software house with annual revenue of more than US$ 500 million. Five years ago, the company defined a software devel-

opment process and deployed a monitoring system to register relevant information about its execution. Since then, a huge volume of event logs has been generated, in a way that became impossible to the software quality team to manually extract useful and trustful information from the database.

In this context, we applied process mining techniques to extract important information on the real software development process from the event logs. The main objective is to discover the actual process being executed by the development teams and compare it against the documented process. The database under consideration includes more than 2,000 instances of the process.

3.1. The Formal Software Development Process

In its documented specification, the software development process begins with the activity *Proposal and Production Budget* (PPB) as it can be seen in Figure 1. The PPB includes two tasks: 1) creating a functional specification document, which aims at detailing the recommended solution; 2) and filling in a worksheet to estimate the software development effort. A manager analyzes the functional specification document in the activity *Functional Specification Document Analysis* (FSDA) before submitting the proposal to the client. In the next step the production planning and budget proposal is sent to the client - activity *Send Production Planning and Budget* (SPPB). Then, the client analyses the production planing and budget proposal and returns an approval/reject response - activity *Client Proposal Analysis* (CPA).

When the customer approves the proposal and production budget (CPA activity), the team leader analyses the technical specification to evaluate its complexity. Only complex specifications are validated - activity *Validate Technical Specification* (VTE). The *Development* (DEV) activity starts after validation. During this activity, programmers implement the software, create the processing scripts and database objects script (triggers, functions, packages, and view). When the development phase is completed, the *Code Verification* (CODV) activity is performed to check whether code complies with the specification and follows the development patterns. After the code verification phase, the program is tested in the *Testing* (TEST) activity. Eventually, with the software validated and tested, the process reaches the *Documentation* activity (DOC) and the process terminates.

This is an iterative process, allowing specification refinements/corrections and negotiation of the production planning and budget proposal. As one can see in Figure 1, activities FSDA, CPA, VTE, CODV, and TEST represent points where the process may move back to previous activities.

3.2. Mining the Software Process Logs

The company's quality team is interested in assessing the model (or models) of the real process and compare it against the process that was supposed to be executed. Such conformance analysis will be the starting point for a process improvement project in the company.

The Mining XML (MXML) is an extensible, XML-based format for storing process event logs which can be analysed by the ProM tool [9]. Since the company's database adopts a private file format, a compiler was developed to translate the event logs into the MXML file format.

ProM allows one to discovery different *perspectives* of the process being analyzed, namely control-flow, performance, and organizational perspectives. In the conformance analysis conducted in this paper, we are interested in the *control-flow perspective*. To discover which tasks are actually performed and their order of execution is of particular importance for the software quality team. The idea is to compare the control-flow model of the formal process against the control-flow model (or models) discovered from the real event logs.

In the ProM tool, information about each event is recorded in the form of an audit trail entry. Our event logs store the following information on each audit trail: 1) **taskID**: name of the task involved in a process event; 2) **event type**: a mark to indicate whether the event is a start or complete point in the process instance; 3) **timestamp**: moment at which the event took place; 4) **originator**: worker who perform the task (originate the event).

Since the audit trail entry identifies the tasks that are executed in a process (*taskID*) and allows for inferring their order of execution (*event type* and *time stamp*), then the control-flow perspective can be discovered.

Existing techniques for process mining perform very well for well-structured and organized event logs. However, the situation is not that simple upon dealing with real event logs. In this case the logs are usually very obscure and have noises, making it difficult to extract useful information. Therefore, in these situations a preprocessing phase to remove noises and organize the event logs is an obligation.

Our event log database was generated in the past five years, in a very active company, with hundreds of process instances executed each year. Thus, the preprocessing phase is essential to produce a well structured event log database. We used the reports produced by ProM tool to carefully analyze the database and a number of problems were found and fixed, as follows.

Incomplete timestamps - a) The monitoring system only registers the moment a given activity initiates, but it does not monitor the activity duration. However, this would be a concern only if we were interested in analyzing the *per-*

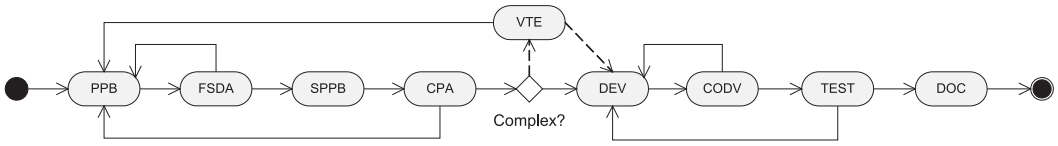

Figure 1. The Formal Software Development Process

formance perspective of the process, which is not the case. b) The original log recorded timestamps using information about days, months, and years, but missing hour, minute, and second details. Thus, activities occurring within a day were assumed to be parallel activities, rather than sequential ones. To solve this problem we redefined timestamps such that all activities in a process instance received different timestamps. We used the formal company's process to determine the order of activities in time. One might argue that the solution is biased by the control-flow of the formal process. However, observing the original database, in more than 90% of the cases, if two activities in the same process instance have different timestamps, they follow the control-flow order defined for the formal process, which is a good result for the conformance analysis being conducted. Therefore, our assumption for the timestamps modification is acceptable. Nevertheless, despite the good conformance results for the control-flow order, in most cases, the set of activities being executed in a process instance are only a subset of the activities defined in the formal process. So, a deeper conformance analysis is still required.

Database corruption - Data stored in the audit trail entry of a small number of process instances appeared to be corrupted. For instance, we found timestamps with invalid date values. Moreover, some process instances had no start or complete events. Fortunately, the number of process instances with this kind of problem represented less than 2% of the whole database. Thus, they were discarded without significative loss for the conformance analysis study.

After the database preprocessing, we proceeded with the conformance analysis. We want to answer two main questions: 1) does the real process respect the ordering of execution defined in the formal process?; 2) which subset of activities in the formal process are actually executed in the real process? As we already observed, the answer for the first question is yes for more than 90% of the cases. But we need to investigate more to answer the second question.

3.3. Conformance Analysis

In this section, we describe the approach employed to analyze the software process based on the information provided by process mining.

ProM features a plugin capable of generating a Markov chain from the discovered model, where each node is a process activity and transitions are labeled with probabilities as in ordinary Markov chains. Through the Markov chain it is possible to discover if sequences of activities defined for the process actually occur, and with which frequency. It is also possible to measure the probability of skipping a given activity that is defined in the flow and the probability of each decision that must be taken during the process execution.

We used Prom's Markov chain model discovery feature in our study. Table 1 presents the Markov chain generated using ProM's *sequence clustering analysis plug-in*.

With the Markov chain in hands, we can start the conformance analysis of the software development process. The purpose is to detect points in the actual process that are not in conformance with the company's expectations and provide useful information for the company to initiate the process improvement project.

Figure 2 presents the formal process enriched with transition probabilities assessed from the Markov chain (Table 1). For clarity and readability, Fig. 2 includes only transitions relevant for the control-flow conformance analysis. Besides the transitions already present in the formal process, we included some transitions (dashed arrows) to indicate undesirable situations observed in the discovered process model.

Now, let us analyze the results presented in Fig. 2 to point out and discuss some conformance problems.

The probability of transitioning from the initial state (in) to the development state (DEV) is of 25.2%. This means that about one in each four projects started by the development activity, skipping the whole planning stage.

The activity send production planing and budget (SPPB) is almost never reached by any other activity in the process model and could be removed from the formal process.

Although *validate technical specification* (VTE) is performed for complex software projects, the execution of such activity in the actual process is fairly rare, with probability of 0.2%. This points out that this activity is executed in very exceptional cases and, therefore, could be removed from the company's standard development process.

A more critical problem can be seen in the end of the process. Software verification, testing, and documentation are important activities of the best practices for software development projects. Nevertheless, such activities are ignored by 43.6% of the software development processes analyzed (see transition from the development phase (DEV) to the

out	-	-	-	-	-	-	-	-	-	-	-

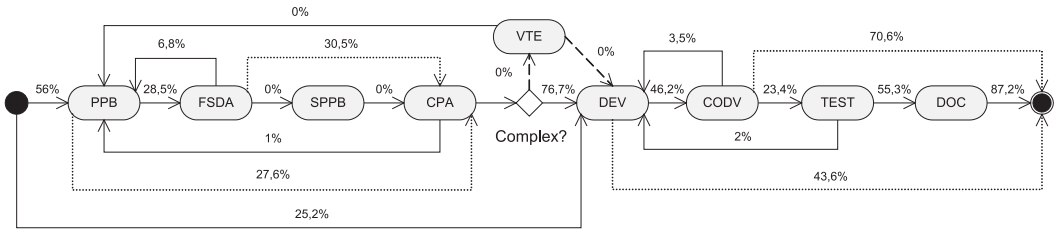

Figure 2. The actual development process with the undesired transitions shown as dashed arrows

Table 2. Activity execution frequency

Activity	Absolute occurrence	Relative occurrence
DEV	1556	27.385%
PPB	1356	23.865%
CODV	853	15.012%
CPA	841	14.801%
FSDA	442	7.779%
TEST	342	6.019%
DOC	250	4.4%
SPPB	38	0.669%
VTE	4	0.07%

terminal state (out)). This shows that the software project terminates in the development stage with a very high probability, without even being verified. Even worst, looking at the transition from the *code verification* activity (CODV) to *testing* (TEST), one can notice that, if the software happen to be verified, it is usually neither tested (TEST) nor documented (DOC).

Eventually, Figure 2 demonstrates that the actual process is not iterative. Thus, it is very unlike to observe a return to previous activity during the process execution. Apparently, when a problem occurs during the process execution, it goes straight to the terminate state.

In ProM, a cluster of process instances with same sequence of activities is called a *process type*. Using ProM's sequence clustering plugin we can discover the process types present in the log and the frequency of occurrence of each one. The goal is to evaluate the conformance of these process types against the formal process.

ProM discovered 190 different process types in our event log. Figure 3 presents the two most frequent. The most frequent process type only executes the development (DES) activity, which is a clear indication of nonconformance against the formal process. On the other hand, the second most frequent process shows that many projects are cancelled by the company after the proposal and production budget (PPB), which is a fairly acceptable behavior.

We then analyzed the list of the ten most frequent process types to select those with at least three activities. Out of the ten most frequent process types, only the 4th, 5th, and 10th had three or more activities. Figure 4 depicts these process types. The *testing* (TEST) and *documentation* (DOC) activities are not executed in the fourth and fifth most frequent process types. A good conformance result is observed in the tenth most frequent process type. Only *validation* (VTE) and *send production planing and budget* (SPPB) activities are missing. Nevertheless, VTE activity is optional in the formal process. Additionally, through the analysis of the Markov chain, we had already identified that the SPPB activity is almost never executed and recommended its elimination from the formal software development process.

Figure 3. The most frequent process types

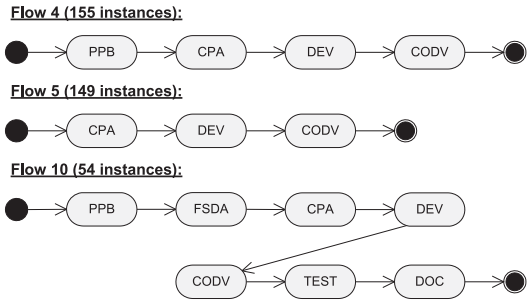

Figure 4. Most similar process types to the formal development among the ten most frequent

4 Conclusions

This paper demonstrated the application of process mining techniques to examine if the actual software development process employed by a company conforms to its formal specification. The work is conducted within the context of a Brazilian software house. A total of 2,000 process instances, recorded in five years of operation, were evaluated.

The conformance checking demonstrated that, although some projects follow the formal process, most of them do not occur as expected. Some serious problems were identified. The initial phase of the formal process, responsible for budged/functionalities proposal/approval, is usually skipped. This may have important impact on the budged planning and increase the costs with software maintainance. Another conformance problem was observed in the final phase of the process. The software implementation is validated against the specification only in 46.2% of the cases. Even worst, if the software happens to be validated, in 70.6% of the cases it is neither tested nor documented.

It is not the purpose of this work to evaluate the impact of the conformance problems in the company's productivity. Indeed, the conformance analysis produced a set of reports indicating inconsistencies detected between a process model and its corresponding execution log. For instance, one of the reports enumerate the most common *process types*[1] in the event logs. In this report, we observed that the tenth most common process type conforms to the formal software development process. However, only the software quality team is able to attest if this is a good scenario and take actions to solve the detected issues.

This work aimed at bridging the gap between process mining and software engineering areas. From a software engineering perspective, it describes how to apply the process mining tool in a practical fashion. We believe that software project managers can benefit from this paper by gaining insights on how to incorporate process mining tools in their professional routines.

Although in the conformance analysis we have explored the *control-flow perspective*, the procedures may be easily adapted to evaluate other software development process perspectives, such as performance, cost, resource allocation, and many others. As a future work, we intend to demonstrate how process mining can be applied to analyze other software development process perspectives and develop a guide to help software engineering people in the use of process mining techniques and tools.

rgarcia@fi.upm.es

***Abstract*—The application of software evaluation technologies in different research fields to verify and validate research is a key factor in the progressive evolution of those fields. Nowadays, however, to have a clear picture of the maturity of the technologies used in evaluations or to know which steps to follow in order to improve the maturity of such technologies is not easy. This paper describes a Software Evaluation Technology Maturity Model that can be used to assess software evaluation technologies in a research field. To illustrate the use of this model, we have employed it for assessing the maturity of software evaluation technologies in some evaluation initiatives within the semantic research field.**

I. Introduction

For research to reach maturity it is necessary to improve the quality of the research processes and their results over time. However, to apply the vague concept of maturity to a research field, which is itself difficult to define, may seem an arduous task.

It is well known that any research field has to periodically assess its status by measuring different aspects of it (e.g., outreach to other fields, quality of publications, technology maturity) and that the results obtained from these assessments are the ones that initiate the actions needed towards improvement and maturity in the field.

Nevertheless, to perform successful assessments for choosing the most appropriate actions, it is necessary to have clear goals and be aware of what is needed to achieve those goals.

Maturity models have been used for decades to guide improvement by providing both a framework of incremental maturity levels to be compared against and different measurable goals that must be satisfied to achieve each maturity level.

The most relevant maturity models are probably the Capability Maturity Model (CMM or SW-CMM) [1] and its successor, the Capability Maturity Model Integration[1] (CMMI). Both maturity models have been defined by the Software Engineering Institute with the goal of improving an organization's software development processes.

Other maturity models have also been defined, most of them inspired by CMM or CMMI, mainly in the software engineering domain but also in domains such as the organization management one (e.g., the Portfolio, Programme and Project Management Maturity Model [2]) or the e-learning one (the e-learning Maturity Model [3]).

One of the measurable aspects of a research field is what technologies support the evaluation of the research outcomes. In fact, the application of software evaluation technologies in any research field to verify and validate research is a key factor for research evolution by means of experimentation-driven research [4].

The goal of this paper is to describe a Software Evaluation Technology Maturity Model (SET-MM) that can be used to assess software evaluation technologies in any research field.

Similarly to other maturity models, the goal of the SET-MM is not to derive a figure for a specific level but to provide some guiding to improve the current activities in the research field.

To illustrate how the SET-MM maturity model functions, we have used it to assess the maturity of software evaluation technologies in some evaluation initiatives within a concrete research field, that of semantic research.

This paper is structured as follows. Section II introduces other maturity models that are related to the one here presented as they cover similar domains. Then, Section III presents the scope of this work and the process followed to define the maturity model, whereas Section IV enumerates the assumptions taken into account when defining this maturity model. Section V describes the five maturity levels of SET-MM and the main notions behind the model. Section VI presents how we have used the maturity model here presented to assess the maturity of software evaluation technologies in the semantic research field. Finally, Section VII draws the conclusions from this work and proposes future lines of research.

II. Related Work

This section presents other maturity models that cover similar domains and that have served us as input for defining the maturity model presented in this paper.

The *Capability Maturity Model for Software* was defined by the Software Engineering Institute in the early 1990s [1]. Since then different maturity models have appeared, each collecting the best practices to be used when comparing an organization's practices and guiding process improvement.

The proliferation of such models has led to their combination into a single improvement framework, namely, the *Capability Maturity Model Integration* that, in its current

[1] http://www.sei.cmu.edu/cmmi/

version, contains three different models: CMMI for Acquisition (CMMI-ACQ) [5], which is used for acquiring products and services; CMMI for Development (CMMI-DEV) [6], for developing products and services; and CMMI for Services (CMMI-SVC) [7], for providing superior services.

The CMMI models focus on the following dimensions that affect organizational improvement: people, procedures and methods, tools and equipment, and processes.

From the number of maturity models that have been defined we present here six, all related to SET-MM and largely inspired by CMM or designed to work in conjunction with it. While the first three models (namely, the Testing Maturity Model, the Measurement Capability Maturity Model and the Software Measurement Process Capability Maturity Model) focus on process maturity, the other three focus on technology maturity (as our model does).

The *Testing Maturity Model* (TMM) [8] was designed to assist software development organizations in evaluating and improving their testing processes.

It covers nine different attributes of a mature testing process: testing policies, test life cycle, test planning process, test group, test process improvement group, test-related metrics, tools and equipment, controlling and tracking mechanism, and product quality control.

The *Measurement Capability Maturity Model* (M-CMM) [9] enables organizations to assess their software and software process measurement capabilities and provides organizations with directions for improving their measurement capability.

It covers the following main areas: measurement focus, measurement design, measure collection, measure analysis, technology support, measurement feedback, measurement training, and measurement management.

The *Software Measurement Process Capability Maturity Model* (SMP-CMM) [10] helps organizations to assess their measurement processes and provides guidelines for improving them.

It supports improvement in five areas: metrics plan, data collection, data gathering, data analysis, and feedback activity.

Daskalantonakis et al. [11] defined a measurement technology maturity model for assessing the software measurement technology of an organization.

Their maturity model covers ten different themes: formalization of the development process, formalization of the measurement process, scope of measurement, implementation support, measurement evolution, measurement support for management control, project improvement, product improvement, process improvement, and predictability.

Wettstein and Kueng [12] defined a maturity model for performance measurement systems, that is, systems that track and manage the performance of an organization (or part of it).

Their maturity model covers six different dimensions: quality of measurement process, scope of measurement, data collection, data storage, use of measures, and communication of results.

Gao et al. [13] define five levels to evaluate the maturity level of software test automation in the test processes of an organization.

In their work, maturity is evaluated through two different perspectives regarding the existence of systematic solutions and tools that support a) the different tasks to be performed during software testing; and b) the measurement of the testing process.

If we classify the main areas covered in these maturity models according to the four improvement dimensions (people, procedures and methods, tools and equipment, and processes) taken into account in CMMI, it can be observed how all these approaches cover the four dimensions and emphasize the areas related to processes while understate those related to people.

While the model presented in this paper is quite similar to the maturity models described above, the main difference is that these maturity models focus on an organization, whereas in our case the focus is on a research field.

This entails two major distinctions between SET-MM and the other models. First, and contrarily to the maturity models presented, we do not cover processes in our model. This is so mainly because at a research field level it is not possible to define, measure, or control any process since the field is composed of highly distributed and heterogeneous members. The second distinction is that data themselves are main topics in SET-MM since the ability to improve largely relies on the capacity of reusing the different evaluation data (e.g., workflows, test data, results). By contrast, in the other maturity models data are secondary issues.

III. Research Methodology

This section presents the scope of the work presented in this paper and the process followed to define the maturity model.

As mentioned above, the maturity model here presented is solely focused on software products and does not cover software processes.

Besides, this maturity model is grounded in the notion of evaluation as defined by the ISO/IEC 14598 standard on software product evaluation [14] and in the following evaluation entities: in any *evaluation* a given set of *tools* are exercised, following a given *evaluation workflow* and using determined *test data*. As an outcome of this process, a set of *evaluation results* is produced.

These entities are depicted in Figure 1. A detailed description of them and of their life cycles can be found in [15].

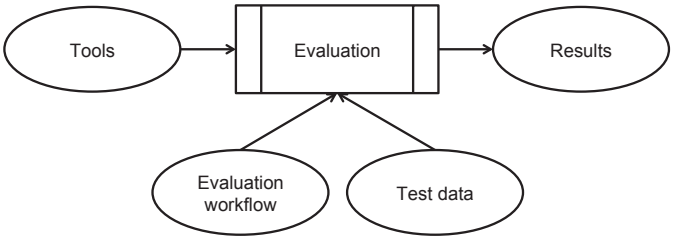

Fig. 1. Main entities in a software evaluation scenario

Furthermore, any evaluation activity is always expected to be the input of some decision-making process. Niessik and

van Vliet [16] exemplify this by proposing a generic process model for measurement-based improvement in organizations; such a model is composed of a measurement cycle followed by an improvement one in which changes in the organization are implemented based on the measurement results.

In our case, the scope is limited to the measurement (i.e., evaluation) cycle; thus, it does not cover improvement, since the analysis and change processes of a research field cannot be controlled nor monitored.

The process followed to define the maturity model contains the same steps than those defined by [11]:

1) First, we identified the set of assumptions upon which the different software evaluation technology maturity levels are defined. Each of these assumptions defines one or more themes (i.e., aspects) that influence maturity.
2) From these themes, five evolutionary stages were defined; these stages have to be followed by any research field in order to reach the highest level of maturity for that particular theme.
3) Then, level *i* of the maturity model corresponds with the *i-th* stage of the themes used to characterize and evaluate the software evaluation technology maturity.

IV. Work Assumptions

This section enumerates the assumptions taken into account while defining the maturity model.

These assumptions (and their corresponding themes) were derived by analysing a) existing maturity models and abstracting their main concepts; and b) evaluations performed in the semantic research field, focusing on the technologies that support these evaluations.

Assumption 1. Software evaluation is facilitated by a well-defined software evaluation workflow and such well-defined workflow will very likely yield quality evaluation results. Furthermore, having both a common framework for defining software evaluations and the means for easily defining evaluation workflows and also automating them is a significant factor that contributes greatly to the improvement of such workflows. Therefore, the following theme is important: *Formalization of the evaluation workflow*.

Assumption 2. Automation of software evaluation tasks enables to perform cost-efficient software evaluations and to diminish manual errors in them. Furthermore, the only way of managing and processing large quantities of software evaluation data is through the use of dedicated evaluation infrastructures. Therefore, the following theme is important: *Software support to the evaluation.*

Assumption 3. The quality of a software evaluation workflow depends on whether such workflow can be applied to different and heterogeneous types of software products. Only by applying the same evaluation workflow across different types of software and under different settings we can validate our hypotheses and conclusions. Therefore, the following theme is important: *Applicability to multiple software types*.

Assumption 4. The automated generation and manipulation of test data for software evaluations helps to focus on how to define test data instead of on how to manage them. Moreover, test data that can be used in different software evaluations are easier to understand, and the results obtained from them are easier to interpret. Therefore, the following theme is important: *Usability of test data*.

Assumption 5. Software evaluation results that are described in some machine-processable format enable the automated integration and exploitation of such results. This integration of results allows the compilation of a significant body of evaluation results, which leads to the exploitation of such results in unexpected ways. Therefore, the following theme is important: *Exploitability of results*.

Assumption 6. The quality of a software evaluation increases when different teams with different viewpoints define and support such evaluation. A software evaluation is more respected when it is supported not by a single team or organization (e.g., the software developers) but by multiple teams (e.g., software providers, users) or by the whole research field. Therefore, the following theme is important: *Representativeness of participants*.

V. Maturity Levels of Software Evaluation Technology

This section describes the five maturity levels of the Software Evaluation Technology Maturity Model. These levels and the goals to be achieved in each of them for a defined theme are presented in Table I.

What follows next is a general description of each level.

A. Level 1. Initial

At this level, a single team defines and carries out the evaluation workflow, which is specific to certain evaluation settings, is informally defined, and is manually performed with no software support. Evaluation is applied to a small number of software products of the same type, using test data not formally defined. The results obtained in the evaluation are also informally described, which makes them impossible to verify.

B. Level 2. Repeatable

At this level, the evaluation workflow is completely defined by one or a few teams and, although it is repeatable, it is still specific of certain evaluation settings. Evaluation software has been developed to partially support the evaluation of a small number of software products of the same type; these software products require to implement evaluation-specific mechanisms so they can be integrated with the evaluation software. The test data used in the evaluation are thoroughly described, and the evaluation results are defined in a machine-processable format, which allows combining the results of the evaluated software products.

C. Level 3. Reusable

At this level, several teams define an evaluation workflow that completely covers one type of software products and that can be reused to evaluate with different test data different

TABLE I
LEVELS AND THEMES OF SOFTWARE EVALUATION TECHNOLOGY MATURITY

Level	Formalization of the evaluation workflow	Software support to the evaluation	Applicability to multiple software types	Usability of test data	Exploitability of results	Representativeness of participants
Initial	Ad-hoc workflow informally defined.	Manual evaluation. No software support.	Small number of software products of the same type.	Informally defined.	Informally defined. Not verifiable.	One team.
Repeatable	Ad-hoc workflow defined.	Ad-hoc evaluation software.	Small number of software products of the same type. Ad-hoc access to software products.	Defined.	Machine-processable. Combined for some software products of the same type.	One or few teams.
Reusable	Technology-specific workflow defined.	Reusable evaluation software: - multiple software products. - multiple test data.	Multiple software products of the same type. Generic access to software products.	Machine-processable.	Machine-processable. Combined for many software products of the same type.	Several teams.
Integrated	Generic workflow defined. Machine-processable and built reusing common parts. Evaluation resources built upon shared principles.	Evaluation infrastructure: - multiple types of software products. - multiple test data.	Multiple software products of different types. Generic access to software products.	Machine-processable. Reused across evaluations.	Machine-processable. Combined for many software products of different types.	Several teams. Stakeholders.
Optimized	Generic workflow defined. Machine-processable and built reusing common parts. Evaluation resources built upon shared principles. Measured and optimized.	Federation of evaluation infrastructures: - autonomous infrastructures. - interchange of evaluation resources. - data access and use policies.	Multiple software products of different types. Generic access to software products. Support any software product requirement.	Machine-processable. Reused across evaluations. Customizable, optimized and curated.	Machine-processable. Combined for many software products of different types. High availability and quality.	Community.

characteristics of such software products. This workflow is supported by evaluation software that can be used to assess any software product of the type covered by the evaluation; the software product must have previously implemented the required mechanisms to be integrated with the evaluation software. Test data and evaluation results are machine-processable; therefore, they can be reused. Furthermore, the results can be combined for all the software products of the same type.

D. Level 4. Integrated

At this level, several teams in collaboration with relevant stakeholders (e.g., users or providers) define a generic evaluation framework that can be used with any type of software product. This generic framework for software evaluation allows building evaluation resources (i.e., evaluation workflow, tools, test data, and results) upon shared principles and reusing common parts. Here, evaluation workflows are defined in a machine-interpretable format so they can be automated. An evaluation infrastructure gives support both to the evaluation of multiple types of software products, taking into account their different characteristics, and to the management of the different evaluation resources. Test data can be reused across different evaluations, and the evaluation results can be combined for software products of different types.

E. Level 5. Optimized

At this level the whole community has adopted a generic framework for software evaluation in which evaluation workflows are measured and optimized. The centralized scenario of the previous levels has now evolved into a federation of autonomous evaluation infrastructures. These evaluation infrastructures must support not only the evaluation workflow but also new requirements, such as the interchange of evaluation resources or the implementation of policies for data access, interchange, and use. This federation of infrastructures permits satisfying any software or hardware requirements of the different software products; customizing, optimizing, and curating test data; and improving the availability and quality of the evaluation results.

One of the notions behind the maturity model, as Figure 2 shows, is that a higher maturity level implies higher integration of evaluation efforts in one field, ranging from isolated evaluations in the lower maturity level to fully-integrated evaluations in the higher level. In this scenario, maturity evolves from a starting point of decentralized efforts into centralized infrastructures and ends with networks of federated infrastructures.

Another notion to consider in this model is that of cost. While the cost of defining new evaluations decreases when the maturity level increases, mainly due to the reuse of existing resources, the cost associated to the evaluation infrastructure (hardware and infrastructure development and maintenance) significantly increases.

VI. ASSESSMENTS IN THE SEMANTIC RESEARCH FIELD

This section presents how we have used SET-MM to assess the maturity of software evaluation technologies in a specific research field.

Other maturity models provide appraisal methods for comparing with the maturity model. However, we do not propose any appraisal method because our scope is a whole research field and, therefore, it would be difficult to obtain objective metrics since any judgment would be subjective.

Therefore, our approach has been, first, to identify some evaluation efforts that stand out because of their impact in the field and, second, to try to assess the maturity of the software evaluation technologies used in them.

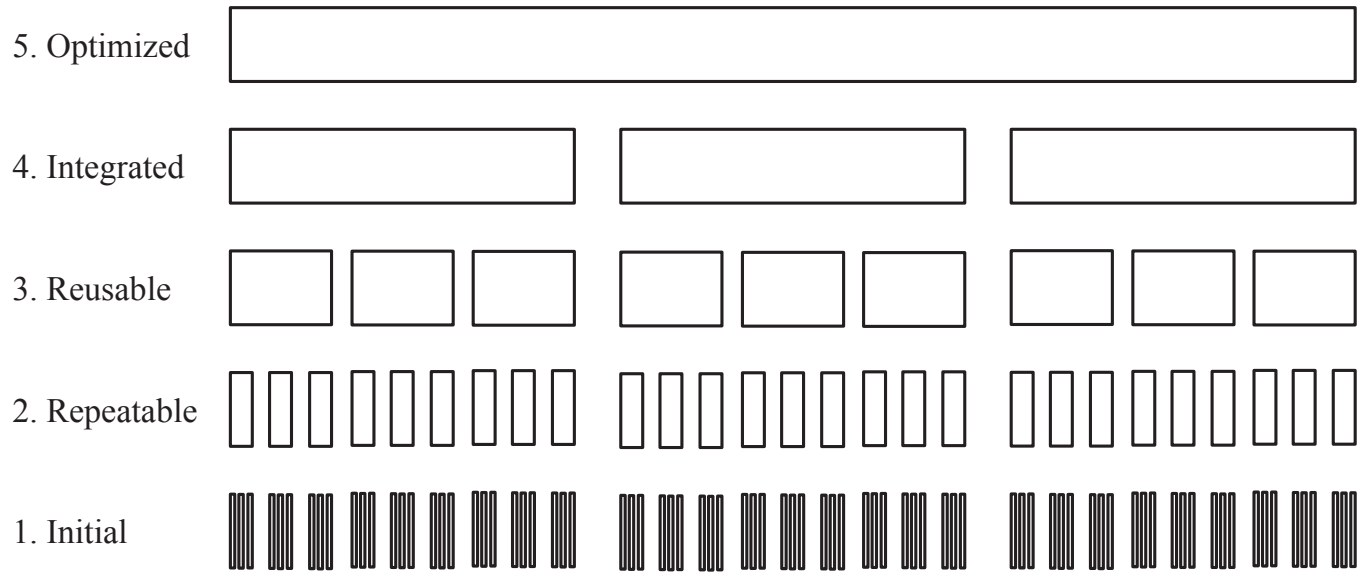

Fig. 2. The SET-MM maturity levels.

A. The Semantic Research Field

The notion of Semantic Web appeared at the beginning of the 21st century [17] and, since then, it has become a research field on its own.

The idea behind the Semantic Web is to have mechanisms to express knowledge and data in the Web so that it can be properly exploited by computers in an automated way.

The way of expressing such knowledge is through ontologies (explicit, structured models of the terminology and conceptual structures used in an application domain), which provide the basis for interpreting and relating data from different sources and that can be used to derive implicit knowledge about data.

One key requirement to make the Semantic Web real is the availability of technologies capable of managing and processing these data at web scale. Because of this, a huge number of research efforts have been devoted to the development and evaluation of semantic technologies.

B. Maturity of Evaluation Efforts

Evaluations in the semantic research field, as in any other field of research, are highly frequent and their main goal is to validate research.

However, if we analyse the technologies used to support those evaluations, we can see that in most of the cases the maturity of such evaluation technologies is at the *Initial* level, which makes almost impossible to reproduce any evaluation.

Nevertheless, there are still some efforts we should highlight because of their maturity in terms of software evaluation technologies.

1) The Lehigh University Benchmark: The Lehigh University Benchmark (LUBM) [18] is the benchmark most used in the semantic field. This benchmark can be used to evaluate the efficiency of ontology storage and reasoning systems and it is composed of a synthetic generator of test data, a set of test queries to be issued to the system, and a test module to automate execution.

LUBM's evaluation technology is at the *Repeatable* level in most of the themes, except in the next two aspects, in which it improves.

The usability of test data is between the *Reusable* and the *Integrated* levels, since the clear definition of test data and their automated generation largely facilitates their reuse across evaluations.

Additionally, the representativeness of participants is at the *Integrated* level because, even if the benchmark was defined by a research group, it is nowadays largely used by researchers and companies.

This high test data maturity can also be observed in the use of LUBM in the field: most of the people that reuse the benchmark only reuse the test data and define their own evaluation settings; furthermore, posterior benchmark improvements have mainly been made on test data [19], [20].

2) The Ontology Alignment Evaluation Initiative: The Ontology Alignment Evaluation Initiative[2] (OAEI) is an international initiative that, since 2004, has been organizing different ontology alignment contests with the goal of establishing a consensus for evaluating ontology alignment methods and their associated tools.

In these contests, ontology alignment systems are compared using a common set of synthetic and real-world tests using a common evaluation framework.

OAEI's evaluation technology is at the *Reusable* level in all themes except one, in which it improves. The representativeness of the participants is at the *Optimized* level; since the OAEI gathers the main stakeholders in the ontology alignment

[2]http://oaei.ontologymatching.org/

topic, its evaluations have become the de facto standard for ontology alignment evaluation.

3) The SEALS Platform: The SEALS Platform [21] is an infrastructure for the evaluation of semantic technologies that offers independent computational and data resources for the evaluation of these technologies.

The SEALS Platform is currently under development in a European project[3] and its goal is to provide the semantic field with an evaluation infrastructure at the *Integrated* level by the end of the project.

To this end, the SEALS Platform provides a common evaluation framework, based on the reusability of evaluation resources, in which different types of semantic technologies can be evaluated. Once the cumulative evaluation results reach a critical mass, the research community will be able to exploit them in novel ways.

VII. Conclusions and Future Work

This paper has presented the SET-MM maturity model that defines the maturity of software evaluation technologies in six different themes.

This maturity model can be used by anyone in a research field willing to assess the maturity of software evaluation technologies, either in the whole field or in specific evaluation initiatives.

SET-MM permits not only to make this assessment but also to guide improvement processes on software evaluation technologies by identifying the different goals to be achieved in each level and for each theme.

This way, the maturity model can be a useful mechanism to increase awareness on the role and on the benefits of software evaluation technologies in research fields.

To illustrate the use of the maturity model, we have assessed the maturity of the software evaluation technologies used in different initiatives within the semantic research field.

Clearly, this assessment is neither exhaustive nor representative of the whole research field. However, it is useful to analyse how software evaluation technologies have been used in different efforts in order to extract those lessons that are worth learning.

CMMI classifies maturity model components into three different categories, namely, required (specific and generic goals), expected (those practices relevant for achieving a goal) and informative (informative material that helps understanding the model). SET-MM currently covers the required components. Future work will deal with the definition of the expected and informative components in order to enrich the model.

Abstract

Role-Based Access Control (RBAC) has been increasingly popular due to its efficiency, flexibility, and scalability. Traditionally, RBAC is concerned with Separation of Duty (SoD) among roles and role hierarchies. However, there have been demands for extensions of RBAC as environments of RBAC systems have changed. As part of response to the demands, privacy RBAC and temporal RBAC have been proposed. While the two extensions address different aspects, they are often needed together in many systems such as hospital systems. In this paper, we present a feature-based approach that enables systematic enforcement of combined privacy and temporal RBAC in development. The approach models the two extensions as features based on partial inheritance which supports verifiable feature composition. We demonstrate the approach using a hospital example.

1 Introduction

Role-Based Access Control (RBAC) [5] is a popular access control model concerning Separation of Duty (SoD) and role hierarchies. As the environment of RBAC systems has changed dramatically, there is a strong demand for extending the traditional RBAC. For instance, in the environment where data objects contain private information, privacy should be protected. If the environment is time-sensitive, time-related policies should be supported. In response to the demands, privacy RBAC (PRBAC) [12] and temporal RBAC (TRBAC) [1] have been proposed. While each PRBAC and TRBAC addresses a well-defined aspect, there are domains where both PRBAC and TRBAC are desired. For instance, in the hospital domain, a doctor should not be granted access to the records of patients who are not assigned to him/her, and even if the patient is his patient, the doctor should not be able to access the patient's record other than his/her working hours. In the banking domain, access to customer accounts by a teller should be allowed only when there is a transaction request during his/her working hours.

In this paper, we present an approach that enables systematic enforcement of combined PRBAC and TRBAC during development. In our approach, PRBAC and TRBAC are modeled as features [8] based on partial inheritance [9], which enables verifiable feature composition. We use the UML and the Object Constraint Language (OCL) for defining the semantics of PRBAC and TRBAC. We demonstrate the approach using a hospital example and discuss tool support developed for the approach.

The rest of the paper is organized as follows. Section 2 gives an overview of related work. Section 3 presents the designs of privacy and temporal features based on partial inheritance. Section 5 describes how PRBAC and TRBAC can be used for the development of a hospital application through composition and instantiation. Section 5 concludes the paper.

2 Related Work

Several researchers describe access control models using the UML. The work can be categorized into two approaches. One is using the UML as is. Shin and Ahn use UML class diagrams to describe the structure of RBAC and the OCL to define RBAC constraints [15]. Our previous work uses object diagrams to visualize RBAC constraints [10]. Priebe *et al.* view an access control model as a design pattern and use the Gang-of-Four (GoF) pattern template to describe it [13]. The other approach uses UML profiles, an extension mechanism in the UML, for defining access control concepts. Jurjens proposed a UML profile called

UMLsec for modeling and evaluating security aspects for distributed systems based on the multi-level security model [7]. Similarly, Lodderstedt *et al.* proposed a UML profile called SecureUML for defining security concepts based on RBAC [11]. Doan *et al.* extend the UML, not by a profile, but by directly incorporating security aspects of RBAC and MAC into UML model elements [3].

Composition of RBAC features in this work is related to model composition in aspect-oriented modeling (AOD) (e.g., [2, 14, 17, 18]). In AOD, cross-cutting concerns are designed as design aspects that are defined separately from functional aspects (referred to as primary models). Clarke and Walker proposed composition patterns to compose design aspects described in UML templates with a primary model through parameter binding [2]. Straw *et al.* proposed a set of composition directives (e.g., creating, adding) for aspect composition [18]. Similar to Clarke and Walker's work, Reddy *et al.* use sequence diagram templates for specifying behaviors of design aspects and use tags for behavior composition [14]. An aspect may include position fragments (e.g., begin, end) which constrain the location of fragment interactions to be inserted in a sequence diagram. The composition method in their work, however, is not rigorous, and thus it is difficult to verify resulting models. Their position fragments influenced join points in our work. Song *et al.* proposed a composition method for composing a design aspect with an application design [17]. They verify composed behaviors described in OCL by discharging a set of proof obligations. However, their verification is limited to OCL expressions, and the entire composed model cannot be verified.

3 Modeling PRBAC and TRBAC as Features

In this section, we design PRBAC and TRBAC as feature based on partial inheritance [9]. Partial inheritance designs RBAC features in terms of a core feature and several component features. The *Core* feature [9] captures the essential functions of RBAC that every RBAC system must possess, while component features inherit from the *Core* feature and define additional functions. Unlike the traditional inheritance, component features inherit only those properties that are needed to carry out its functions, which establish partial inheritance. This simplifies feature design and composition.

Privacy feature. The *Privacy* feature provides support for privacy-related policies. Fig. 1 shows the feature where the symbol "|" denotes parameters.

In addition to the inherited classes (*User*, *Role*, *Session*, *Operation*, *Object*, *Permission*, and *Reference Monitor*) from the *Core* feature, the *Privacy* feature includes concepts of *Purpose*, *DataCondition*, and *Obligation*. *Purpose*

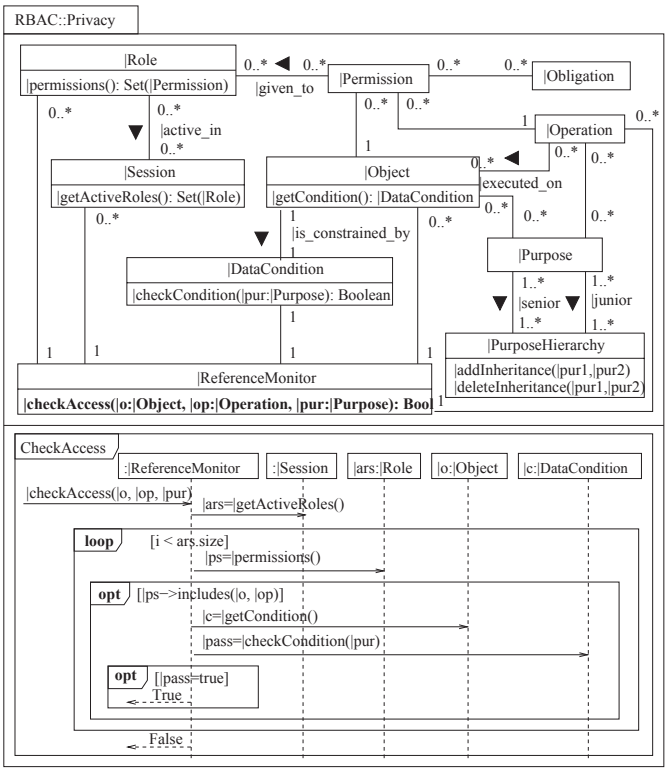

Figure 1. Privacy Feature

is the intention to perform a task that causes access to privacy information. The purpose can be organized according to the hierarchical relationships to simplify the management of purposes since purposes by nature have a hierarchical relationships among them in common business environments. *DataCondition* describes restrictions/qualifications for access to privacy information and the purpose of information use. *Obligation* specifies additional protection measures to personally identifiable information.

These privacy concepts enable privacy policies to be better supported at the modeling level. Suppose that an account receivable clerk requests for access to read customer contact information for sending a bill to customers. This policy can be specified using the template in [4] as follows:

"*Allow [Accounts Receivable Clerk] to perform [Read] on [Customer Contact Information] for [Billing] provided [Billing is the Data Purpose for Customer Contact Information]. Carry out [immediate logging of access and deleting of banking information from customer information for customers with no billing activity for the last 12 months].*" where *Accounts Receivable Clerk* represents role, *Read* represents operation, *Customer Contact Information* represents object, *Billing* represents purpose, *Billing . . . Information* describes data condition,

and *immediate . . . months* describes obligation.

The *checkAccess()* operation in the *ReferenceMonitor* class is redefined, which is denoted in bold, to check data purpose of the object being accessed. The new semantics is defined as follows:

```
1. context ReferenceMonitor::checkAccess (o:Object,
2.                                op:Operation,pur:Purpose):Boolean
3.    pre : true
4.    post: let act:OclMessage = Session^getActiveRoles()
5.    in Act: act.hasReturned() and act.result() = acrs and
6.      let pss:Sequence(OclMessage) =
7.          acrs → collect(r | r^^permission())
8.      in if ((pss → notEmpty()) and
9.          (pss → includes (ps|ps.result()→includes(o,op))))
10.          let cond:OclMessage = o:Object^getCondition()
11.          in Cond: cond.hasReturned() and
12.             cond.result() = c and
13.             result = c:DataCondition^checkCondition(pur)
14.     endif
```

In the semantics, privacy-specific constraints are specified in lines 12-14 checking access purpose against data condition. The sequence diagram *CheckAccess* in Fig. 1 describes checking accessibility based on privacy constraints. In addition to the traditional RBAC checking, the *Privacy* feature checks if the purpose of access matches the data condition. If it does not match, access is denied.

Temporal feature. The *Temporal* feature supports temporal constraints on user-role assignments, role-permission assignments, role hierarchies, and SoD. Fig. 2 shows the feature.

In the feature, the *TemporalConstraint* class is responsible for enforcing temporal constraints on enabling and disabling roles and activating and deactivating roles in session during a specified period or duration. Two types of time constraints are supported by the feature, namely periodicity and duration, which is captured by the hierarchy of temporal constraints in Fig. 2. A periodic constraint is a periodic time interval expressed in terms of (begin time, end time, periodic expression). For example, the policy that the working time of a day-duty doctor starts from 9 am to 5 pm everyday can be specified as *Enable [day-duty doctor] from [9 am] to [5 pm], [Everyday]*. A duration constraint specifies a specific time duration. For example, "*After [1 hours] of [day-duty nurse enabled], enable [nurse on training] for [4 hours]*" describes that a nurse on training is enabled to work 4 hours during day time after 1 hour working of a day-duty nurse. Both constraints can be used in role enabling/disabling, user-role assignments, or role-permission assignments. However, duration constraints can only be

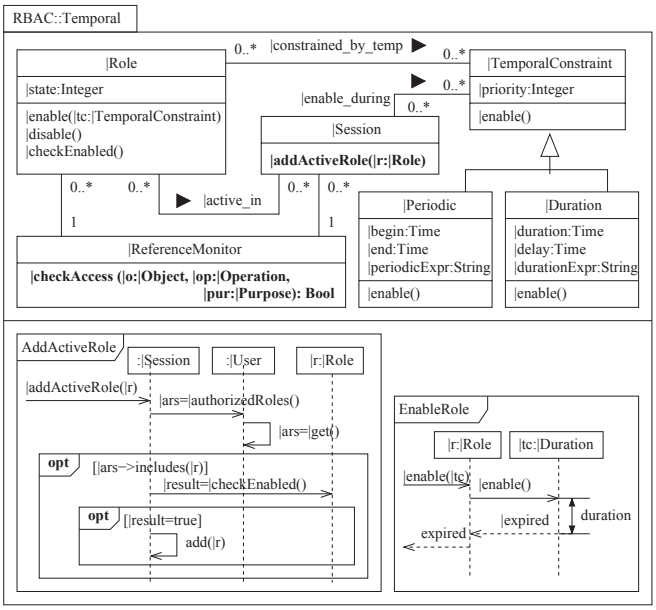

Figure 2. Temporal Feature

specified for role activation/deactivation as a user can activate or deactivate a role at any time [4].

Role hierarchies with temporal constraints can be categorized into *unrestricted* hierarchies, *enabling time restricted hierarchies*, and *activation time restricted hierarchies* based on the effect of temporal constraints. Unrestricted hierarchies are not affected by temporal constraints. In enabling time restricted hierarchies, when a senior role is enabled for a specific time, the permissions of its junior roles are also acquired. Enabling time restricted hierarchies can be either weak or strong. In weak hierarchies, a senior role can acquire permissions of its junior roles without the junior roles being enabled, while in strong hierarchies, the junior roles must be also enabled in order for the senior role to acquire junior roles' permissions. In activation time restricted hierarchies, a junior role can be activated only at the time when its senior roles are activated [6]. Both periodicity and duration place time contraint on SoD in the traditional RBAC.

The *Temporal* feature redefines the *CheckAccess()* operation inherited from the *Core* feature and requires that the requested role be enabled and activated before access is granted. The sequence diagram *AddActiveRole* in Fig. 2 describes role activation in a session. It redefines the *AddActiveRole* sequence diagram in the *Core* feature by adding checking the enable/disable status of the requested role before it can be activated in the session. Note that the *AddActiveRole* scenario does not take into account role hierarchies as role hierarchy is defined as a separate feature (see [9] for the *Hierarchy* feature). The role hierarchy version can be

built by configuring the *Temporal* feature with the *Hierarchy* feature. The *EnableRole* sequence diagram describes role enabling during a specific time.

4 Feature Composition

We use the composition method in our previous work [9] for composing the *Privacy* and *Temporal* features when they are configured together. Syntactically, the composition method combines the properties of configured features into the composed feature based on name matching. Semantically, the behavioral properties that have the same name are composed to be refinement of the behaviors that were composed. The formal definition of refinement for operations and interaction behaviors can be found in [9]. Using the definition, one can reason about the resulting feature for correctness.

Built upon partial inheritance, the composition method also enables step-wise feature composition, allowing immediate evaluation of the impact of composition. The *Core* feature, which is the base of any RBAC configuration, is selected by default forming the first configuration and the n^{th} configuration is built upon the $(n-1)^{th}$ configuration. We view this approach as a special kind of multiple inheritance where the elements having the same name get composed rather than renamed as in the traditional multiple inheritance.

5 Case Example: Hospital Application

In this section, we demonstrate how the resulting feature from composition can be used for designing a hospital application via instantiation. The application is used by day-duty doctors, night-duty doctors, day-duty nurses, night-duty nurses, nurses on training and medical students to perform read/write operations on privacy information such as patients' medical records. Fig. 3 shows the privacy and temporal policies of the hospital system.

Role	Read Access	Write Access	Purpose	Time
Day Resident Phys.	All documents	Surgical Report	Treatment	9 am − 5 pm
Night Resident Phys.	All documents	Surgical Report	Treatment	2 am − 9 pm
Non−resident Phys.	Patient Presc. Order, Progress Notes, Equipment Order	Surgical Report, Patient Presc. Order,	Treatment	9 am − 5 pm
Day Reg. Nurse	Progress Notes, Equipment Order	Surgical Report, Progress Notes, Patient Presc. Order,	Attendance	0 hour after Day Resident Phys.
Night Reg. Nurse	Progress Notes, Equipment Order	Surgical Report, Progress Notes, Patient Presc. Order,	Attendance	0 hour after Night Resident Phys.
Nurse in Training	Progress Notes, Equipment Order	Progress Notes, Patient Presc. Order,	Attendance	1 hour after Day Reg. Nurse
Medical Student	Surgical Report	None	Research	9 am − 5 pm

Figure 3. Permissions

Based on the privacy templates and the temporal templates in [4], we present templates for describing both privacy and temporality as follows:

- **Privacy-periodic events.** *Allow [Role] to perform [Operation] on [Object] for [Purpose] provided [DataCondition]. Carry out [Obligation] from [begin time] to [end time], [Periodic Expression]*
- **Privacy-duration events.** *Allow [Role] to perform [Operation] on [Object] for [Purpose] provided [DataCondition]. Carry out [Obligation] after [delay time] of [event].*

Using the templates, the privacy and temporal policies of the hospital system can be described as follows:

- Allow [Day Resident Physician] to perform [Read] on [All Documents] for [Treatment Purpose] provided [The doctor is the patient's on-duty doctor] carry out [Logging of access and closing the patient's case if the patient is transferred to other hospital] from [9:00 am] to [5:00 pm]
- Allow [Day Registered Nurse] to perform [Write] on [Surgical Report, Progress Notes and Patient Prescription Order] for [Attendance Purpose] provided [The nurse is the patient's on duty nurse] carry out [Logging of Access] after [0 hour] of [Enabling Day Resident Physician]

First Configuration. In order to support the above policies, the system is configured with the *Privacy* feature and the *Temporal* feature together on top of the *Core* feature, which is the first configuration. The configured features are composed using the RBAC composition method in Section 4 to produce configured RBAC. Enabled by partial inheritance, features can be composed in any order. In this demonstration, we compose features in the order of *Core*, *Privacy*, and *Temporal*.

Second Configuration. The *Core* and *Privacy* features are composed, which results in the second configuration, by (1) adding the *Purpose*, *Purpose Hierarchy*, *Obligation*, and *DataCondition* classes and their associated relationships to the core feature, (2) composing the *Role*, *Session*, *ReferenceMonitor*, *Permission*, *Object*, and *Operation* classes which appear in both features, and (3) composing the matching operations (e.g., *checkAccess()*) in both features. Based on the composition method, the semantics of composed operations must refine both core operations and privacy operations that were involved in composition, which can be formally verified using the refinement definition in [9].

For sequence diagrams, the *CheckAccess* sequence diagram in the *Core* feature is composed with the corresponding sequence diagram in the *Privacy* feature. This results in the *O:Object* and *c:DataCondition* lifelines in the *Privacy* feature being added to the *Core* feature. The *O:Object* lifeline is responsible for obtaining data purpose from the requested object and the *c:DataCondition* lifeline checks if

the data purpose matches the purpose of the operation request.

Third Configuration. The second configuration is composed with the *Temporal* feature, which results in the final configuration in this demonstration. They are composed by (1) adding the hierarchy of temporal constraints involving the *TemporalConstraint*, *Periodicity*, and *Duration* classes and their associated relationships to the second configuration, and (2) composing the *Role*, *Session*, and *ReferenceMonitor* classes which appear in both features, and (3) composing the matching operations (e.g., addActiveRole()) in both features. The resulting class diagram is shown in Fig. 4. Ensured by the composition method, the composed operations in the final configuration refines both privacy operations and temporal operations.

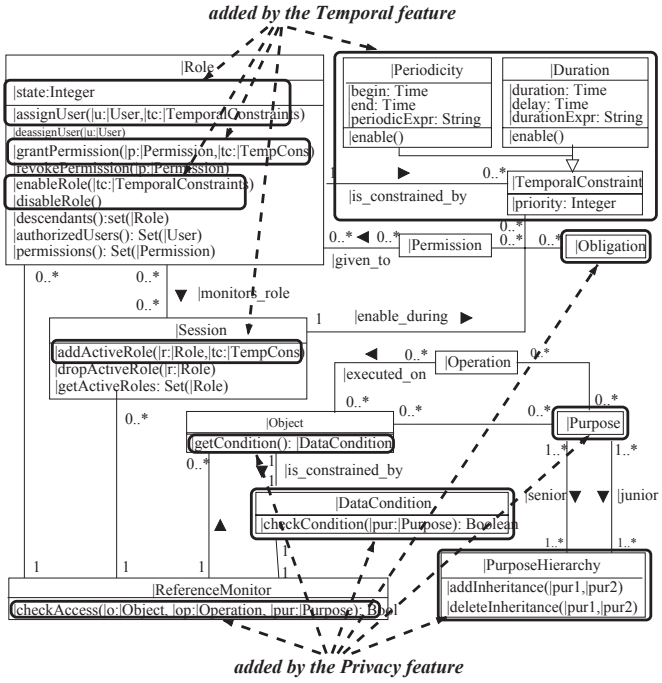

Figure 4. Partial Class Diagram after Third Configuration

For sequence diagrams, the *AddActiveRole* sequence diagram in the second configuration is composed with the corresponding sequence diagram in the *Temporal* feature. This results in adding the *tc:Duration* lifeline to the *AddActiveRole* sequence diagram in the second configuration. Fig. 5 shows the resulting diagram.

The *tc:Duration* lifeline is added to activate the requested role during a given duration. In addition, a role needs to be enabled before it is activated (checkEnabled()).

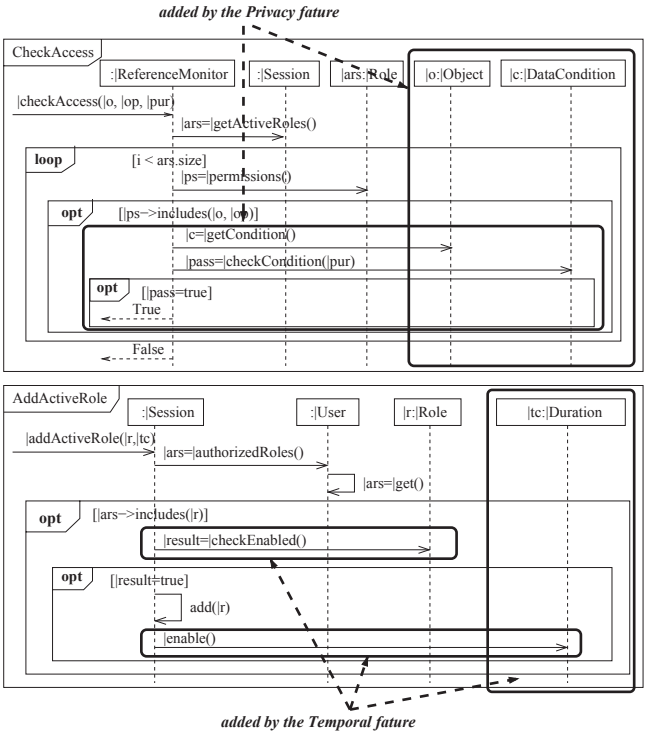

Figure 5. Partial Sequence Diagram after Third Configuration

Fig. 5 shows the composition of *CheckAccess* in *Core* and *Privacy* and *AddActiveRole* in the second configuration and *Temporal*. The composition of the second configuration and the *Temporal* feature results in the final configuration. Fig. 4 shows partial design of the final configuration.

The final configuration can be used for building a design of the hospital system via instantiation. Fig. 6 shows an instantiation of the final configuration in the context of the hospital application. The instantiation is carried out based on a mapping between RBAC elements and application concepts. For instance, the |*Object* and |*Operation* classes in RBAC are mapped, respectively, to the hospital objects such as the *Patient Prescription Order* and *Equipment Order* classes and transaction operations such as *Read* and *Write*. The instantiated model lends itself as an initial design model for the application addressing access control concerns.

6 Conclusion

We have described a feature-based modeling approach for designing PRBAC and TRBAC as features of RBAC to support systematic use of both PRBAC and TRBAC in the development of access control systems. The composition

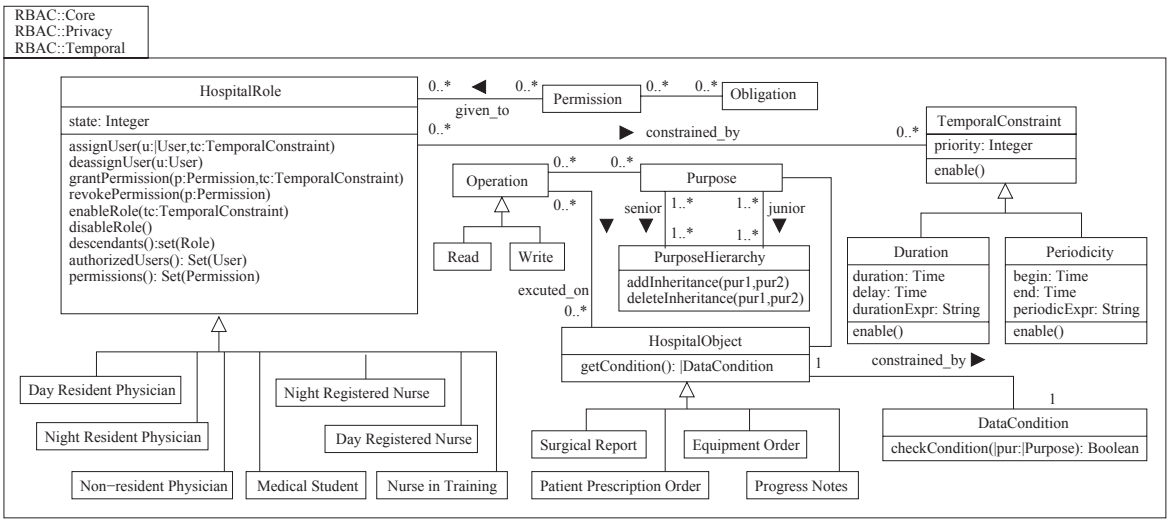

Figure 6. Partial Instantiation in Hospital Domain

in the paper involves only the *Core*, *Privacy*, and *Temporal* features for demonstration, but other traditional features such as the *Hierarchy* and *SoD* features may also be composed with the *Privacy* and *Temporal* features to account for the needs emerged from enivornment changes. Besides the hospital example presented in this paper, we have also carried out a case study using SmallSQL [16], a database management system. Other domains to which the presented approach can be applied include the banking domain and the academic domain where privacy and temporal issues are critical. We have developed a prototype that implements the composition method and feature instantiation based on Rational Software Architect and Eclipse.

Abstract — Secure software development processes can reduce the quantity of security errors and the vulnerabilities involved in software projects. A secure development process is composed by activities that propose the insertion of security requirements in all software development phases. These activities can be based on standards and/or security models such as SSE-CMM, ISO/IEC 27001, ISO/IEC 15408. The problem is that the standards and security models describe security requirements which can be followed but do not describe how these requirements must be implemented in software processes. Security patterns describe good security practices which can be incorporated to the software process and satisfy the requirements that are described by the standards and models. This work proposes a methodology for the tailoring of software processes based on security requirements that are defined by the security practices of the Systems Security Engineering Capability Maturity Model (SSE-CMM). The tailoring has as basis a process framework that is elaborated from the Rational Unified Process (RUP) and security patterns proposed on the literature.

Keywords - software processes, information security, processes tailoring, security patterns.

I. INTRODUCTION

The lack of security in software projects is one of the main concerns of the organizations. It is through the vulnerabilities that are present in software projects that the secrecy breaking and the information theft occur. Due to this factor, the organizations are seeking to adopt measurements that are more and more rigorous in terms of protection aligned with standards and security models [1].

The SSE-CMM model (System Security Engineering Capability Maturity Model) [2], currently known as the ISO/IEC 21827 standard, provides a set of good security practices which can be adopted by the organizations in order to increase the software security. The model is recommended for the development of secure software and the elaboration of security management processes.

The security patterns provide solutions that are already consolidated for recurrent problems and serve as reference for the organizations that seek to satisfy security requirements [3]. Thus, patterns can be associated to the SSE-CMM practices, identifying how they may be incorporated into a software process. The incorporation of the patterns into the software process happens at the moment of the process tailoring to answer to the specific needs of a project.

This article proposes an approach to processes tailoring that have as basis a process framework which is built from the Rational Unified Process and from security patterns association rules to the SSE-CMM process areas. The processes that are obtained from the framework aim at the development of secure software.

Tailoring processes consists in altering or adapting the descriptions of a process for a particular purpose. In this article, the tailoring is given by means of selecting and incorporating patterns into organization's software process, which is instantiated from the framework, originating the specific software process to use in a project. A methodology for processes tailoring that is based on the framework is proposed.

The contributions of this work include the methodology proposal for software processes tailoring based on security requirements, the framework for elaborating secure processes, which can be customized by the user, and a tailoring support tool.

II. SOFTWARE PROCESS SECURITY

Elaborating secure processes can be obtained by means of the security patterns incorporation, which describe consolidated solutions for recurrent security problems, that are associated to the practices of the SSE-CMM Model.

The System Security Engineering Capability Maturity Model (SSE-CMM) describes the essential characteristics that must exist in the processes of an organization in order to assure a good systems security by means of 22 process areas (PAs) that are organized in two groups: Security Base Practices and Organizational and Project Base Practices. In this work we considered the Security Base Practices because they are responsible for implementing security in software processes, which is the objective of this work.

Security patterns have been associated to security base practices because they provide solutions for recurrent security problems. The patterns capture the experience of security specialist individuals and provide solutions for security related problems which can be applied by non-specialist individuals. Associating security patterns to the base practices facilitate the processes tailoring, since once the association rules are defined it is not necessary that the process engineer is a security specialist.

The solution that is proposed by a pattern can be implemented with the help of other patterns, which solve parts of the whole problem [4]. The most known pattern catalogues are: Schumacher et al. [3], Rosado [5], Romanosky [7], Kienzle and Elder [8].

III. Elaborating the Security Methodology Tailoring (SMT) Framework

The processes tailoring that is proposed by this work is based on a process framework elaborated from Rational Unified Process. This framework is extended by adding a set of security related activities. The security related activities aims to satisfy the PAs of the SSE-CMM and have been defined from security patterns catalogues [3][5][7][8][9][10]. It is important to highlight that new activities can be added to the proposed framework according to the organization necessities.

The process for elaborating the SMT framework followed the undermentioned stages: elaborating rules to associate process areas to security patterns and incorporating these rules, security patterns and process areas to the framework.

A. Elaborating the Association Rules

Considering that the PAs have a list of objectives that indicate the expected results after its implementation and a list of BPs (Base Practices) that assist in the making of the objectives, the systematics followed to identify the patterns was the undermentioned: based on the objectives of the PA and its BPs, we have analyzed pattern catalogues to search for patterns, one or more, that addressed to these objectives. Examples provided in the PA description were also considered.

The association of each PA to the patterns that satisfy their objectives originates an association rule. As an example of an elaborate rule, we quote the usage of the AssetValuation [4]; ThreatAssessment [4]; VulnerabilityAssessment [4] and RiskDetermination [4] patterns for implementing PA03 – Assess Security Risk.

The purpose of Assess Security Risk is to identify the security risks involved with relying on a system in a defined environment. This process area focuses on ascertaining these risks based on an established understanding of how capabilities and assets are vulnerable to threats. Specifically, this activity involves identifying and the assessing the likelihood of the occurrence of risk exposures. The risk assessment is made in order to support the decisions related to the development, maintenance or system operation whose environment is known.

Table I shows the rules of association to the process areas that are elaborated in this work.

TABLE I – Associating Security Patterns to SSE-CMM Process Areas

Process Areas	*SuggestedPatterns*
PA01 – Administer Security Controls	*Security Provider [7];* *Controlled Process Creator [3];* *Access Control Requirements [3];* *Role Rights Definition [3];* *Role-Based Access Control [3];* *Authorization Pattern [5];* *Multilevel Security Pattern [5];*
PA02 – Assess Impact	*Risk Determination [3];*
PA03 – Assess Security Risks	*Asset Valuation [3];* *Threat Assessment [3* *Vulnerability Assessment [3];* *Risk Determination [3];*
PA04 – Assess Threats	*Threat Assessment [3];*
PA05 – Assess Vulnerabilities	*Vulnerability Assessment [3];*
PA06 – Build Assurance Argument	*Patch Proactively [8];* *Engage Customers [9];* *Check Point [10];* *Red Team the Design [8];*
PA07 – Coordinate Security	*Enterprise Partner Communication [3];* *Share Responsibility for Security [8];* *Gatekeeper [9];* *Buffalo Mountain (organizational) [9];*
PA08 – Monitor Security Posture	*Minefield [8];* *Security Accounting Requirements [3];* *Security Accounting Design [3];* *Audit Requirements [3];* *Audit Design [3];* *Audit Trails & Logging Requirements [3];* *Audit Trails & Logging Design [3];* *Non-Repudiation Requirements [3];* *Non- Repudiation Design [3];*
PA09 – Provide Security Input	*Document the Security Goals [8];* *Document the Server Configuration [8];* *Enterprise Security Approaches [3];* *Enterprise Security Services [3];*
PA10 – Specify Security Needs	*Security needs Identification for Enterprise Assets [3];*
PA11 – Verify and Validate Security	*Task Process Pattern – Technical Review [10];* *Check Point Pattern [5];* *Whitehat, Hack Thyself [7];* *Technical Guide to Information Security Testing and Assessment [11].*

The rules of association pattern to process areas are suggestions elaborated through the literature and may be improved by the organization by analyzing past projects, retrospective sessions, etc.

B. Incorporating the Association Rules to the Framework

After defining the association rules, it is necessary to incorporate them to the framework, as well as their constituent elements (security patterns and process areas).

So that security patterns may be incorporated into software processes, it is necessary that they are described by means of concepts that will be used in the processes modeling. Metamodels are used to describe elements that can be used for the process elaboration. In this work, we have decided to use the PRiMA-M (*Project Risk Management Approach – Metamodel*) metamodel (Fig. 1), which was elaborated in previous works by one of the authors [12]. PRiMA-M represents a set of concepts that are used to elaborate software processes. Process elements, instantiated from the PRiMA-M, can be used in the definition of planned, agile or hybrid processes.

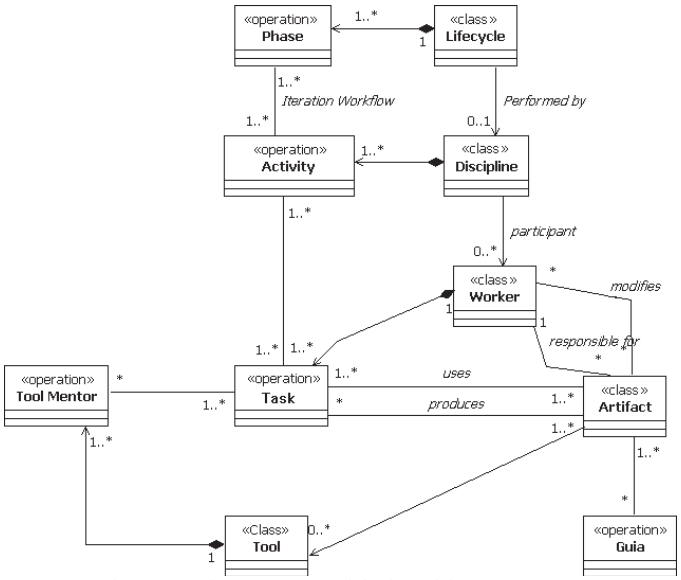

Figure 1. PRiMA – Metamodel adapted from [12][13]

This metamodel was elaborated from the concepts described in the Rational Unified Process. The following is an explanation about the classes of this metamodel. More information can be obtained in [12][13].

Lifecycle of a process is an aggregation of *Phases* which, in turn, are associated to *Activities*. A *Discipline* identifies a set of *Workers* which participate in the *Discipline* and define a set of *Activities* that compose the *Discipline*. An *Activity* specifies a particular collaboration within a *Discipline* and represents *Tasks* grouping, given that a *Worker* is responsible for each *Task*.

Artifacts are products generated during the execution of *Tasks* and may be models, plans, software versions, reports, etc. *Workers* represent the roles executed by individuals in a project. *Tools* are used to assist the making of tasks. *ToolsMentors* describe how to execute a *Task* by using a certain *Tool*.

In order to exemplify how security patterns can be described by means of process elements, instantiated from the PRiMA-M, the AssetValuation pattern, described by using the process elements proposed in the framework, can be visualized in the Fig. 2.

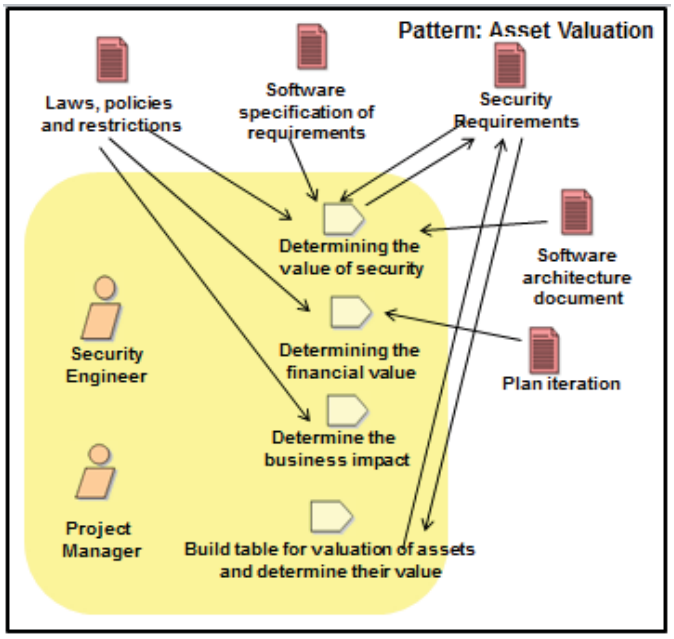

Figure 2. *AssetValuation* pattern represented by using process elements proposed in PRiMA-M

The security engineer executes the tasks with the assistance of the project manager. The main artifact elaborated during the execution of these tasks is the *Security Requirements* document which describes the assets along with the security value, financing value and the impact that the asset may have in the business, as well as the assessment tables that were elaborated for the asset assessment.

Each pattern that is described in an association rule has been defined by using the process elements proposed in the metamodel. The execution sequence of the activities has been defined by means of an activity diagram proposed by the UML. In the RUP, activity diagrams are proposed for each discipline in order to organize the activities that are possible to be executed in the software processes instantiated from it.

Considering that disciplines in the RUP seek to group activity collections related to a concentration area, we opted to group the proposed activities in order to add security to the RUP in one single discipline, named "Software Security".

Another alternative would be to set activities related to security in the existing disciplines in the Unified Process, for example, "Specify Security Needs" could be inserted to the Requirements discipline. Several disciplines would have their activity diagrams altered, which makes difficult for the understanding and implementation of the process. Another advantage of having a separate discipline for dealing with security issues is the facility that organizations will have if they wish to extend their process based on this work.

This discipline has been elaborated according to the orientations for tailoring of the RUP [5], and it must be executed in all phases but with more intensity in the inception and elaboration phase. Considering that, supporting disciplines are concerned with the overall management and structure of a RUP project, Software Security is this type because it concerns security management.

Each activity proposed for patterns implementation has been analyzed in order to define the activity execution sequence. This sequence has been defined from analyzing artifacts that are necessary to the activity execution and artifacts that were generated by activities. The sequenced activities have been organized in an activities diagram for the security discipline (Fig. 3).

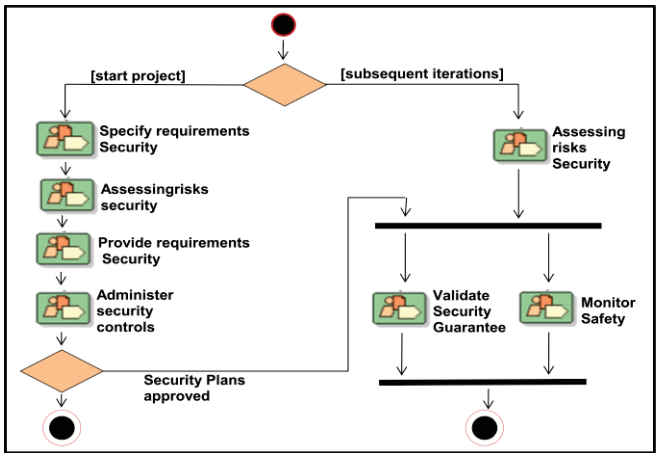

Figure 3. Activities Diagram for the Security Discipline

IV. METHODOLOGY PROPOSED FOR TAILORING

The methodology for software processes tailoring has the objective of allowing the elaboration of a software development process for a specific project, considering security practices that are described in the SSE-CMM and the SMT framework that is described in the section III.

In this work, the processes tailoring considers that there is an organization's standard software process (OSSP), which describes the process elements that must exist in all projects of the organization. The tailoring consists in altering OSSP in order to satisfy the project needs, especially in relation to security, and it results in the project-specific process (PSP). Fig. 4 shows the activities proposed methodology.

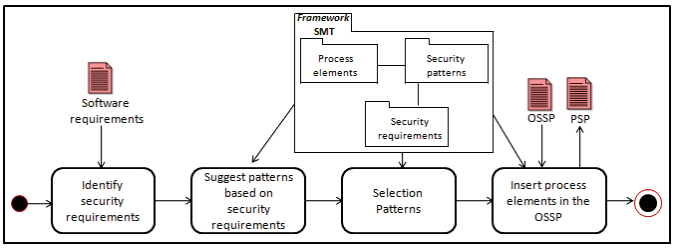

Figure 4. Security Methodology Tailoring (SMT)

Based on the security requirements identified for the project, the security engineer, who is assisted by the project manager, selects a set of process areas SSE-CMM that must be incorporated to the project (software requirements). In this selection, the opinion of specialists and stakeholders must be considered besides the security requirements that were defined for the project.

The patterns that seek to satisfy the PAs are selected based on the association rules defined in the SMT framework. The process engineer selects the patterns that they wish to incorporate to the OSSP from the suggested list. After selecting the security patterns, the process elements associated to their implementation are incorporated to the OSSP originating the PSP.

V. SMT – TOOL

An experimental environment to processes tailoring based on security requirements was developed and it is composed by the tools: *Security-Based Methodology Tailoring* (SMT-TOOL), *Project Risk Management Approach* (PRIMA-TOOL) [12] and *Pattern-Based Methodology Tailoring* (PMT-TOOL) [15].

PMT-Tool is responsible for cataloguing the security patterns. SMT-Tool is responsible for registering the processes areas and associates them to the security patterns. PRIMA-Tool module is responsible for the elaboration of the project software process, from organization's standard process tailoring, inserting in it the elements of the process associated to the selected patterns to the satisfaction of the processes areas proposed by SSE-CMM.

Having concluded the project process tailoring, PRIMA-Tool generates a website with the description of the project-specific software process to be consulted by developers, managers and process engineers. The website facilities easier the adoption of the software process by the developing team. These tools were used for the achievement of the case studies.

VI. CASE STUDIES

Two case studies were carried out to validate the proposed methodology. The first case study was made on XirooPACS system from Animati Computação Aplicada enterprise.

XirooPACS is a system about filing and communication of medical images. Examinations scheduling, patients' registers and the appraisal delivering of doctors and patients ordering by the internet are the main features of this system.

The system analysis was made considering mainly the matter of visualization of exams on web systems by patients and doctors, what makes this to need a highlevel of security.

The second case study was made on Plex system, from Elevata enterprise. PLEX is a credit card system which aims to enable the enterprises to have their own credit cards. This system joins services of cards administration including monitored selling services and evaluated risks.

The access to PLEX system is made on web. As the data bases of this system will involve data of many clients and several enterprises, and also flaws may cause a huge financial loss, this is a system which needs a high level of security involved in the process. The system analysis was made considering mainly the data bases and the integration on clients register and charge.

For the study case realization was used SMT framework proposed by this work. In the database of tools was inserted the elements of the process recommended by Rational Unified

Process, as well as the rules of association presented on Table I. Each pattern associated to a process area was described using the process elements proposed by the metamodel.

The first step in the realization of the case study was the filling of a questionnaire to the identification of the process area necessary for each project. The questionnaire was distributed to the project manager who with his team, answered the questionnaire for the prioritization of the security requirements (process areas) proposed by SSE-CMM model. The questionnaire contains the needs specifications to the understanding of the process areas. It was used a scale of relevance to the following levels: highest, high, medium, low or not relevant. The project manager attributed a level to each process area.

Based on the answers and on the framework configured on the tools the processes were adapted and are analyzed on next section.

A. *Case Studies Analysis*

The developed studies generated project-specific software process to each of the systems. These processes are used as a guide to the project development.

The case studies were made with projects which have very distinct features, although both of them need a high security level and therefore, generate specific-process similar. At the first case study, some process areas were not prioritized for the project security, yet on the second case study all the process areas were considered high or highest to the project, all of these prioritized (Table II).

The verification of whose activities are really high important to the project is not an easy task, once the consideration of adding requirements, which are not really necessary, it can be added extra and unnecessary costs to the project.

Through the two case studies was possible to verify the second project demands more security because the security engineer assigned to all process areas a high or highest importance. More preoccupation related to assess threads and vulnerabilities, build assurance argument, coordinate security and monitor security posture were presented; corresponding to process areas which were not implemented at the first study.

TABLE II. PRIORITIZATION OF THE PROCESS AREAS

PROCESS AREAS	XIROOPACS	PLEX
PA01 – Administer Security Controls	High	Highest
PA02 – Assess Impact	High	Highest
PA03 – Assess Security Risks	High	Highest
PA04 – Assess Threats	Medium	High
PA05 – Assess Vulnerabilities	Medium	Highest
PA06 – Build Assurance Argument	Low	Highest
PA07 – Coordinate Security	Medium	High
PA08 – Monitor Security Posture	Medium	Highest
PA09 – Provide Security Input	High	High
PA10 – Specify Security Needs	Highest	High
PA11 – Verify and Validate Security	High	Highest

The generated processes as the tailoring result were evaluated jointly to the project managers who on their analyses described that the process tailored to security presents clear activities to be implemented.

The rules of pattern association to the process areas are suggestions elaborated through the literature and may be improved by the organization by analyzing past projects, retrospective sessions, etc.

VII. RELATED WORKS

The development of reliable software has been discussed on many works which seek ways of enhancing the assurances of a project security or a software process. Some related works are presented next.

Mellado, Mediana and Piattini consider security requirements since the initial level of development of production lines, through an interactive and incremental process which where can be added additional tasks, according necessities. Through this tasks incorporation these authors search to make easier the conformity with the security requirements and manage the possible varieties which can happen on security requirements. The authors do not exemplify how the security requirements, out of security rules can be unfolded into task. In this sense, this article aims to define the tasks from the patterns association, which, usually, are widely explained or even suggest the tasks to be realized to fulfill the associated requirement.

Paes and Hirata (2007) propose an extension to the RUP with the inclusion of a discipline called "security". The discipline is based on good-practices and on experiences of the authors [5], but does not consider security standards or models. It is not described on this work how the defined process can be tailored to the projects needs.

Hafiz, Adamczyk and Johnson (2007) aim on using patterns to meet the criteria of security software. Although, the authors relate that there is a huge numbers of available security patterns and it is hard to choose which pattern is more recommended to each situation, as well as how to organize them to be used in a project.

This work is different from the others because it purposes a tailoring of software processes using security patterns and also because it elaborates a framework to make easier the elaboration of secures processes. The utilization of practices recommended by SSE-CMM model and of security patterns aim to use practices already consolidated for the development of reliable software.

VIII. CONCLUSIONS

This work proposes a methodology for processes tailoring that considers security requirements, which are proposed by a security model as criterion for tailoring, generating reliable software processes.

Information security has shown itself to be more and more important for the organizations, developers and users, and considering security from the beginning of the software development is desirable.

Elaborating a methodology for software processes tailoring is important to ease the tailoring task. The efficiency of the processes elaborated from the framework will depend of the rules of association pattern to process areas. An initial framework has been elaborated from the Rational Unified Process and activities proposed by the literature; from the security requirements proposed by the SSE-CMM e by the ISO/IEC 27001 Standard; and from security patterns described by Schumacher et al. [4], Rosado [5], Romanosky [7], Kienzle, among others.

The framework proposes a way to organize different elements used to elaborate new process. The organization can define patterns, processes elements and association rules that are adequate to their reality. The framework can be updated and must improve with time and as the team gets more experience. Results of post-mortem analysis of projects can help in this task.

Future work includes the definition of criterion associated to the security rules that seek to facilitate the prioritization of patterns to be applied in determined context and the experimentation of processes tailored by SMT in real projects.

ACKNOWLEDGMENT

We want to express our gratitude to CAPES (Coordenação de Aperfeiçoamento de Pessoal de Nível Superior) for the financial support and a special gratitude to the organizations Animati and Elevata and their projects managers Jean Carlo Albiero Berni and Marcio Puntel for all their feedback and the very useful scientific discussions.

***Abstract*— FTP is a widely used protocol for working with remote file systems. Various FTP implementations have had security problems reported as late as 2010. There lacks a systematic analysis of FTP security. In this paper, threat models are built to provide a systematic coverage of potential security attacks against an FTP server. Security tests are then generated from the threat models and applied to FileZilla Server, a popular FTP server implementation. When FileZilla Server is properly deployed, it holds fast against our security attacks. To further evaluate the effectiveness, the security tests are used to exercise a number of security mutants of FileZilla Server where various vulnerabilities are injected deliberately. The security tests have detected all but one of the injected vulnerabilities. This indicates that the threat model-based approach to security analysis of FileZilla Server is effective.**

Keywords- Security testing, FTP, threat modeling, threat tree, mutation testing

I. INTRODUCTION

FTP (File Transfer Protocol) is a widely used method for working with remote file systems. While FTP is an old protocol, various implementations show security problems that were reported as late as 2010 [1-3]. Using FTP across an untrustworthy network (e.g., Internet) can still expose an organization or business to security risks, yet there is no systematic analysis of FTP security to help understand the risks and mitigate them.

This paper presents an approach to FTP security analysis using threat models. We build threat models against most of the FTP services using the STRIDE threat classification system [4]. STRIDE stands for Spoofing, Tampering, Repudiation, Information disclosure, Denial of service, and Elevation of privileges [4]. It provides a systematic coverage of the potential security attacks against an FTP server. We generate security tests from STRIDE threat models and apply them to FileZilla Server, a popular open source FTP implementation. When FileZilla Server is properly deployed, all of the attacks against it fail. When the deployment uses the default settings, however, one of the security tests leads to a successful denial of service attack.

To further evaluate the effectiveness of our approach, we created a number of security mutants of the FileZilla server program by injecting various vulnerabilities into the code. Then we ran the security tests against each of the mutants. A mutant is said to be killed if one of the security tests is a successful attack. The security tests have killed all but two of the mutants. This demonstrates that the threat model-based approach to security analysis of FileZilla Server is effective.

II. THREAT MODELING OF FTP SERVER

Security threats are potential security attacks. Threat modeling usually consists of four steps: modeling system functions, specifying security threats, ranking threats for risk analysis, and mitigating threats [4]. Functional modeling helps identify the system assets (e.g., data) that need to be protected and the entry points that an attacker might exploit. As this paper focuses on the security analysis of an existing system, we are not concerned with threat ranking or mitigation.

Table 1. Partial list of FTP Services vs. STRIDE Threats

Service	S	T	R	I	D	E
Login	4			1	3	2
Change directory	1	3	1	2	1	1
Get current directory						
Change to passive mode		2	2			
Put file to server		4	1		3	1
Get file from server		3	2	1	1	
Create directory		1			1	
Delete a directory		2	1		1	
Delete a file		3	2		2	
Execute commands on server		1		1	1	1
Rename a file		2	1		2	1
Append to a file					1	1
Non-service specific	1		1	1		

The FTP standard has evolved over many years via RFCs (959, 1123, 3659, 4217) published by the Internet Engineering Task Force (IETF). FTP operations include login, change directory, list directory, get current directory, change to passive mode, put file to server, get file from server, create directory, delete directory, delete a file, execute commands on server, rename a file, append a file, etc. These operations are listed in the first column of Table 1. To provide a systematic coverage of the potential attacks against the FTP services, we identify the STRIDE threats with respect to each service. We have also considered the vulnerabilities reported by various

sources, including but not limited to SANS [1], US-CERT [3], Security Focus [2], Vulnerability Scanning [5], Offensive Security's exploit database [6], the now extinct website milw0rm.com (went down during our research) [7], and FileZilla's own bug report system [8].

Attack (threat) trees [9][10] are used to visualize the threat models, An attack tree shows the steps an attacker would go through to compromise a system. The root of an attack tree specifies the ultimate goal of an attack; child nodes represent the sub-goals of their parent node (or the steps to achieve the parent's goal); and leaf nodes describes the primitive attack conditions or actions. An "AND" relation between two or more nodes means that all of the sub-goals or conditions in these nodes must be satisfied in order to achieve the parent's goal. An "OR" relation means that the parent's goal is reached when one of the sub-goals or conditions is satisfied [10].

Figure 1 shows denial of service attacks that prevent a legitimate user from logging in. The first attack attempts to fill up the login table that keeps track of the user connections. The second attack fills up the receive buffer of the server to the point to of crashing. The protocol requires a carriage return to be sent at the end of the command. Otherwise, it just keeps buffering the data coming in until it overflows.

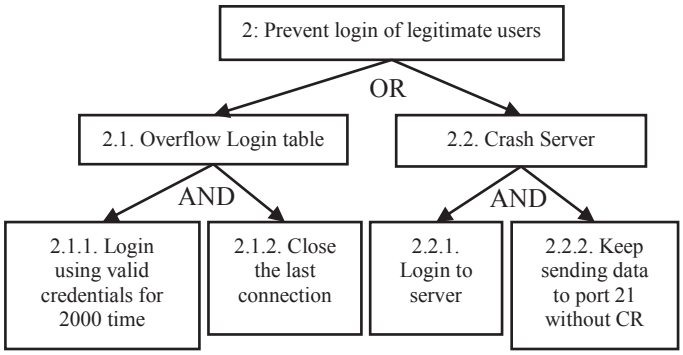

Figure 1. Prevent legitimate login

We have built 14 attack trees for the FTP services. They include 52 unique attack paths. An attack path is the minimalist set of leaf nodes taken to achieve some goal of the tree (root or sub-goal) [10]. Table 1 shows the number of threat trees that apply to each STRIDE category. Note that a threat tree can belong to multiple STRIDE categories. For example, an elevation of privilege attack often leads to information disclosure and tampering.

III. SECURITY TESTING OF FILEZILLA SERVER

After the attack trees have been constructed, we conduct security testing as follows. For each attack tree, we first generate all attack paths (also called test sequences). Then they are converted into security tests. Consider the attack tree in Figure 2. A is achieved if B or C are satisfied. B can be satisfied by 1 and 2 and node C by 3 and 4. Therefore, the attack paths are <1, 2> and <3, 4>. In our approach, we generate the test sequences from an attack tree automatically.

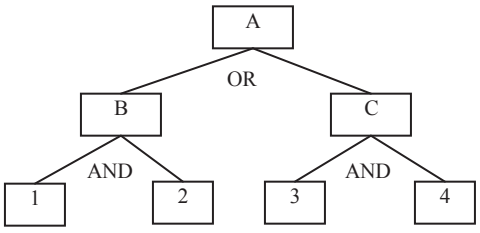

Figure 2. A sample attack tree

Definition 1. Suppose S[i] ($0 \le i \le n$) is a set of sequences. The combinational concatenation of all sequences in S[i], $S[0] \times S[1] \times \ldots \times S[n] = \{\langle s_0, s_1, \ldots, s_n\rangle$: for $\forall s_0 \in S[0], \forall s_1 \in S[1], \ldots \forall s_n \in S[n]\}$.

For example, let S[0] = {p1, p2, p3}, S[1] = {q1, q2}, S[2] = {r1, r2}, where $p_i (1 \le i \le 3)$, $q_j (1 \le j \le 2)$, r_k $(1 \le k \le 2)$ are sequences. Then S[0]×S[1]×S[2] yields the following 12 sequences:

{<p1, q1, r1>, <p1, q1, r2>, <p1, q2, r1>, <p1, q2, r2>
<p2, q1, r1>,<p2, q1, r2>,<p2, q2, r1>,<p2, q2, r2>
<p3, q1, r1>,<p3, q1, r2>,<p3, q2, r1>,<p3, q2, r2>}

Algorithm 1 below describes how to compute the combinational concatenation of sequences, where "∪" in line 7 refers to union of sets.

Algorithm 1: concatSequences
Function: combinational concatenation of sequences
Input: {S[0], S[1], …,S[n]}; Output: S[0] × S[1] × …× S[n]
Declare: S is a set of sequences
S[i][j] is the j-th sequence in *S[i]*

```
1.  begin
2.      if n=0
3.      then return S[0];
4.      S = ∅;
5.      for i=0 to S[0].size-1
6.        for j=0 to S[1].size-1
7.          S ← S ∪ {<S[0][i], S[1][j]>}
8.        endfor
9.      endfor
10.     if n=1
11.       return S;
12.     else //n>1
13.       return concatSequences(S, S[2],…, S[n]);
14. end
```

Algorithm 2 describes how to generate test sequences from (the root of) a threat tree, where "∪" in line 12 refers to union of sets and "×" refers to combinational concatenation of sequences in Definition 1 and Algorithm 1.

Algorithm2: genSequences
Function: Generate attack paths from a threat tree node.
Input: threat tree *node*; Output: attack paths
Declare: *childNodes* is the list of child nodes of a node;
childNodes[i] is the i-th node in *childNodes*
S[i] is a set of sequences

```
1.  begin
```

```
2.    if node is leaf
3.    then return {<node>};
4.    childNodes ← all child nodes of node
5.    if childNodes.size()=1
6.    then  return genSequences[childNodes[0];
7.    for i=0 to childNodes.size-1
8.      S[i]←genSequences(childNodes[i])
9.    endfor
10.   if the relationship between child nodes is "OR"
11.   then
12.     return S[0] ∪ S[1] ∪ …∪ S[childNodes.size-1]
13.   else  // the relationship is "AND"
14.     return S[0] × S[1] × …× S[childNodes.size-1]
15. end
```

Let us apply Algorithm 2 to the attack tree in Figure 2, genSequence(A) = genSequences(B) ∪ genSequences(C) because the relation between B and C is "OR". genSequences(B) = genSequences(1) × genSequences(2) = {<1>} ×{<2>} = {<1,2>} because the relation between 1 and 2 is "AND" , genSequences(1) = {<1>}, and genSequences(2) = {<2>}. Similarly, genSequences(C) = genSequences(3) × genSequences(4) = {<3>} ×{<4>} = {<3,4>}. Thus, genSequence(A) ={<1,2>}∪ {<3,4>} = {<1,2>, <3,4>}.

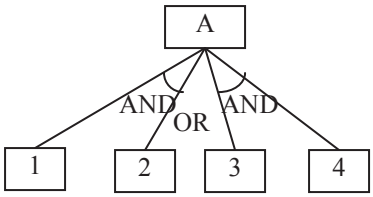

Figure 3. Informal attack tree with combined AND and OR

For simplicity, Algorithm 2 assumes that all the child nodes of a node, if any, have a single logical relation, i.e., either "AND" or "OR", but not a combination of them. This does not lose generality because a mixed relation of "AND" and "OR" can be easily converted into a tree without mixed relation. For example, the nodes in the attack tree in Figure 3 have a combination of "AND" and "OR". It can be converted to the attack tree in Figure 2. They have the same attack paths {<1,2>, <3,4>}.

Once the sequences were generated, they were converted into security tests by determining the system settings (i.e., user accounts and server setting), the actual parameters for the attack actions and conditions in the test sequence (e.g., user name and password for a login session), and oracle values (e.g., criteria about whether or not the attack is successful). If the primitive attack actions or conditions in the security test are programmable, we write code for the security test so that it can be executed automatically. It should be noted that security tests generated from the threat models are different from traditional functional tests in success and failure terminology. If a security test passes, the attack is successful (which would violate security requirements or policies). A failure can be due to a variety of issues, such as failure to connect to server, failure to get to a specific directory, unexpected response from the server, etc., or that the actual attack didn't work.

Table 2. Summary of security tests

Service	S	T	R	I	D	E
Number of threat trees	5	6	3	3	4	2
Number of test cases	8	33	7	24	10	15
Number of automated test cases	7	28	2	17	4	10

From the 14 threat trees we created, we generated 52 security tests. 39 of them can be executed automatically, another 8 can be executed automatically with some tester intervention and 5 are entirely manual tests. Table 2 shows how many tests are related to each classification of STRIDE. Again, one test can belong to multiple STRIDE categories.

IV. EXPERIMENTS

Our experiments consist of two phases. First, we run the security tests generated from the attack trees against FileZilla Server (version 0.9.34). Second, we create security mutants of FileZilla Server by vulnerability injection and run the same security tests against each of the mutants. FileZilla Server version 0.9.34 has 88,596 lines of code (71,940 actual C++ code lines), 107 classes, 1,716 methods, 193 functions, with an average method complexity of 4.74. Method complexity is defined as the number of unique execution paths that can be made through a function or method. In the following, we present the results of testing FileZilla Server and its mutants and discuss the lessons learned from this work.

A. Security Testing of FileZilla Server

When FileZilla Server is properly deployed (i.e., settings are configured properly), all generated security attacks failed to accomplish their goal. This indicates that FileZilla Server is secure against these attacks. When the security tests were first executed against FileZilla Server with the default settings, two of the attacks were successful. One achieved denial of service through creating thousands of login connections with the same id. The attack overflowed the login table of FileZilla Server, which keeps track of the active users and the current activity of that id. A proper setting should limit the number of concurrent connections any given id may have. The default is zero which means unlimited. This default setting doesn't give any hint to the administrator that there is an actual limit that might be exploited. The other successful test gained the version of the server that was running. While the version information is not always harmful, it can give the attacker clues as to what attacks might be possible by looking at the public bug tracker. In the attack trees, the disclosure of version information for production use (not development use) is considered as a security risk although the risk is not necessarily high.

B. Security Mutation Analysis of FileZilla Server

The fact that the properly deployed FileZilla Server has warded off our security tests indicates the good security profile of FileZilla Server. But it does not reflect how effective the

security tests can be. In this paper, we use security mutation testing to evaluate the vulnerability detection capability of the security tests and the thread modeling process.

Mutation testing has been used for evaluating software for the past several decades [11]. The fundamental idea of mutation testing is to run test cases against mutants which are obtained by injecting faults deliberately into the correct or baseline version of a program. These faults would represent the same programming errors a programmer might make. Usually, the percentage of mutants killed by the test cases is an indicator of how effective the tests are [12]. So far, creation of mutants in the existing mutation testing research has focused on syntactic changes, such as replacing && (and) with || (or). However, syntactic changes may not result in meaningful vulnerabilities in security-intensive software. In this paper, we create security mutants according to the causes and consequences of vulnerabilities. The causes of vulnerabilities include design-level defects (e.g., incorrect policy enforcement) and implementation-level programming errors (e.g., buffer overflow and unsafe function calls). Design-level vulnerabilities are a major source of security risks in software [13]. To create design-level mutants we took a high level look at the program by creating a software architecture document of the program. This document, along with a thorough code review gave us a broad view of how pieces fit together throughout the program and gave us the necessary insight to create some design level mutants. A mutant allowing a user to create directories without the necessary permissions would be classified as a design-level vulnerability in the FileZilla program. This is because no matter what the programmer does it is an unfixable problem using the current design. The consequences of vulnerabilities refer to various potential STRIDE attacks. We have created 30 mutants of FileZilla Server, 13 with design-level vulnerabilities and 17 with implementation vulnerabilities. The mutants have also included reported vulnerabilities of FileZilla Server.

Injection of security vulnerabilities into FileZilla Server is conducted independently of threat modeling and test generation. A different person from the team not involved with the threat modeling studied the FileZilla server and created the mutant injections. The security tests generated from our initial set of threat models killed 8 of the first 14 mutants (57.14%). The other mutants were not killed because the threat models did not cover these vulnerabilities. Then, we built more threat models and thus generated more tests to exercise the mutants. It is important to note that no implementation details were discussed between the person that implemented the mutations and the person that implemented the threat models. Only generic information such as "List command causes crash" is given. In the end, we were able to kill 28 of the 30 mutants for a 93.33% success rate. The two remaining mutants were a memory leak which is difficult to capture by threat models and an implementation dependent issue of an FTP command not covered by the threat model.

C. Discussion

Our experiments show that threat model-based testing is an effective approach to the security analysis of FileZilla Server. The security tests generated from the threat models have killed 93.33% of the deliberately-created mutants. One reason for this effectiveness is that the security tests generated from the threat models directly target the unintended behaviors or invalid inputs that are exploited by attacks. They meet the need of security testing to test the "presence of an intelligent adversary bent on breaking the system" [14].

From the experiments, we have learned several lessons. First, compared to traditional modeling that focuses on the intended behaviors of software, threat modeling requires a significantly different way of thinking. It would not be effective unless the threat models are built as if the builder were an intelligent adversary. Examining STRIDE threats against each system function can help build threat models in a systematic manner. This greatly reduces the chance of missing critical threats. Second, the vulnerability detection capability of the threat-based testing depends upon the threat models. A vulnerability may not be revealed if it is not captured by the threat models. Since threat models typically represent known or anticipated attacks, it can be hard to detect unknown vulnerabilities. Third, test automation can reduce the testing workload because the test execution can be easily repeated. For example, the security tests were executed against each of the 30 mutants. It would have been a daunting task if the security tests had not been automated. Although automation is desirable, not all tests can be automated. For example, user interactions may be needed to change server configuration (e.g., permissions), use administrative functions, and verify attack effects. Fourth, security mutation through injection of vulnerabilities is more difficult than traditional mutation. The former requires an in-depth understanding about the system functions and security requirements. The latter usually focuses on syntactic changes. Although the 30 distinct mutants have covered all FTP services and different vulnerabilities leading to various STRIDE attacks, they are far from complete.

V. Related Work

Threat modeling has been a viable practice for secure software development for some time [15]. Threat models can be used to generate security tests for exercising an implementation. In the past, we have proposed security testing approaches based on threat models represented by UML sequence diagrams [16] and threat trees [17]. Our previous work on testing with threat trees focused on web applications. This paper applies threat modeling and testing to FTP services, which has not been found in the literature. This paper has formally described the algorithms for generating test sequences from attack trees and used the security mutation to evaluate the vulnerability detection capability of the threat model-based testing approach.

Blackburn et al. [18] have developed an approach for generating test vectors (i.e., test cases with test input values, expected output values and traceability information) from security properties. Jürjens [19] has developed an approach for testing security-critical systems based on UMLsec models. Test sequences for security properties are generated from UMLsec models to test the implementation for vulnerabilities.

Julliand et al. proposed an approach to generating security tests in addition to functional tests [20]. The above work does not involve threat models in security testing.

Recently, testing of access control policies has gained increasing attention. Martin et al. [21] have been investigating techniques for test generation from access control policy specifications written in XACML (OASIS eXtensible Access Control Markup Language). Masood et al. [22] have investigated a state-based approach to test generation for role based access control (RBAC) policy. Their approach first constructs a finite state model of the RBAC policy and then drives tests from the state model. Le Traon et al. have investigated various issues of model-based testing of access control policies [23]. Mallouli [24] et al. have used formal access control models for generating tests. None of this work has used threat models for security testing.

VI. CONCLUSIONS

We have presented the modeling of various security threats against FTP services. These threat models can be used for security testing of different FTP server implementations. In this paper, the security tests generated from the threat models are executed against Filezilla Server, a popular FTP server implementation. Our experiments demonstrate that this is an effective approach to the security analysis of FileZilla Server. Although the security tests did not find risky vulnerabilities in the properly deployed FileZilla Server, they have detected the vast majority of the injected vulnerabilities in the security mutants. Our study indicates that modeling and testing with attack trees has some limitations. It is difficult to describe data flows among attack conditions and actions and represent repetitive actions. As a result, it requires some effort to transform the test sequences generated from attack trees to meaningful or executable security tests. This is a barrier to automated generation of executable code for those security tests where the attack actions are programmable. We are exploring how to generate executable security tests from formal threat models represented by Petri nets [13].

Currently, our study has created and used 30 security mutants of the FileZilla Server program. To better evaluate the vulnerability detection capability of the threat model-based testing approach, we plan to create mutants in a more systematic way. For example, we can try to inject vulnerabilities according to the various programming bugs that lead to security vulnerabilities.

***Abstract*—Cloud Computing is a new computing architecture that allows providers to deliver services on demand by means of virtualization. This work presents misuse patterns that describe how some typical attacks are performed and indicates appropriate countermeasures. These misuse patterns provide insight on how to build secure clouds and are also useful to evaluate the security of existing cloud systems. Specifically, we present a pattern for Malicious Virtual Machine Creation and describe two other patterns we have written.**

Keywords--; cloud computing, misuse patterns, security patterns, virtualization threats

I. INTRODUCTION

The Internet has been developing very rapidly during the last decade. The cost of storage is increasing as well as the cost of the power consumed by the hardware [9]. Thus, organizations need new solutions for these problems. Cloud computing is a new paradigm that improves the utilization of resources and decreases the power consumption of hardware. Cloud computing allows users to have access to resources, software, and information using any device that has access to the Internet.

Virtualization is a key feature for cloud computing [5], it allows many virtual machines to run on a single physical machine. Virtual machines are created and monitored by a Virtual Machine Monitor (Hypervisor), a software layer that mediates between the hardware and the operating systems running in each virtual machine. Virtualization allows users to create, copy, share, migrate, and roll back virtual machines, which provide significant benefits for the users [4]. However, it also brings new security problems.

To design a secure system, we first need to understand possible threats to the system. In [2], we proposed an approach to identify threats by considering the activities in each use case. That approach finds threats as goals of the attacker that must be realized by the lower levels of the system. We need to understand how the specific components of the architecture are compromised or used by an attacker in order to fulfill her objectives. To do this, we apply misuse patterns [3], to describe threats in cloud computing. A misuse pattern describes how a misuse is performed from the point of view of the attacker. It defines the environment where the attack is performed, countermeasures to stop it, and it provides forensic information in order to trace the attack once it happens. Misuse patterns are useful for developers because once they determine that a possible attack can happen in the environment, a corresponding misuse pattern will indicate what security mechanisms are needed as countermeasure. Also, misuse patterns can be very useful for forensic examiners to determine how a misuse is performed, and where they can find useful evidence information after the attack is done. Note that the misuse pattern describes a complete misuse, e.g. stealing information from a database, not just specific steps used to perform the misuse, such as SQL injection or buffer overflow. Misuses do not provide steps to be avoided when building the system, so they are not antipatterns, although they have common aspects.

We present here one example of a misuse pattern to illustrate our approach. While the specific attacks we describe are known, our contribution is describing the attacks in a systematic way, indicating how they can be neutralized. In particular, sharing virtual machine images brings new threats. Virtual machine images are prepackaged software templates that are used to instantiate virtual machines [8]. Cloud providers offer a repository service where providers and users can store their images. Users can either create their own image, or they can use any image stored in the repository. An attacker who creates a valid account can create an image containing malicious code such as a Trojan horse. If another customer uses this image, the virtual machine that he creates will be infected with the hidden malware. This malware can then perform a variety of misuses.

Section 2 presents a template used to describe misuse patterns. In Section 3, we present a misuse pattern for cloud computing, Malicious Virtual Machine Creation. In Section 4, we present some discussion on how misuse patterns can be used, and in Section 5 we offer some conclusions and possible future work.

II. TEMPLATE FOR MISUSE PATTERNS

A. *Name*

The name of the pattern should correspond to the generic name given to the specific type of misuse in standard attack repositories.

B. *Intent or thumbnail description*

A short description of the intended purpose of the pattern (what problem it solves for an attacker).

C. *Context*

It describes the generic environment including the conditions under which the attack may occur. This may include

minimal defenses present in the system as well as typical vulnerabilities of the system.

D. Problem

From an attacker's perspective, the problem is how to find a way to attack the system. The forces indicate what factors may be required in order to accomplish the attack and in what way; for example, which vulnerabilities can be exploited.

E. Solution

This section describes the solution of the attacker's problem, i.e., how the attack can reach its objectives and the expected results of the attack. UML class diagrams show the system under attack. Sequence or collaboration diagrams show the exchange of messages needed to accomplish the attack.

F. Affected system components (Where to look for evidence)

The pattern should represent all components that are important to prevent the attack and are essential to the forensic examination.

G. Known uses

Specific incidents where this attack occurred are preferred but for new vulnerabilities, where an attack has not yet occurred, specific contexts where the potential attack may occur are enough.

H. Consequences

Discusses the benefits and drawbacks of a misuse pattern from the attacker's viewpoint. The enumeration includes good and bad aspects and should match the forces.

I. Countermeasures and Forensics

It describes the security measures necessary in order to stop, mitigate, or trace this type of attack. This implies an enumeration of which security patterns are effective against this attack. From a forensic viewpoint, it describes what information can be obtained at each stage tracing back the attack and what can be deduced from this data in order to identify this specific attack.

J. Related Patterns

Discusses other misuse patterns with different objectives but performed in a similar way or with similar objectives but performed in a different way.

III. MISUSE PATTERNS FOR CLOUD COMPUTING.

We present one of our patterns, although not complete due to space restrictions.

Malicious Virtual Machine Creation

1) Intent

A Virtual Machine Image is a type of virtual appliance that is used to instantiate a Virtual Machine (VM). Virtual Machine Images contain initial file system state and software for the machine. An attacker may create a virtual machine image that contains malicious code so it can infect other users when they create their virtual machines. The attacker may read also confidential data from images that are publicly stored in the provider's repository.

2) Context

Some IaaS (Infrastructure as a Service) providers offer a VM image repository where users can retrieve images in order to initialize their VM. These VM Images can be created and published by the provider or by a client.

3) Problem

To perform some types of misuse it is necessary to be able to create and publish VM images.

The attack can be performed by taking advantage of the following vulnerabilities:

- Any person who has a valid account can create and register a VM image.
- There should be a common place where the users can share VM images.
- VM images contain prepackaged software components for an application. Thus, an attacker can create a VM image with malicious code.
- VM images contain installed and fully configured applications. The configuration may require sensitive operations such as creating username and password [8].

4) Solution

When a user publishes a VM image as public, any other user of the cloud is able to use it to instantiate his VM. This VM image can contain malicious code. The Virtual Machine Monitor (VMM) will run this image in order to instantiate the user's VM. Now, the attacker can have control of the virtual machine and perform malicious activities such as infect other computers. Infected virtual machines may appear briefly, infect other virtual machines, and disappear before they can be detected [4].

Structure

Figure 1 shows a class diagram for the repository for VM images in cloud computing. A Virtual Machine (VM) is an isolated software container that has a CPU, RAM, hard disk, and network controllers. It requires the installation of operating system and applications. A Virtual Machine Image (VMImage) is a pre-installed operating system and application stack. A User retrieves a VMImage from the Provider's Repository. These images can be created and published by other users or by the provider. The Provider is composed of a Hypervisor and Hardware (server, storage and network). The Virtual Machine Monitor (VMM) creates VMs by instantiating a VMImage, and it assigns their instances to the users who requested them. When the instance is launched, it is assigned to a physical server and given other hardware resources. The VM passes system calls to the VMM which executes those calls in the Hardware.

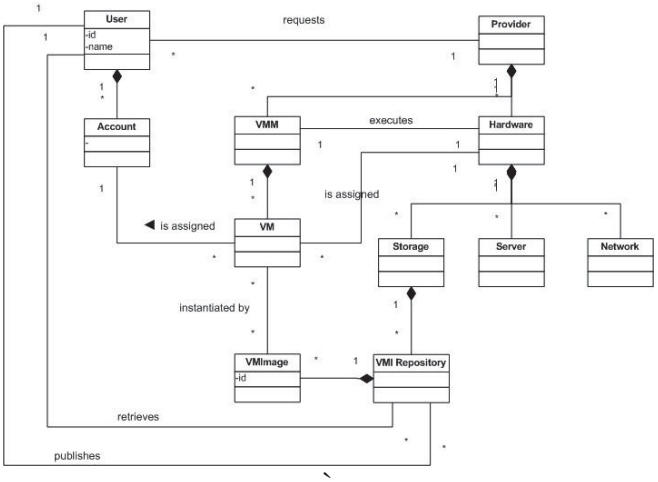

Figure 1. Class diagram for VM Image Misuse Pattern

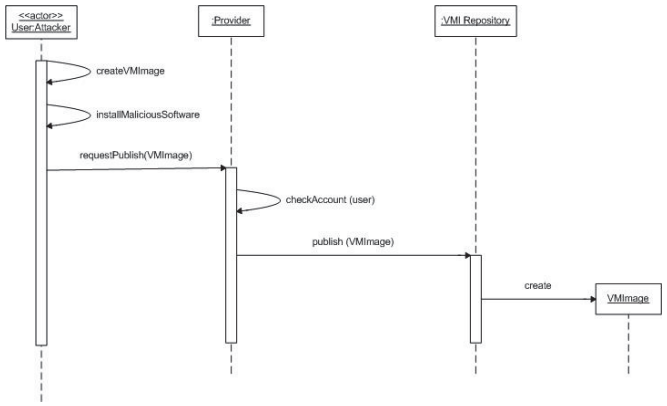

Figure 2. Sequence Diagram for the use case Publish a Malicious VM Image

Dynamics

UC1: Publish a Malicious Virtual Machine Image (Fig. 2)

Summary: The Attacker publishes a Virtual Machine Image that contains malicious code.

Actor: Attacker

Precondition: The Attacker must have an account with the Provider

Description:

a) The Attacker creates a VM Image.

b) The Attacker installs malicious software within the VM image

c) The Attacker requests to the Provider to upload the VM Image.

d) The Provider checks if the attacker (legal user) has an account.

e) The Provider uploads the VM Image into the repository.

f) The Provider sends an acknowledgement to the attacker.

Postcondition: A VM Image is created and placed into the Provider's repository, so any other user can use it and get infected.

UC2: Launch a VM using an infected VM Image (Figure 3)

Summary: A user launches a VM using an infected VM Image.

Actor: User

Precondition: The user must have an account, and the attacker has published her VM Image into the Provider's repository. Also, the user should choose the VM Image created by the attacker.

Description:

a) The User request to the Provider to retrieve a VM Image.

b) The Provider checks if the user has a valid account.

c) If the user is valid, the Provider sends the list of VM Images.

d) The User chooses the VM Image, and he requests to launch a VM to the Provider.

e) The Provider forwards the request to the VMM that will create the VM.

f) Once the VM is launched, it executes the malicious code.

Postcondition: The user's VM is infected and it may infect other VMs.

5) Consequences

Some of the benefits of the misuse pattern are the following:

- An attacker can open an account using a valid credit card and register malicious VM images into the provider's repository.
- VM Images contain all the software dependencies needed to run the Trojan horse, so the attacker does not need to worry whether the victims' software stacks satisfies the Trojan horse's dependencies [8].
- An attacker can get control of the infected virtual machines and obtain some confidential information.
- Repositories that contain malicious VM images can be a way to distribute malware.
- Infected virtual machines may infect other virtual machines. For example, an attacker may create a malicious VM image in order to infect other machines creating a collection of infected machines, Botnet [6].

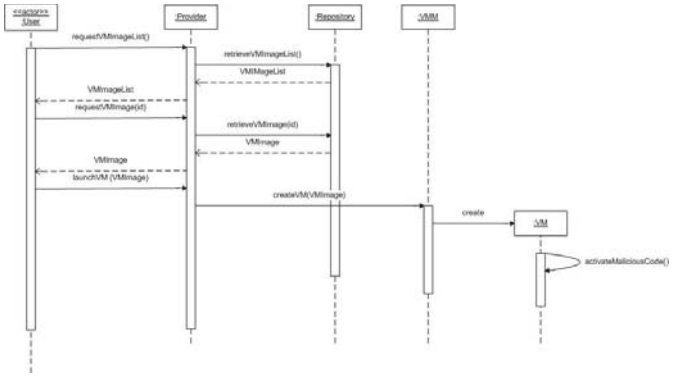

Figure 3. Sequence Diagram for the use case Launch a VM using a malicious VM Image

Possible sources of failure include:

- There is a possibility that the users choose to create their own VM images instead of using a public VM Image.
- Since VM images are dormant artifacts that reside in the repository, they are not harmful if they are not executed.
- Users can only retrieve images that are from certified owners.

6) Countermeasures

Malicious VM Images can be stopped by the following countermeasures:

- [8] proposed an image management system that control access to images, tracks the origin of images, and provides image filters and scanners that detect and repair security violations.
- Verify the background of the user when opening an account; however, this is very hard to do.
- Users can only retrieve images from certified owners.
- Use an Intrusion Detection System (IDS) to identify malicious activities such as in [7].

7) Forensics

Where can we find evidence of this attack?

- Providers can keep logs of the users that publish/retrieve VM Images.
- We can audit a suspicious VM Image.

IV. DISCUSSION

Designers need to understand first possible threats before designing secure systems. However, identifying threats is not enough; we need to understand how a whole misuse is performed. Misuse patterns appear to be a good tool to understand how misuses are performed. It is possible to build a relatively complete catalog of misuse patterns for cloud computing. Having such a catalog we can analyze a specific cloud architecture and evaluate its degree of resistance to these misuses. The architecture (existing or under construction) must have a way to prevent or at least mitigate all the misuses that apply to it. When potential cloud customers buy cloud services they negotiate a Service Level Agreement (SLA) with the provider. This SLA could indicate what misuses the provider is explicitly able to control. Many providers do not want to show their security architectures; showing their list of misuse patterns would give them a way to prove a degree of resistance to misuses without having to show their security details.

V. CONCLUSIONS AND FUTURE WORK

We can describe cloud computing threats as misuse patterns, which describe in a systematic way how cloud misuses are performed. We illustrated our ideas with a specific pattern. We are continuing developing misuse patterns for cloud environments in order to create a relatively complete catalog for it that can be used by designers of secure cloud environments. Finally, we intend to incorporate these patterns into a secure systems design methodology.

***Abstract*—The software product line approach has been applied as a successful software reuse technique for specific domains. Such an approach takes advantage of domain and application engineering concepts. One of its most important artifacts is the product line architecture because it explicitly represents similarities and variabilities of a product line, as well as the products that can be generated. Product line architecture evaluation can serve as a basis for analyzing the managerial and economical values of a product line for software managers and architects. Such an evaluation might be carried out in terms of a trade-off analysis of the architecture quality attributes. Thus, this paper presents a Trade-off Analysis Meta-Process for Product Line Architecture, the TAMPro-PLA. TAMPro-PLA must be instantiated to define the essential artifacts for product line architecture trade-off analysis, such as business drivers, quality attributes, and respective scenarios. Therefore, TAMPro-PLA can be used to carry out product line architecture evaluations. It differs from current literature as it allows the definition and application of prodcut line architecture quality attribute metrics to provide support for performing quantitative and qualitative analysis. A proof of concept example based on the SEI's Arcade Game Maker (AGM) product line is presented.**

***Keywords*-meta-process, metrics, product line architecture, quality attributes, software product line, trade-off analysis.**

I. Introduction

A Software Product Line (PL) represents a set of systems sharing common features that satisfy the needs of a particular market or mission segment [8], [14]. This set of systems is also called a product family. The family's members are specific products developed in a systematic way from the PL core assets. The core asset has a set of common features as well as a set of variable parts, which represent later design decisions [14]. The composition and the configuration of such assets yield specific products.

The PL Architecture (PLA) is one of the most important asset of a PL because it abstractly represents the architecture of all potential PL products from a specific domain. The PLA addresses common design decisions, called similarities, as well as its postponed design decisions, called variabilities [16].

The results obtained from a trade-off analysis of PLA quality attributes are important from both academic and industrial view-points due to their potential to increase the productivity and the quality of products, decrease the time to market, improve the PL production capability [8], and to be used as a parameter for evaluating the PL in general [6]. PLA quality attributes take into account variabilities, which increase the effort to evaluate the quality of the overall PL [6]. Thus, we proposed a **T**rade-off **A**nalysis **M**eta-**Pro**cess for Software **P**roduct **L**ine **A**rchitectures, the TAMPro-PLA.

TAMPro-PLA aimed at analyzing PLA quality attributes in order to prioritize them based on quantitative and qualitative analyzes. Such analyzes are carried out by instantiating TAMPro-PLA, performing its activities and defining its elements for a given PLA, such as business drivers, scenarios, and metrics. The instantiation of TAMPro-PLA is illustrated, as a proof of concept, by performing its activities. Such activities generate the artifacts that allow PLA trade-off analysis taking into account the Arcade Game Maker (AGM) [15] PLA complexity and extensibility quality attributes.

This paper is organized as follows: Section II presents important concepts of quality attribute trade-off analysis for single product architectures as well as PLA principles; Section III describes the TAMPro-PLA meta-process, its activities, and essential artifacts for a PLA trade-off analysis; Section IV illustrates the application of TAMPro-PLA to the AGM PL; Section V discusses related work; and Section VI provides final remarks and directions for future work.

II. Quality Attribute Trade-Off Analysis and Product Line Architecture

Trade-off is the term used when one wishes to balance one situation or quality against another, in order to produce an acceptable result. With regard to software quality attributes, trade-off analysis means analyzing between multiple conflicting quality attributes to satisfy user requirements and come up with a better overall system [2].

One of the most consolidated method applied in industry to perform software architecture evaluation by means of trade-off analysis is ATAM (Architecture Tradeoff Analysis Method) [4]. ATAM's trade-off analysis allows discovering architectural problems during early software development phases. The cost to fix such problems in early stages is way less than in later stages.

Trade-off analysis usually takes into consideration the following artifacts of a software architecture [4]: (i) business drivers, which are statements about the architecture's overall goals; (ii) quality attributes defined for an architecture; and (iii) scenarios specified to exercise such quality attributes by taking into account the business drivers.

As the number of scenarios tends to be large in an architecture evaluation [4], stakeholders usually rank and select the most important scenarios. Thus, a widely known technique, applied in ATAM for instance, is the stakeholders voting. Each stakeholder involved in the evaluation process must assign a priority for each scenario based on predefined factors, such as the importance of a scenario. Then, scenarios are ranked and the most important are taken into consideration for performing quality attributes trade-off analysis.

Trade-off analysis can be performed to a PLA [7], [13] to prioritize its quality attributes for PLA evolution and deriving PL products. PLA differs from a single product architecture as it must represent the single architecture of all products that can be generated from a PL for a specific domain. The PLA gives stakeholders a means to develop multi-product architectures, while keeping their explicit models and visualizations in single product architectures. It results in product reduced cost and high quality. In addition, the PLA encompasses similarities, as well as postponed design decisions, the variabilities [16].

III. The TAMPro-PLA Meta-Process

TAMPro-PLA aims at defining artifacts for PLA quality attribute trade-off analysis. This involves the definition of business drivers and scenarios, selection of the PLA quality attributes to be analyzed; definition of managerial and technical questions to be answered with respect to the selected quality attributes; and application of quality attribute metrics to support data collection and analysis.

TAMPro-PLA takes as input the PL quality attributes, PL models, including the feature model. TAMPro-PLA does not depend on specific model notations or approaches. It can take into consideration, for instance, UML models. Regardless their granulatiry, PL models represent the main source of information to support the definition of the TAMPro-PLA's artifacts.

The artifacts that can be defined throughout TAMPro-PLA instantiation activities are:

- **Business Drivers (BD):** represent the main goals of PLA, based on the PLA quality attributes;
- **Defined Scenarios (DS):** a set of scenarios is defined for each PLA quality attribute;
- **Ranked Scenarios (RS):** scenarios are ranked based on PLA factors such as cost/risk of a scenario;
- **Managerial and Technical Questions (MTQ):** they should be answered in order to analyze a PLA and support the quality attribute metrics definition;
- **Quality Attribute Metrics (QAM):** they are defined to support the prioritization of PLA quality attributes in a trade-off analysis.

Figure 1 presents a UML activity diagram, which represents the TAMPro-PLA's activities (rounded rectangles) and their inputs and outputs (squared rectangles).

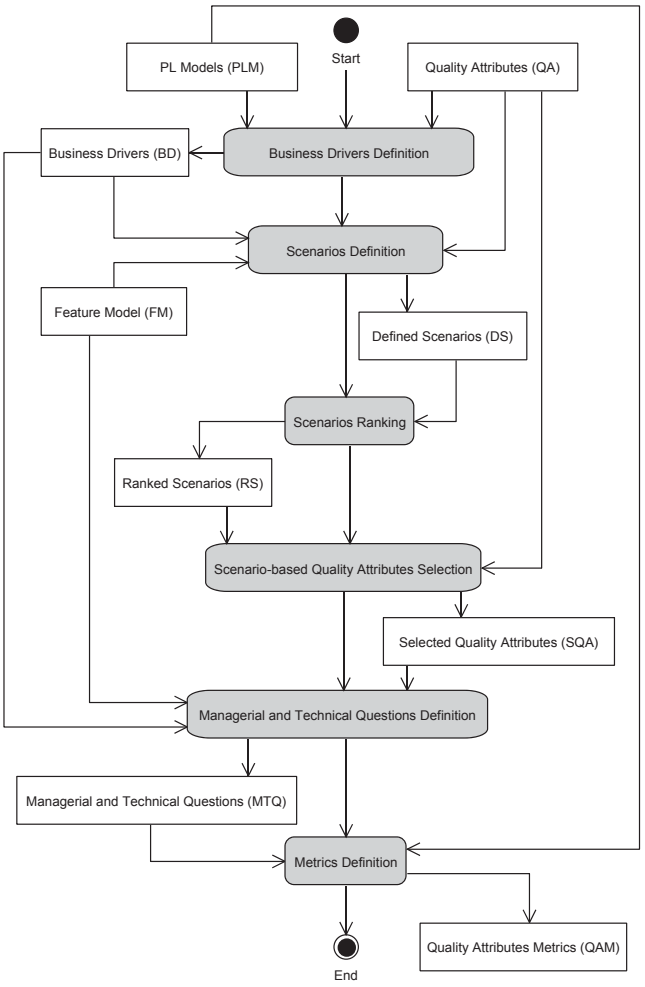

Figure 1. The TAMPro-PLA Meta-Process Activities and Artifacts.

The following items present a brief description of each TAMPro-PLA's activity:

The **Business Drivers Definition** takes as input the PL Models (PLM) and the PLA Quality Attributes (QA), and defines the Business Drivers (BD) that a PLA should reach to develop products. The defined business drivers support the definition of scenarios and managerial and technical questions, as well as they comprise the modeled PL variabilities.

The **Scenarios Definition** takes as input the Business Drivers, Feature Model (FM), and PLA Quality Attributes. It generates the Defined Scenarios (DS) for each PLA quality attribute to support its selection activity.

The **Scenarios Ranking** takes as input the Defined Sce-

narios (DS) in order to rank them based on the following PLA factors: (i) the overall importance of a scenario for the PLA, (ii) scenario generality (mandatory, alternative or optional), (iii) scenario cost/risk associated, and (iv) amount of variability associated to a scenario. It generates as output Ranked Scenarios (RS).

The **Scenario-based Quality Attributes Selection** takes as input the Ranked Scenarios (RS) and selects which quality attributes will be evaluated for a certain PLA as they tend to be in a large number. Its output is a set of Selected Quality Attributes (SQA), which is a subset of the Quality Attributes (QA) set.

The **Managerial and Technical Questions Definition** takes as input the Business Drivers (BD), Feature Model (FM), and Selected Quality Attributes (SQA). It defines the Managerial and Technical Questions (MTQ) that might be answered by defining metrics to support trade-off analysis. Such questions are defined with regard to the PLA business drivers, and they take into account the roles involved in the PL process as in [3].

The following items show some examples of roles and questions. More examples can be found in [16]:

– **PL Manager:** carries out activities such as planning, monitoring, and controlling the PL. Example of PL manager questions are: (i) `what is the effective investment for adopting the PL approach for a company?` and (ii) `which PL configuration is most feasible for a certain domain?`.

– **PL Architect:** in charge of the management of the PLA evolution, as well as for providing quantitative and qualitative design decision support. Examples of PL architect questions are: (i) `what is the required amount of effort to develop a product from a PL, based on the PL artifacts and their variabilities?` and (ii) `what is the impact of adding/modifying/removing the features of/from a PL on its PLA quality attributes?`.

The **Metrics Definition:** takes as input the PL Models (PLM), Selected Quality Attributes (SQA) and the Managerial and Technical Questions (MTQ). It defines Quality Attributes Metrics (QAM) to answer such questions and support data collection and quantitative analysis in PLA evaluations.

Although TAMPro-PLA contains the cited activities, performing of all of them are not mandatory. Stakeholders might already have defined, for instance, quality attribute scenarios and/or metrics. Therefore, TAMPro-PLA might be partially instantiated, as predefined artifacts might be incorporated.

IV. TAMPro-PLA Instantiation Example

As a proof of concept, this section illustrates the instantiation of TAMPro-PLA to perform a trade-off analysis to the Arcade Game Maker (AGM) [15] PLA quality attributes.

AGM is a pedagogical PL created by the Software Engineering Institute (SEI) to support learning and experimenting based on PL concepts. It has a complete set of documents, as well as a set of tested classes and source code for three different games: Pong, Bowling, and Brickles. Although AGM is not a commercial PL, it has been used to illustrate the concepts of several different PL approaches, as well as to support performing PL and architecture evaluation case studies [5], [9].

For this example, it is taking into account the AGM models, specially the feature model, as they are provided by the SEI [15]. The **feature model**, presented in Figure 2, is concerned with four top-level features for AGM products, which are: `services`, `rules`, `configuration`, and `action`.

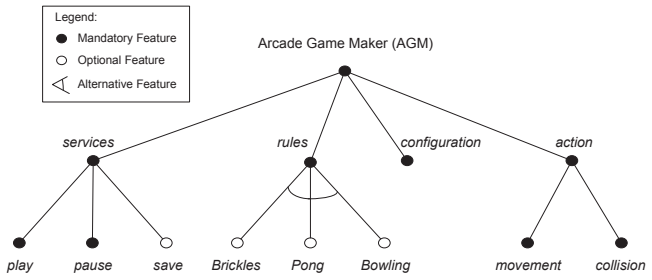

Figure 2. The Arcade Game Maker Feature Model.

In order to illustrate the TAMPro-PLA instantiation, complexity and extensibility quality attributes are considered. Thus, the activities of Figure 1 are realized. TAMPro-PLA takes as inputs the AGM PL models, its feature model and the PLA quality attributes. Therefore, next items present the TAMPro-PLA instantiation by realizing each of its activities.

Business Driver Definition: for the AGM example, we defined two business drivers based on [13] and [7] suggestions, as well as the analysis of the AGM PL models and the complexity and extensibility quality attributes:

- **BD.1 - keep game complexity degree lower than 0.7 (70%), compared to the overall PLA complexity, for at least 50% of produced products**: uphold low maintainability and low cost rates by focusing on complexity. Complexity degrees can provide an indicator of how dificult is to maintain the products derived from a PLA.
- BD.2 - **keep game extensibility degree higher than 0.75 (75%), compared to the overall PLA extensibility, for at least 50% of produced products**: maintain high reuse rate by focusing on extensibility. Extensibility factors can provide an indicator of how reusable is a product in terms of its components.

Scenarios Definition: taking into account the feature model, defined business drivers, and PLA quality attributes, Tables I and II present AGM defined scenarios. Features support the scenarios definition by linking a business driver to one or more scenarios and quality attributes.

Table I
AGM DEFINED SCENARIOS FOR COMPLEXITY.

AGM - Quality Attribute Utility Tree		
Quality Attribute	*Complexity*	
Related Feature(s)	*services, rules, actions*	
Related Business Driver(s)	***BD.1:*** *keep game complexity degree lower than 0.7 (70%), compared to the overall PLA complexity, for at least 50% of produced products*	
Scenario(s)	Sc.1	Variation points and/or variants are added, modified, or removed maintaining the BD.1 true.
	Sc.2	50% of variabilities are removed maintaining the BD.1 true.
	Sc.3	One-game environments have complexity values at most 0.65 (65%) compared to the overall AGM PLA complexity.

Table II
AGM DEFINED SCENARIOS FOR EXTENSIBILITY.

AGM - Quality Attribute Utility Tree		
Quality Attribute	*Extensibility*	
Related Feature(s)	*services, rules, actions*	
Related Business Driver(s)	***BD.2:*** *keep game extensibility degree higher than 0.75 (75%), compared to the overall PLA extensibility, for at least 50% of produced products*	
Scenario(s)	Sc.4	Variation points and/or variants are added, modified, or removed maintaining the BD.2 true.
	Sc.5	50% of variabilities are removed maintaining the BD.2 true.
	Sc.6	Two-game environments have extensibility values at least 0.8 (80%) compared to the overall AGM PLA extensibility.

Scenarios Ranking: stakeholders might take into consideration the following attribute concerns to support ranking each scenario as High (H), Medium (M), or Low (L):

- its **overall importance** for the PLA and its business drivers;
- the **generality** of the scenario with respect to the PLA. It is ranked as mandatory (High), alternative (Medium), and optional (Low) as in [13];
- its **cost/risk**, i.e., the effort involved in providing proper responses to the scenarios, as well as its perceived risk;
- the **number of variability**, encompassed by a scenario.

Table III presents the complexity and extensibility quality attribute scenarios ranking for our AGM example.

Scenario-based Quality Attribute Selection: in a trade-off analysis the number of PLA quality attributes can be large. Stakeholders might wish to select a subset of them to analyze. A widely known adopted strategy is the voting system as in the ATAM method [1], [4]. However, stakeholders can define their own strategy. For the AGM example both complexity and extensibility quality attributes are analyzed. However, as a matter of illustration, we present the rationale for it based on Table III: scenarios Sc.1, Sc.4, and Sc.5 are mandatory and have high number of variability and overall importance to the PLA with medium cost/risk; scenario Sc.6 is optional and it has the same ranking for amount of variability and overall importance as Sc.1, Sc.4, and Sc.5, as well as a low cost/risk; scenario Sc.2 is alternative and it has a high amount of variability and cost/risk, with medium importance to the overall PLA; and scenario Sc.3 is alternative and it has a low cost/risk, and high importance to the AGM PLA.

Table III
AGM COMPLEXITY AND EXTENSIBILITY SCENARIOS RANKING.

Business Drivers			***BD.1***			***BD.2***		
Quality Attributes			***Complexity***			***Extensibility***		
Scenarios			***Sc.1***	***Sc.2***	***Sc.3***	***Sc.4***	***Sc.5***	***Sc.6***
Scenarios Ranking	**Overall Importance**	**H**	X		X	X	X	X
		M		X				
		L						
	Generality	**H**	X			X		
		M		X			X	
		L			X			X
	Cost/Risk	**H**		X			X	
		M	X			X		
		L			X			X
	Number of Variability	**H**	X	X		X	X	X
		M			X			
		L						

Thus, scenarios Sc.1, Sc.4, and Sc.5 are the most important for the AGM example. Sc.1 is related to the business driver BD.1, whereas Sc.4 and Sc.5 are related to BD.2. Therefore, both complexity and extensibility quality attributes are related to important scenarios and are selected for the AGM example.

Managerial and Technical Questions Definition: Table IV presents questions defined by analyzing the AGM feature model, business drivers, selected quality attributes, and scenarios.

Table IV
AGM MANAGERIAL AND TECHNICAL QUESTIONS FOR THE PLA BUSINESS DRIVERS.

Business Driver / Feature / Selected QA (Goals)	**Questions**	
Low Complexity (business driver)	Q.01	What is the complexity of a class/interface in a class model?
	Q.02	What is the complexity of a variation point class/interface in a class model?
	Q.03	What is the complexity of a variability class/interface in a class model?
	Q.04	What is the complexity of a variable component in a model?
	Q.05	What is the complexity of a PLA based on its class model?
High Extensibility (business driver)	Q.06	What is the extensibility of a class/interface in a class model?
	Q.07	What is the extensibility of a variation point class/interface in a class model?
	Q.08	What is the extensibility of a variability class/interface in a class model?
	Q.09	What is the extensibility of a variable component in a component model?
	Q.10	What is the extensibility of a PLA based on its class model?

The **Metrics Definition** activity is not completely presented in this paper, as its realization involves theoretical and empirical validation of metrics. Thus, it was previously defined and validated [11] metrics for complexity and extensibility based on a basic metrics suite [10] for UML models [12]. Therefore, Figure 3 presents a GQM (Goal-Question-Metric) model relating the defined business

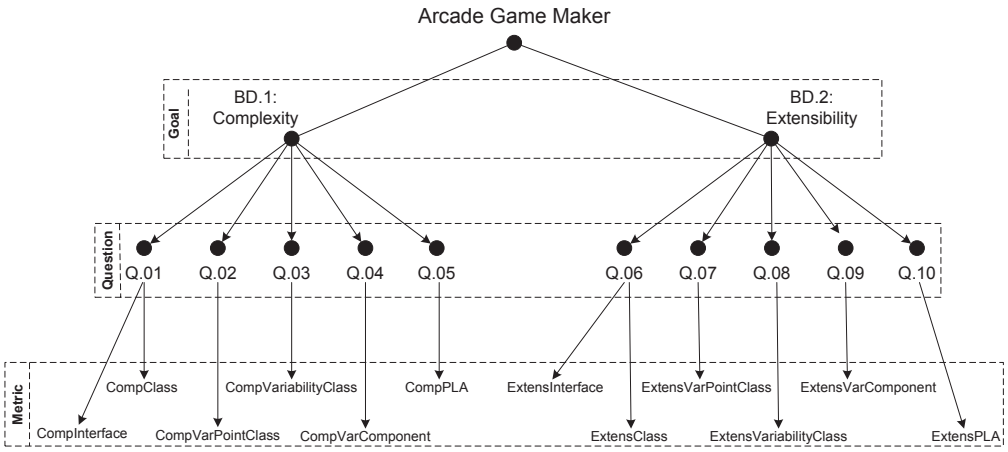

Figure 3. AGM Example Goal-Question-Metric Model.

drivers, questions and metrics.

Once TAMPro-PLA is instantiated and its artifacts are defined, stakeholders are able to perform a PLA trade-off analysis. As such analysis is usually based on the stakeholders analysis experience and knowledge of the domain, and they do not have a systematic realization of activities, some guidelines are suggested. They allow performing a PLA quality attributes analysis based on the instantiated TAMPro-PLA and its defined artifacts. Such guidelines are as follows:

1) generate a set of PLA configurations (PL products), sufficient to apply statistical normality tests and parametric or non-parametric methods for data interpretation;
2) collect quality attributes metrics from the generated configurations;
3) analyze the collected metrics descriptive statistics and present its important data, such as mean, median, and standard deviation;
4) identify how many scenarios satisfy the analyzed quality attributes and verify if either these scenarios are appropriated to the quality attributes or they must be re-stated; and
5) verify which quality attributes satisfy the PLA business drivers.

Therefore, based on such guidelines, stakeholders might decide which quality attribute(s) must be prioritized for PLA development and evolution. Stakeholders can also: provide potential PL products and PLA analyzes; share all data, keeping it for future analyzes; and write a final trade-off analysis report.

V. Related Work

Current literature presents two main works related to ours. Both are extensions of the ATAM method for PLA evaluation and emcompass quality attribute trade-off analysis.

The EATAM (Extended ATAM) method is proposed by Kim et al. [7]. Its main goal is PLA evaluation based on four methods: (i) identification of quality attributes, (ii) identification of architectural views, (iii) definition of PLUC (Product Line Use Case) tags for quality attribute variation points, and (iv) perform ATAM activities to validate the PL products single architecture separatelly. Basically, they use the first three methods to identify and represent variability and the fourth method to analyze the PL products architecture. The first method is strictly based on four main quality attributes: modifiability, portability, scalability, and extensibility. Thus, ATAM PLA trade-off analysis concerns general PLA quality attributes for qualitative analyzes. EATAM does not take into account nor provides metrics to support PLA quantitative analysis. EATAM provides, by means of the PLUC tag, directions of how to identify and relate scenarios to PLA variabilities which is used to perform trade-off analysis. TAMPro-PLA takes some of these directions to create scenarios. However, TAMPro-PLA does not use specific tags to represent variability as it does not depend on the type of the PL models.

The HoPLSAA (Holistic Product Line Software Architecture Assessment) approach, proposed by Olumofin [13], is aimed at evaluating PLA by means of qualitative analysis of variation point scenarios. It emcompasses two stages: (i) PLA analysis and (ii) single product architecture analysis. Its outputs are similar to the ATAM's outputs. Thus, it allows performing trade-off analysis based on PLA quality attributes during its first stage. HoPLSAA does not explicitly provide quantitative analysis due to its ATAM qualitative nature. In addition, HoPLSAA does not take into account metrics for performing trade-off analysis nor quality attribute metrics to support quantitative analysis. However, HoPLSAA allows the statement of scnearios based on PLA variabilities, providing TAMPro-PLA interesting directions fot the scenarios definition activity.

VI. Final Remarks and Future Work

This paper presented the TAMPro-PLA, a **T**rade-off **A**nalysis **M**eta-**Pro**cess for **PLA** to support performing PLA quality attribute trade-off analysis. TAMPro-PLA provides important artifacts for PLA trade-off analysis, such as: business drivers, scenarios, and metrics. Stakeholders must realize the TAMPro-PLA activities to instantiate TAMPro-PLA and produce its artifacts. As it does not depend on the type of PL models, it can be applied in general to perform PLA analyzes.

TAMPro-PLA differs from existing trade-off approaches as it both provides activities, that are realized systematically to produce essential trade-off analysis artifacts for a PLA, and allows the definition and application of quality attribute metrics, corroborating its quantitative and qualitative analysis results.

An example of how to instantiate TAMPro-PLA for quality attribute trade-off analysis of the Arcade Game Maker (AGM) PLA was demonstrated. In addition, guidelines to perform PLA trade-off analysis were suggested. At the end of the trade-off analysis process, stakeholders are able to: (i) decide which quality attribute(s) must be prioritized for PL development and evolution; analyze the potential PL products to predict their generation behavior; confirm the PLA accuracy of its modeled variabilities; share all data, keeping it for future analyzes and write a final trade-off analysis report; and use performed trade-off analyzes as parameter to evaluate overall PLs.

Based on current results, some directions for future work and contribuition might be: (i) the application of TAMPro-PLA to a commercial PL; (ii) the establishment of TAMPro-PLA's feasibility and effectiviness by carrying out experiments taking into account well-qualified industry professionals; (iii) the definition of relevant PL domains to apply TAMPro-PLA in several case studies; (iv) the development of an automated tool to support the TAMPro-PLA instantiation, as well as trade-off analysis; (v) the investigation of how TAMPro-PLA can provide Model-driven Architecture (MDA) support for definition and transformation of PL models; and (vi) how to incorporate TAMPro-PLA into PL evaluation approaches.

***Abstract*—This paper proposes an instrumented solution to integrate feature diagrams with UML models to be used as part of a general approach for designing software product lines and for product generation. The contribution is implemented in IBM®Rational Software Architect (RSA). It is intended to be used in the context of large, complex and multi-domain projects, and at allowing model transformations to derive products. Our RSA implementation makes it possible to link feature diagrams with UML model artifacts. It allows traceability between feature models and other different kinds of models (requirements, class diagrams, sequence or activity diagrams, etc.). It is used in a project dedicated to create smart building optimization systems.**

I. Introduction

IT projects are closely related to business domains. However, there exist few techniques to gather, link and manage the knowledge related to each domain. Nowadays projects are particularly confronted to problems where instrumentation of specific business domains is required to enhance their efficiency. Examples of these projects are smart buildings, grids, water management, health care or food systems. The research presented in this paper is done in the context of the RIDER project[1], which brings together several actors who works on improving energy efficiency of buildings. This context requires to be able to link several domains, such as building system components, IT infrastructure, air flow modeling, building thermal management, database models, *etc.* Each domain can be modeled by a different stakeholder, or sometimes being based upon a standard. Software product line approach is perfectly appropriate to manage the variations that can be found in building instrumentation systems. The solutions presented in this paper are applied to the RIDER project and benefit of its feedback. Our approach is used as a part of a general approach for software product lines and for product generation.

There exist several commercial tools such as [3], [9], [21] that allow linking features to model artifacts extracted from various modeling tools; eclipse plug-ins [20], [1], [13], [10], [27], [15], [12]; and standalone feature modeling tools [22], [24], [26]. These tools do not implement the latest feature modeling concepts and are not well integrated in UML modeling tools. There also exist several UML profiles [5], [30] and meta-models [29] implementations but they address neither the latest UML specification nor all feature model concepts that are useful in our context.

This paper is organized as follows. Section II presents a new synthetic and expressive feature diagram model based on the state of the art. Section III presents our feature meta-model which synthesizes this state of the art. Section IV explains how the corresponding UML profile has been created and implemented using RSA, and shows an excerpt of the project feature model. Section V will sum up what has been presented and suggests some perspectives for further study.

II. Synthesis of Existing Feature Diagram Models

Various feature diagram semantics and implementations have been proposed since the initial one given in *FODA* [16]. We use the following criteria to analyze them and to define our model:

1 – Feature definition.

2 – Feature relationships. We identify four criteria to classify existing proposals regarding relations among features.

- *2.1 – Hierarchical relationships.*
- *2.2 – Feature choice constraint relationships.* necessary to guide the user through feature selection (feature dependency, or mutual exclusion).
- *2.3 – Mandatory and optional feature identification.*
- *2.4 – Sub-feature selection semantics.*

3 – Feature logical groups. Allowing to group arbitrary features by business domains, or abstraction layers.

4 – Product and implementation information. To determine what kind of information can help implementing a product from a set of selected features.

[1]The RIDER project ("Research for IT as a Driver of EneRgy efficiency") is led by a consortium of several companies and research laboratories, including IBM and the LIRMM laboratory, interested in improving building energy efficiency by instrumenting it.

Table I
HIERARCHY RELATIONSHIP

	Decomposition	Specialization	
		Enrichment	Realization
FODA [16]	Consists of		
FORM [18]	Composed of	Generalization Specialization	Implemented by
Fey et al. [11]	Refine		Provided by
Zhang et al. [29]	Decompose Detail	Specialize	
Czarnecki et al. [8]	Relation		

A. Feature Definitions

The initial definition of features was introduced by Kang et al. in *FODA* [16] which is extended by the *FORM* [17] method. Features are defined as being essential characteristics of applications, described with domain vocabulary.

FORM has introduced four different perspectives to enrich the semantics of feature diagrams: capability, operating environment, domain technology and implementation technique. Indeed, features are also able to model knowledge of the various domain experts involved in the project. Fey et al. [11] add the *pseudo feature* concept in order to allow for specialization with non-exclusive alternatives and to avoid feature redundancy thanks to implicit inheritance. Zhang et al. define features [28], [29] as being essentially a cohesive set of individual requirements representing the user-visible capability of a software system. Czarnecki et al. [8], [6] consider that features are system properties relevant for some stakeholder, and that any kind of functional or non-functional characteristic of a described system can be represented by a feature. This extends the *intention* definition presented by Zhang et al. [28].

The definition proposed by Czarnecki et al. allows more freedom of expressiveness in feature diagrams. Its combination with *FODA* perspectives allows us to apply feature diagrams to the numerous domains involved in a project. The *property* concept introduced by Fey et al. and the *attribute* concept presented by Czarnecki et al. are semantically very close. It could be assessed that a property expresses the same information that an attribute, *i.e.*, a measurable characteristic. We will use the *property* concept to describe specific feature typed values (*e.g.*, a room volume, *etc.*) and how one property can influence another one.

We extend this concept to allow the customer to choose the property value. Therefore, we will add the necessary semantics to restrict the possible choices to consistent ones.

B. Feature Relationships

1) Hierarchical Relationships: Features and sub-features can be bound by either decomposition or specialization. Table I illustrates the different variations on these concepts. The FODA *consists-of* relationship [4], [16], [25] is designed to represent decomposition. One parent feature can have several sub-features grouped either by an *AND* or *XOR* decomposition semantics. *FORM* [17], [18] introduces the relations *Composed-of*, to describe the constituents of a feature; *Generalization / Specialization*, to specialize or generalize a feature; and *Implemented-by*, to define how a high-level feature can be implemented by a lower-level one. Fey et al. [11] uses two kinds of hierarchical links between features: *refine*, to detail a given feature at a lower abstraction level; and *provided-by*, to link a pseudo-feature with the features which it realizes. *Pseudo-features* express an abstract functionality, quality or characteristic. Fey et al. make it possible to build directed acyclic graphs, which is impossible with *FODA*, by allowing one feature to refine several ones. Zhang et al. [29] identify three different kinds of hierarchy relationships: *decomposition*, to refine a feature into its constituents; *detailization*, to identify feature attributes; and *specialization*, to add further details into a feature. Czarnecki et al. [8], [6], [7] decided not to consider relationships between features in favor of entity-relationship or class diagrams.

We have chosen to keep the hierarchy relationships categorized in Table I. with the following concepts: *decomposition*, which consists in *detailing* the sub-features that compose the parent feature; *specialization*, which encompasses the concepts of *enrichment* for sub-features that add functions to the parent feature, and *Realization* (or *implementation*) that describes how a feature can be implemented.

2) Feature Choice Constraint Relations: FODA [16] uses the concept of *composition rules* to describe how features relate to one another: one feature can *require* another one, or two features can be *mutually exclusive*. Riebisch et al. [23] introduce the *hint* relationship which recommend features to the user.

We have kept the constraints *require* and *conflict* to ensure a coherent product generation. Furthermore the *hint* relation is also convenient to make recommendation to the user during the feature selection process.

3) Mandatory and Optional Features Identification: In the *FODA* [16] and *FORM* [18] specifications and tools, all features are mandatory by default; optionality is represented as a feature property as in [23], [14], [29]. Czarnecki et al. [6] use cardinalities to express optionality. For instance, a *(1,1)* cardinality describes a mandatory feature and *(0,1)* describes an optional one. Setting a cardinality greater than 1 specify how often the sub-features of a parent can be duplicated.

We keep for our model the cardinality based relationship introduced by Czarnecki et al. [6] that brings an interesting enhancement to the initial definition, useful to describe more complex products from a product line.

4) Sub-feature Selection Semantics: FODA [16] and *FORM* [18] methods propose two ways to manage sub-feature selection. A simple link between the parent and its sub-features means that there is no choice constraint; equivalent to an *or* binary choice. A semi circle drawn

across the links means that there is an alternative choice; equivalent to the *xor* binary choice. Likewise, Fey et al. [11] express with a simple link that the choice is an *or*, but the alternative choice is expressed with a complete graph of mutually exclusive constraints among all sub-features. Riebisch et al. [23] and Czarnecki et al. [8] use cardinalities to define how many sub-features can be chosen.

The most convenient semantics relies on cardinality based selection semantics. It allows a maximum flexibility to describe how many sub-features can be selected. Furthermore, we chose to keep the *"or"*, *"and"*, and *"xor"* groups to ease the feature models semantics understanding for non-IT specialists end-users.

C. Feature Logical Groups

The *FORM* [18] method classifies features into four categories called layers, from a functional point of view. Riebisch et al. [23] use logical groups to represents aspects valuable to the customer and explain that *abstract features* could be used to encapsulate features related to a given concept. Fey et al. [11] present *feature-sets* to group features from an arbitrary point-of-view. Zhang et al. [29] present the *binding-time* concept to represent the phases of the software life-cycle in which each feature must be chosen. Czarnecki et al. [6], [8] use abstract features to reference other feature diagrams to reuse a set of features. They also introduce different types of features that can be considered as feature groups.

The *binding-time* concept can be extended according to the software development process chosen by the final user to allow him to assign features or groups of features to a development phase. It can be modeled by the *feature set* concept presented by Fey et al. The different kinds of features presented by Riebisch et al. [23] could be easily modeled by sub-layers. Hence, we choose to keep the layer concept to organize features in logical groups and sub-groups accordingly to the type of information they represent. We propose to enhance Fey et al. *feature-set* concept by adapting Zhang et al. [29] constraints meta-model to describe constraints inside a group of features, and constraints between two groups of features. The feature-sets could also be used along with the Kano method [19] to help the user choosing a set of product features that yield high customer satisfaction. The customer preference categories can be modeled as feature-sets encompassing the corresponding features. We also keep the feature-sets idea to reference sub-parts of a feature diagram. Hence, a feature-set could be a leaf of the diagram that encompasses another feature hierarchy. Staged configuration can be modelled by creating one feature-set for each configuration stage, and associating it with a group of stakeholders that have the same business concern. Czarnecki et al. [6], [8] have presented four types of features that have been integrated in our meta-model proposal: *concrete features* can be stored in the implementation layer; *aspectual features* can be stored in a sub layer of implementation layer; *abstract features*, *e.g.* performance requirements, can be represented by feature properties; and *grouping features* can be modeled as a feature set.

D. Product and Implementation Information

Riebisch et al. [23] argue that the feature hierarchy must be organized to make easier the choice of features by using composition relations and require associations. Zhang et al. [29] present a feature attribute for representing the feature *binding-state*. It must be used in a *binding-time* context, *i.e.* when features are implemented in the software product at a given software life-cycle phase. Mathematical relationships have been presented to describe the relative impact of one feature to another.

III. A Synthesis Meta Model for Feature Diagrams

This section describes a meta model synthesizing the choices we presented and motivated in the previous section. This work extends the work of Asikainen et al. [2] in order to apply our work in the context of a rich industrial project.

As depicted in Figure 1, a product line contains features, and a feature belongs to one product line. A product belongs to one product line and can be composed of as many features as needed. Features associated to a product must be analyzed in order to check whether all constraints, like mutual exclusion between features or require relations, are satisfied.

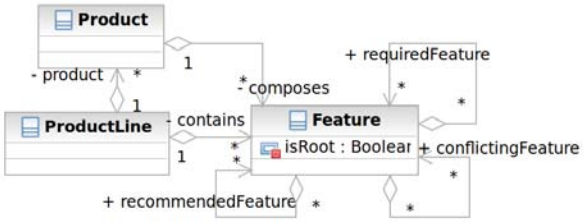

Figure 1. Product lines relation to features and products

Mutual exclusion and require relations link features regardless of their position in the hierarchy, they are modeled by the *conflictingFeature* and *requiredFeature* relationships. Furthermore, we add the *recommendedFeature* role used to advise a user to choose another feature pertinent in the product. These roles are depicted in Figure 1 in reflective association on the *Feature* class.

Feature properties (Figure 2) are used to describe either a feature parameter related to its inner requirements (*e.g.* the bandwidth capacity of a network) or a characteristic chosen by the user during the product definition (*e.g.* the frequency of automatic backups of a word processing software).

Features can have a variability type (*VariabilityKind*) which is further described below:

- *fixed*, A property value is fixed throughout all products of the product line.
- *variable*, A property value can change, within a product, depending on other features properties, *e.g.* the text buffer size of a text field in the user interface can vary accordingly to the type of information we want to store (*i.e.*, name or address).
- *family-variable*, A property can vary from product to product accordingly to the selected features, *e.g.* the phone book capacity depends on the presence of internal memory property and the sim card capacity.
- *user-defined*, A property value can be freely chosen in a given product, *e.g.*, the frequency of automated backups in a word processing software.

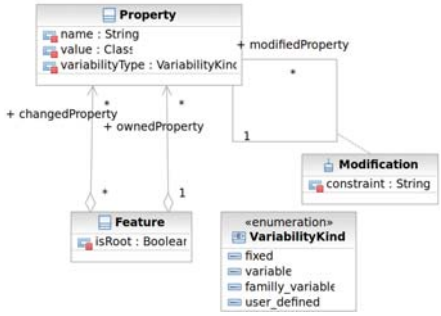

Figure 2. Feature properties

The hierarchy relationships and sub-feature groups are depicted in Figure 3. The relations between a feature and its sub-features are grouped by the *RelationshipGroup* class that contains the cardinalities necessary to restrict the number of sub-features to choose. Cardinalities can be chosen freely, but some groups have fixed cardinalities: *OrGroup*, *(0,*)*; *AndGroup*, *(*,*)*; and *XorGroup*, *(0,1)*. The *DirectedBinaryRelationship* class represents the kind of association that links a parent feature and a sub-feature. It is specialized either by *Enrich*, *Implement*, or *Detail* classes.

Figure 4 shows how layers and feature sets can be associated with the project stakeholders. A stakeholder represents any kind of people (*e.g.* domain experts, IT architects, *etc.*) allowed to choose features. Feature sets and layers can be attached to a concern specific to the project, *e.g.* network architecture, or business requirements. A *Layer* represents a specific view onto the software application, a feature can be in only one layer at a time. A *FeatureSet* inherits from the *Feature* class, and allows grouping features from an arbitrary point of view, *e.g.*, a business domain, or representing the features that must be implemented to fulfill a norm.

Figure 5 depicts how constraints can be applied to feature sets: *mutex*, when only one feature can be selected in the feature set; *None*, when there is no constraint among features;

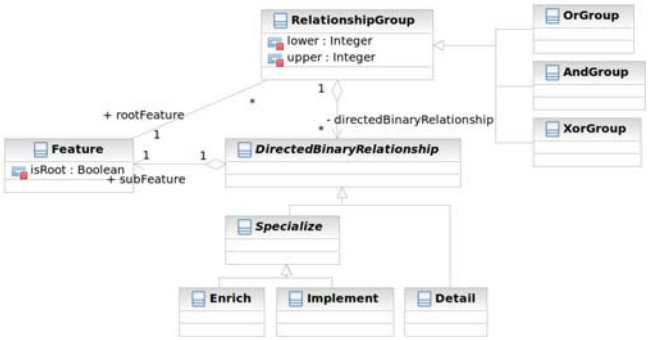

Figure 3. Groups and hierarchy relationships

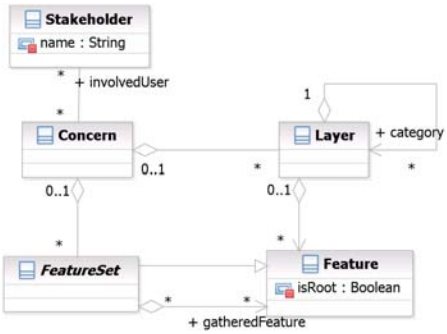

Figure 4. Stakeholders concerns

All, when all features or none of them can be selected. The *ConstraintRelation* class describes the relation between two feature sets: one feature set can require another one, two feature sets can mutually require each other, or be mutually exclusive. A *BindingPredicate* is used to represent how a constraint must be applied on each constrained feature-set. The choice of the specialized class must be made according to the kind of feature-set.

IV. UML Profile Implementation

A. Description

Our profile integrates the previously described feature meta-model into the UML meta-model hierarchy with an appropriate semantics. We describe here which UML meta-classes we have chosen to extend, which information has been added with the stereotypes and how we have restricted the semantics of extended meta-classes thanks to OCL constraints. However, the profile could be implemented in different ways by choosing to extend different meta-classes. We chose the meta-classes that had the closest semantics to our concepts, added the required information with the stereotypes and restricted the initial semantics of meta-classes to what is necessary for our profile with the Object Constraint Language (OCL) constraints.

Contrary to [5] we have based our feature diagram profile on the *Components* UML meta-class. A component, as a

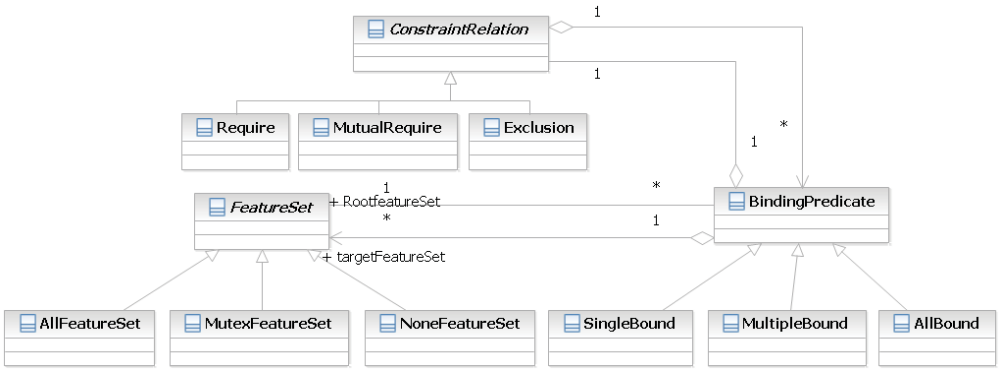

Figure 5. Constraints on feature sets

feature, can be seen as a high level view of a software element and, as such, is the concept the closest to what we want to express. Components have ports, which can be linked together. Ports are thus reasonably well suited to support the relationships between features and other elements defined in section III. It is the UML 2 concept the closest to what we want to express because it is a high level view of the structure of a software element. This first choice influences the other meta-classes selection.

Table II
STEREOTYPES EXTENSIONS

Stereotype	Extended Meta-class
Feature	Component
Stakeholder	Actor
Concern	Class
ModelRelationship	Dependency
Layer	Package
ProductLine	Component
Product	Component
Property	Port
RelationshipGroup	Port
Modification	Usage
DirectedBinaryRelationship	Association
BindingPredicate	Port
ConstraintRelation	Association

The *port* meta-class allows us to represent the interaction of a feature with other elements. It can be linked to other ports or components. The modification of a property value can be modeled by textual or OCL constraints placed upon the relationship between two properties.

We choose to create a Rational Software Architect plug-in to leverage its UML modeler, modeling editors, views and tools. All managed models are instances of EMF models. Hence using Rational Software Architect allows simplifying tasks like creating a specific plug-in for integrating feature modeling capabilities into standard EMF-based UML models and diagrams. The plug-in is currently used in the RIDER project.

Table II gives an abstract of our specialization choices, but due to space constraints we did not explicit all our design choices.

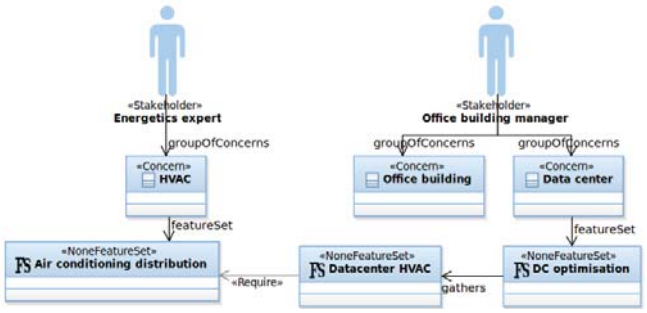

Figure 6. Stakeholders and feature sets

B. Example

Figure 6 shows an excerpt of a RIDER feature diagram expressed, using our profile, by two stakeholders having different concerns on a RIDER smart building project. One focusing on HVAC (Heating Ventilation Air Conditioning) domain and the second on data centers and office building optimization problems. Each feature set encompasses several features that are not shown in this example because of space limitation. The example shows in particular *require* high level constraints applying on groups of features (feature sets). The example also shows how *properties* can be used to add further information on the product context (such as the building volume).

The feature selection process is achieved by showing feature diagrams to the user accordingly to his concerns thanks to model transformations.

V. CONCLUSION AND PERSPECTIVES

In this paper we have presented a new feature diagram model and its profile implementation in UML2. This feature diagram model is first based on a synthesis of existing ones, and it has then been improved to fit the requirements of the

RIDER smart buidings project in which it is applied. Thanks to Rational Software Architect, we have generated a tool making it possible to produce feature diagrams conforms to our model. This synthesis is achieved by classifying the existing concepts into categories. This approach allows a full integration of feature diagrams into UML models and facilitates model transformations. In comparison with [2] we add several concepts such as *layers*, *stakeholder concerns*, *feature-sets*, and *group constraints*.

For the time being, we still need to guide users to organize features into layers and sub-layers in order to best integrate them into the software development life-cycle. Hence, the next steps will be to create a framework able to use the full potential of our feature meta-model, and to develop automated model transformation functionalities to automatically generate UML models.

***Abstract*—Nowadays the decision whether to work with Software Product Lines *(SPL)* or not becomes a binding requirement for the strategic planning of companies. Learning how to choose the ideal tools to test a SPL is beneficial for companies in this planning process. Even though the ascending number of available software engineering testing tools, SPL testing lacks specific tools capable of supporting the SPL Testing Process and managing the variability of test assets. This paper evaluates how to reduce the effort during the SPL Testing Process and consequently, how to make the variability of test assets manageable. We propose a software product line testing tool to build system tests from use cases that addresses challenges for SPL Testing we identified in a literature review.**

***Keywords*-Software Testing; Software Product Lines; Software Reuse; Testing Tools;**

I. Introduction

Software testing tools are available for testing in every stage of the software development life cycle, although it is not commercially viable for the tools vendors to produce a tool that suits every organization. It is inevitable, then customizations of tools is desirable [1].

Software product lines testing tools are not an exception, choose testing tools suitable for test applications and support process could be one of the most critical tasks of a project. In the SPL context, the amount of available tools decrease drastically, and the need of tools to reduce the effort during the SPL testing process is an obvious gap that need to be filled.

Software product lines is a planned, systematic and proactive reuse strategy, through exploiting the similarities within a set of products. SPL can enable organizations to achieve significant reductions in terms of development and maintenance cost and time-to-market as well [2], and remarkable quantitative improvements in productivity, quality and customer satisfaction [3], thus addressing the problems aforementioned.

In order to manage the variability, avoid the explosion of test cases due to the great number of variation points combinations and reduce the effort to test a software product line we need to implement testing tools that would allow for improvements in costs, time-to-market and quality [4].

The availability of tools makes testing a more systematic activity and can minimize the cost and time consumed, as well as the errors caused by human intervention [5]. A wide range of tools, with both commercial and academic purposes can be found. However, these tools have almost always been implemented for specific purpose and they are isolated from others, presenting its own architecture and internal structures [5]. As a consequence, difficulties in integration, evolution, maintenance, and reuse of these tools are very common. These tools often focus on automating specific testing techniques and criteria, without considering the whole testing process [5].

In this paper, we propose a SPL Test Tool for create system test cases based on use cases that supports the RiPLE-TE [6] test discipline of the RiPLE project. The RiPLE project is an effort of developing a framework to support a set of disciplines that compose the life-cycle of a SPL, namely Scoping [7], Requirements [8], Design [9], Implementation [10], Testing [11], Evolution Management [12].

We also investigate tools that can help during all tests levels of the SPL phases. Furthermore, in order to gure out the needs of the research field, we split our investigation into two steps. Firstly we analyzed test tools that have been developed for testing single systems; and secondly, we focused on tools that have been developed specifically to product lines. The question that motivates our work is: *How to handle variation points and their combination within a test case?*

The remainder of this paper is organized as follows. Section II describes the related work. Section III is an introduction to software product lines testing tools. Section IV analyzes the challenges of SPL Testing. Section V discusses the proposal. Finally, Section VI summarizes and concludes this paper.

II. Related Work

There are few studies describing and detailing tools for testing SPL projects. If we decide to narrow the scope, encompassing the search for only system test related tools, within the SPL context, the findings are worse.

According to [13] the ScenTED-DTCD (Domain Test Case Scenario Derivation) is a prototype tool focused on generating test cases scenarios that describe the test engineer's activities and the systems response if modeled within the activity diagram.

Another prototype tool can be found [14]. It generates system test scenarios from use cases. The approach is based on the automation of the generation of application system tests, for any chosen product, from the system requirements of a product line.

These studies are deemed to be good sources of information regarding tools for testing SPL. In order to develop our work, we considered every mentioned study, since they bring relevant information that comprises the knowledge to develop SPL system testing tools.

III. SPL Testing Tools

Testing is an expensive and laborious phase of the software process [15]. In SPL, this assumption continues to hold true. As a result, testing tools were among the rst software tools to be developed. These tools now offer a bunch of facilities and their use can signicantly reduce the costs of testing [15].

Finding an effective and efficient software testing tool could be a life-saver for a project or a company. There is no single test tool suitable for all possible systems and industry sectors. Deciding what criteria to apply when selecting a specific tool for a project is quite tricky [16].

A software product line is a large system, with large volume of source code, and such automated tools can aid developers and testers to scan through the large volume of product lines source code and reveal unreliable program features to the human program. Testing tools can support testing large size of software product lines to achieve its goals [17].

An important factor in SPL Testing is automated testing and the use of testing tools. This decreases the effort when reusing test assets and makes the complex testing process more manageable [18]. There are numerous mature testing tools available. Despite the seeming abundance of available testing tools SPL testing lacks efficient tool support. The problem with testing tools is that few of them directly support SPL [18].

A. Literature Review

This section presents how we identied papers reporting single systems testing tools and product lines testing tools, how we extracted data and information from the research papers, and how we analyzed them with respect to identify the requirements to compose a new testing tool focused on SPL Testing.

In order to extend the research and better understand the needs of tools for SPL Testing, we performed a research that firstly identified 26 relevant studies using dened search items related with the subject SPL testing tools. Then, we rened the search by applying some exclusion criteria to the study title. Next, we excluded studies on the basis of exclusion criteria applied to abstract and conclusion reducing the number to 15 papers. Finally, we obtained the primary studies set to be critically appraised. This set comprised 8 papers, that accordingly describe the implementation of a SPL testing tool.

In accordance with our findings, it is possible to check a huge amount of tools that support testing, but very few support SPL testing.

IV. Software Product Lines Testing Challenges

SPL Testing may be represented as two instances of the V-model, according to [6]. First, the domain assets are tested. Then, the products are tested according to the model. This raises two problems. First, complete integration and system testing in domain engineering is usually not yet specified [18]. Try to test the different combinations of components leads to exponential growth of tested configurations [19]. Second, it is hard to decide on how much we can depend on the domain testing. According to [18] it does not seem to be clear where testing belongs in the overall SPL process.

Another challenger is the organization of test assets. Management of testing becomes very difcult if testers cannot tell the difference between assets that belong to the domain and assets that belong to a product. Commonality and variability in product lines require rich traceability, from requirements to implementation and test assets, encompassing the whole development life cycle [19].

Integrating test environments and the test asset repository is a cumbersome work, that is even worse due to the lack of automated support tool, which leads to be a manually performed task. There is a need for specic testing tools that should help to manage the reusable testing assets and automate the execution of tests and the analysis of their results as well [18].

It is also evident the need of tools that integrate the whole process of software product lines testing including test environments and a test asset repository. A feasible approach for this would be to use a product lines specific integrated testing environment [20].

The product line approach requires a carefully planned testing process that can be easily adapted and used in different domains. Currently, there is a gap between the overall product line engineering processes and the assumed testing processes using the practical testing methods, because it is not clear how the processes and test assets are aligned to test

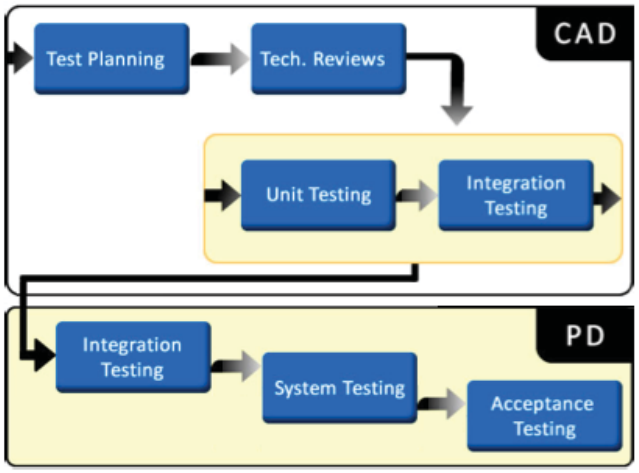

Figure 1. RiPLE-TE [6]

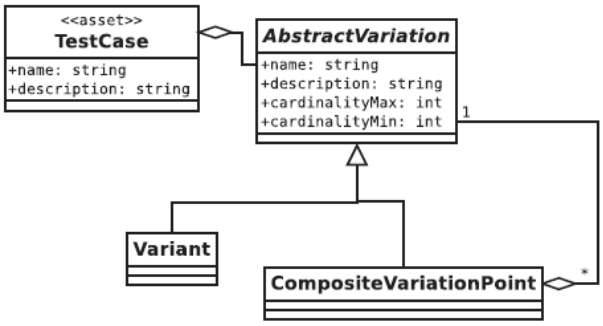

Figure 2. The tests model excerpt - from [21]

a product lines in cost-effective manner, while preserving quality [18]

In order to lessen some of these problems, this work is focused on the building of a tool to support testing activities, at the system test level, aiming at reducing the required effort. It builds on the definition of a structured process for testing SPL, the RiPLE-TE [6], as next described.

V. Towards a Tool to Support SPL Testing

In RiPLE-TE, test assets are built in parallel to the development assets. Thus it is possible to maintain traceability among these artifacts, and consequently ease the process of developing and rebuilding them, if necessary. Testing a SPL includes the core asset, product specific assets, and their interactions.

In this effect, RiPLE-TE consists of two processes, considering the particularities of each phase, as showed in Figure 1. In Core Asset Development, when assets have to be developed with a special attention to the forthcoming reuse, the process advocates that unit and integration testing levels should be performed, whereas system and acceptance testing have to be postponed to Product Development, where the assets previously developed will be reused. Hence, knowledge produced in the core asset testing can be reused in product testing, reducing the overall effort.

Every test case created in the basis of the RiPLE-TE process can represent variability in a way that reuse is encouraged. Figure 2 shows an extract of a metamodel [21] developed in order to capture the relationship among the artifacts created in a SPL project. This figure basically depicts the Test model fragment, in which test cases are considered the main artifact to be handled.

Since each use case in a SPL project is supported by one or more test cases, the variability herein in handled as the same way than in use cases elaboration. This latter expands on the abstract use case definition, in which variability is represented in the use cases. A use case is herein composed by the entity AbstractFlow, that comprises the subentity Flow, which actually represent the use case steps. Every step can be associated with a subflow, that can represent a variation point. In both, fragments compose every (*use* or *test*) case, and are thus considered when deriving some product. This way, dependencies among test cases fragments and use case fragments make sense.

In addition the model also include other involved artifacts, such as planning and management assets.

A. Software Product Lines System Test Case Tool

The literature still lacks works describing tool support for testing software product lines [11], [17], [18]. In this effect, we propose a tool focused on the elaboration of system test cases for a SPL projects, thus encouraging reusable artifacts to be produced. We will use the test model previously mentioned (and fully described in [21]) to manage the test assets and dependencies.

Additionally, Figure 3 illustrates how the system test cases are built from use cases. According to [22], a use case goal can be decomposed recursively into sub-goals, as a result is necessary to create test cases for each fragments ensuring the use cases coverage.

1a. The use case document are composed by the use cases of the SPL project.

1b. The tool allow users to select all the use cases or part of these. The selected use cases will be extracted from the document described in 1a.

2a. Each use case can generate a system test case. When the use case is more complex the tool will generate a test cases group described below.

2b. Test Cases groups will be composed by two or more system test cases.

2c. The combination of system test cases generated by the tool will compose the *Test Case Document*. The tool also allow users to select specic test cases in order to generate customized test cases documents.

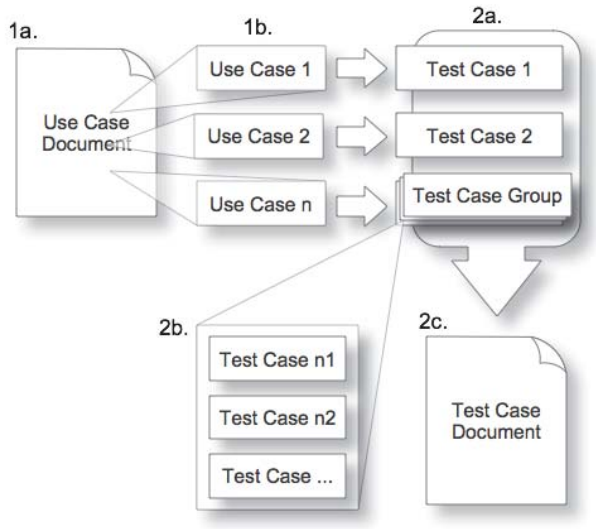

Figure 3. Proposal

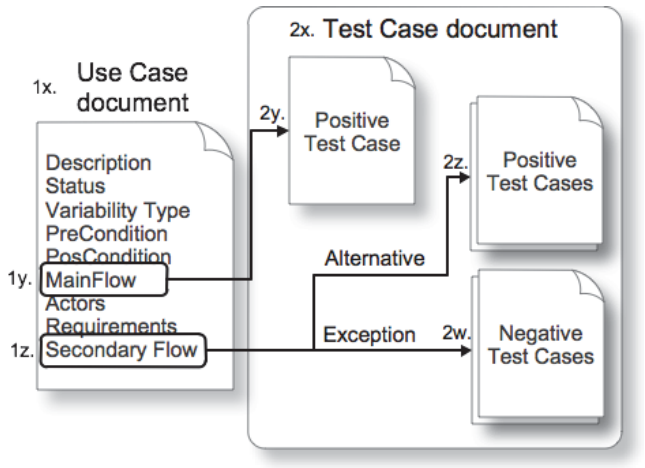

Figure 4. Test Case Composition

Next, the system test cases are formed by the following fields: an ID (unique identication number created automatically by the tool), the name of the test case, its summary and classication (positive and negative test cases), steps of the test case, pre and post conditions, variability type, use case references and screen path (describes the path of the system that should be tested).

When all the use cases were selected the application will focus at the construction of mandatory test cases. Thus the optional test cases can be built in accordance with the needs of specic products of the SPL product development phase. However, every mandatory use case, have to be validated, which consequently demands the creation of mandatory test cases. Besides test cases priority will be also classied in agreement with requirements priority dened by [8] as High, Medium and Low.

In addition to the proposal, test cases are composed by extracting information from use cases. Figure 4 illustrates the data extraction from the use case document (1x) for the construction of test case document (2x). The main flow (1y) of the use cases leads to the building of positive test cases (2y - when determined action should succeed [23]) that analyze if the main functionalities are working properly. Secondary flows (1z) of the use cases are divided in Alternative and Exception flows. Alternative secondary flows result in positive test cases (2z) that validate instructions that should succeed [23]. Finally, exception secondary flows result in negative test cases (2w - when determined action should not succeed [23]) that verifies errors messages and unsuccessful procedures.

In order to manage the variability, all the variation points are associated with requirements specified in the SPL requirement document detailed by [21]. As requirements include variability, test cases must also contain explicit variability information. Test cases that include variability are called variant test cases. Test cases without variability are called common test cases and can be applied to all applications [13].

Moreover, each variation point are related with a use case, consequently for every single use case is possible to create test cases. Hence, variation points leads to the creation of test cases in this way preserving the variability within the tests cases.

The prioritization of the variation points is established in line with the variability type and priority of the requirements. Mandatory requirements with high priority have to be examined first. For this reason we propose that tests cases of mandatory variation points with high priority should be created first.

Figure 5 explains how the test case document can support the test architect. Using the document the test architect can delegate which tests should be created by developers (Unit and Integration tests because they need source code knowledge to support White-box techniques. White-box test cases consider the entire source code of the program while grey-box test cases only consider a portion of it [24]) and which tests must be done by test analysts (System and Acceptance tests because they need part or the entire system working, will be useful to support Blackbox techniques. Blackbox test cases are those in which no details about the implementation, in terms of code, is provided. These test cases are based exclusively on the inputs and outputs of the system under test [24]).

1) Tool Architecture: [21] presents a web tool implemented using the Django[1] framework, which enabled the fast development of a functional prototype. Through Django, the metamodel mapped entities and their relationship into

[1]http://www.djangoproject.com

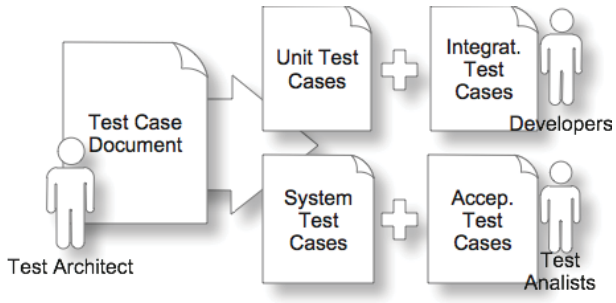

Figure 5. Using of the Test Case Document

Python[2] classes, and then it is automatically created a relational database for these entities. Finally, Django generates a Web application where it is possible to test the mapping by inserting some test data, the documentation regarding features, requirements and so on.

Currently, it is possible to use the tool to document all the assets regarding the metamodel, however the test cases derivation from use cases is not supported yet [21]. This is the focus of our proposal and to bridge this gap we propose the architecture showed in Figure 6.

In order to understand the architecture of the proposed tool is necessary to know that Django follows the Web Server Gateway Interface *(WSGI)* protocol, so we can model incoming communication as browser and server.
Figure 6 describes the architecture of the proposed tool combined with the SPL Metamodel. Details of the layers are described below:

- **Browser:** Users access the application through web browsers.
- **Template:** A Django template separates the application from the data. A template defines the presentation logic that regulate how the information should be displayed.
- **URL Dispatcher:** It defines which view is called for a given URL pattern. Basically, it is a mapping between URL patterns and the view functions that should be called for those URL patterns.
- **Model:** It describes the data structure/database schema. It contains a description of the database table, represented by a Python class. This class is called a model. Using it, is possible to create, retrieve, update and delete records in the database using simple Python code.
- **View:** It contains the business logic. View layer is itself a stack. Python view methods call a restricted template language, which can itself be extended with custom tags. Exceptions can be raised anywhere within a Python program, and if not handled they rise up as far as the environment.
- **Database:** All the data information will be recorded at the repository. Django attempts to support as many features as possible on all database backends. However, not all database backends are alike, and we have to make design decisions on which features to support and which assumptions we can make safely.

[2]http://www.python.org

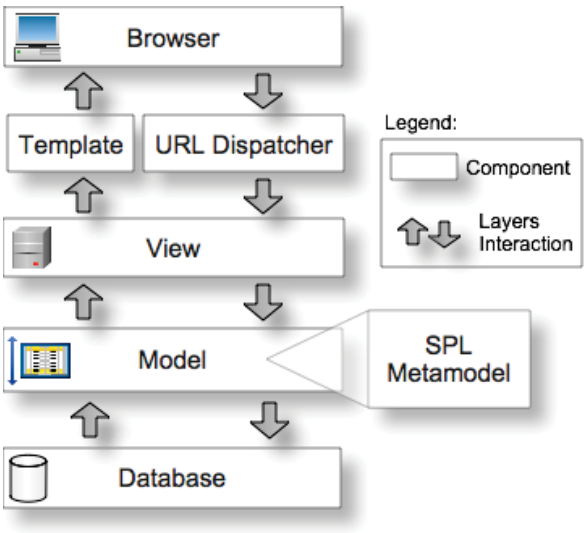

Figure 6. Proposed architecture

The view and the model layers can raise exceptions, but Python uses exceptions for control flow. So not all of these rise to the server.
The architecture of the proposed tool is suitable to support the construction of the test case document. However, to work managing source code is necessary to adapt the architecture, more details can be seen at Section VI.

VI. Concluding Remarks and Future Work

Currently, despite of the increasing interest by the research community regarding SPL testing [11], it is very difficult to find suitable tools to support SPL testing processes. It has a direct impact in the high costs this activity poses, since testing becomes a cumbersome and laborious work [17].

This work proposes a system test tool to support the test process of a Software Product Line. The tool is aimed at reducing the effort of testing, by reducing the work required to follow a SPL testing process.

The creation of system tests cases will help to manage the traceability between use cases and tests cases. It is also necessary to organize and manage the variability of the tests assets after the creation of the test case document.

During the definition of our proposal we identify the necessity of extend the architecture in order to allow support the management of source code and subsequently automatically generate unit and integration test cases.

As a future work, we are intended to conduct a series of experimental evaluations in order to analyze the effectiveness of the proposed tool.

Abstract— **Having set up reusable core assets for a Software Product Line (SPL), it is a common practice to apply Variation Techniques (VTs) to manage variant features. As each VT can handle only certain types of variability, multiple VTs are often employed, such as conditional compilation, configuration parameters or build tools. Our earlier study of an SPL at Fudan Wingsoft Ltd revealed potential scalability problems of multiple VTs. As a remedy to the above problems, in the follow-up study we replaced multiple VTs originally used in the Fudan Wingsoft product line, with a single, uniform VT of XML-based Variant Configuration Language (XVCL). This paper provides a proof-of-concept that commonly used variation techniques can indeed be superseded by a subset of XVCL, in a simple and natural way. We describe the essence of the XVCL solution, and evaluate the benefits and trade-offs involved in multiple VTs solution and single VT - XVCL solution.**

Keywords- Generative technique; Software Product Line; Variability management

I. INTRODUCTION

In previous paper [16], we analyzed a Software Product Line (SPL) called Wingsoft Financial Management Systems (WFMS-PL), developed by Fudan Wingsoft Ltd. WFMSes provide web-based financial services for employees and students at universities in China. Following a common practice, Wingsoft set up product architecture, identified core assets for reuse, and then applied a range of common design-time Variation Techniques (VTs), such as conditional compilation, design pattern or configuration parameters, to manage product-specific features in core assets.

Features vary in the granularity and in the scope of their impact on core assets [5][12]: *Fine-grained features* affect many core assets of an SPL, at many variation points [8]. Code of such features becomes scattered across core assets. A *Coarse-grained feature*, on the other hand, can be contained in a component (e.g., a class or package) that is included into a custom product when a given feature is needed. *Mixed-grained features* involve both fine- and coarse-grained impact.

Coarse-grained features are easier to manage than fine-grained features. Feature granularity depends to some extent on the design of core assets. Good architectural design can change feature granularity in our favor, increasing the number of coarse-grained features, and reducing the number of variation points in core assets for the features that remain fine-grained.

Variation Techniques (VT) must match feature granularity. Therefore, it is common to use multiple VTs, for example, conditional compilation to handle fine-grained features or a build tool such as Ant to handle coarse-grained features. Such VTs are easy to apply, and most of developers are familiar with them. However, as our study revealed [16], applying multiple VTs does not scale well, especially in cases of mixed-grained features. While reuse and modification of mixed-grained features is inherently difficult, applying multiple, often poorly compatible VTs aggravates the problems.

As a remedy to the above problems, in the follow-up study we replaced VTs originally used in the Fudan Wingsoft product line, with a single, uniform VT of XVCL (XML-based Variant Configuration Language) [15]. XVCL applies generative mechanisms to organize software into highly parameterized meta-components. These meta-components form SPL core assets that are adaptively reused in product derivation, automated by the XVCL Processor [9]. In this paper, we propose to use XVCL as a uniform VT to replace the original ones described in [16]. We also present an initial evaluation of benefits and trade-offs involved in adopting a uniform VT.

A practical lesson learned from our study is that in small- to medium-size product lines, applying multiple VTs may be a viable solution, as it requires less training, and variability can still be effectively managed in that way. As the product line grows in size and the impact of features on core assets becomes more complex, a company may experience problems. Then moving towards a uniform variation technique approach may be beneficial. However, this will require a more systematic approach to reuse, and training of SPL personnel.

The paper is organized as follows: Section II summarizes the findings from our earlier study of multiple VTs in WFMS-PL [16]. Section III describes the XVCL solution to WFMS-PL, and explains how it alleviates problems of the multiple VTs. We evaluate the XVCL approach in Section IV. Related work and concluding remarks end the paper.

II. PROBLEM OF MULTIPLE VARIATION TECHNIQUES

WFMS for Fudan University developed in 2003 evolved into a Software Product Line WFMS-PL [16] with more than 100 customers including major universities in China such as Shanghai Jiaotong University (WFMS for this university can be found at http://www.jdcw.sjtu.edu.cn/wingsoft/index.jsp), Zhejiang University, Chongqing University and others.

Main functionalities of WFMS include the Financial Management Subsystem (FMS) that manages all the university income and expenses, the Salary Management Subsystem (SMS) that manages salary of employees, the Reward Management Subsystem (RMS) that manages rewards for

employees and students, and the Tuition Management Subsystem (TMS) that manages student tuition fees. The TMS is a web-based portal for students to pay their tuition fee online, with functions such as login, service customization, on-line payment and history query. In addition, the TMS also provides accounting services (e.g., report generation and bill settlements) that interface universities with banking systems.

First five WFMS product variants were developed by ad hoc copy-and-paste reuse, and each WFMS was maintained as a separate product. As the number of customers was growing, ad-hoc reuse and maintenance was becoming more and more taxing on company resources. To address this problem, Wingsoft set up SPL core assets as follows: First, Wingsoft designed architecture to be shared by future products and adopted commonly available VTs, such as conditional compilation and configuration parameter files. Wingsoft did not use any advanced VTs due to the practical need for an easy-to-implement, cost-effective SPL. Such an SPL was built and reused with minimum training of the staff in SPL techniques.

We described implications of using multiple variation techniques in WFMS-PL in [16], so here we only summarize the main results. We analyzed the Tuition Management Subsystem (TMS), as it involved types of variability and variation techniques that are representative for the whole WFMS. The code of TMS is 25% of the whole WFMS system, comprising 58 Java source files, 99 JSP web pages, and several configuration files. In TMS feature model, there are 32 variant features and 9 mandatory features[1].

Wingsoft adopted simple, freely available VTs, selecting the right VT for features at hand [16]. Fine-grained features were managed by conditional compilation and commenting code in core assets. Coarse-grained features were managed by build tool Ant. Mixed-grained features were managed by configuration parameters. For the 32 variant features in TMS, conditional compilation or commenting technique was involved in 31 variant features. Ant was used by 19 variant features, overloading fields - by 13 features, configuration file - by 12 features, and design patterns - by 3 features.

Our study [16] revealed potential problems of multiple VTs in an SPL: One feature was often handled by several VTs which had to be properly synchronized. 26 among 32 variant features were managed by more than one VT, 13 features - by 3 VTs, and 3 features - by 4 VTs. The difficulty roots in the management of variant features involved in several VTs at the same time. Examples below illustrate what was involved in managing such features, and hint at complications that are bound to arise as the size of the system and the number of inter-dependent variant features grow.

Feature *PayByItem* (Fig. 1, Fig. 2 and Fig. 3) is a mixed-grained feature managed by configuration parameters that parameterize reflection, *strategy* design patterns [7], and also the build tool Ant. In Fig. 2, method *user.getPayMode()* at line 6 returns the value of the parameter *paymode* at line 2 in the configuration file (Fig. 1). According to that value, *strategy* pattern generates the specific code skeleton for feature *PayByItem*.

13     </copy>
14   </target>…
15 <project>
```

Fig. 3. Managing PayByItem with Ant

Coarse-grained impact of feature *PayByItem* is managed by build tool Ant (Fig. 3). Using parameters, Ant could include/exclude source files that were relevant/irrelevant to a given feature. An Ant script sets the target path for the source code to be included in the final build. Feature *PayByItem* has a related JSP file selFeeItem.jsp, which was included by the command <**fileset dir>** at line 12.

Mixed-grained impact of features is the main source of problems for scalability of the multiple VTs to manage SPL variability. Scattered impact of mixed-grained features brings forth the difficulties to keep multiple VTs in synchronization one with another. Inter-related configuration parameters control both Ant and Java conditional compilation. There are many examples of such interactions between multiple VTs in the original TMS core assets. Its maintenance entails the accurate understanding of multiple VTs, and familiarity with variant features and core assets. As the size of the system grows and the feature dependencies increase, the above inconveniences aggravate. These observations encouraged us to experiment

[1] Details on TMS's feature particulars and feature dependency are available at this link: www.comp.nus.edu.sg/~yinxing/TMS-information.html.

with a single VT to manage the common variability situations found in TMS core assets in a uniform and traceable way.

III. SINGLE VARIATION TECHNIQUE APPROACH TO TMS CORE ASSETS

XVCL [9][15], based on Frame Technology [2], is a generative language-independent variation technique for SPLs.

XVCL encapsulates core assets in so-called *x-frames*. Coarse-grained features are contained in dedicated x-frames. Each variation point in core assets is marked with a suitable XVCL *command*, such as **<adapt>**, **<insert-before> <insert>**, **<insert-after>** and **<break>**, to enable customizations. SPL variant features are formally mapped into all the relevant variation points in core assets by means of XVCL parameters and commands. The SPeCification x-frame, called **SPC**, sets values of XVCL parameters according to feature selection. XVCL Processor interprets x-frames starting from the **SPC** (Fig. 4), traverses x-frames, propagates customization information (parameters) to them, adapting visited x-frames accordingly, and emitting code for a custom product. XVCL mechanisms allow us to manage features with fine-, coarse- and mixed-grained impact on core assets. Due to its language-independence, any type of SPL artifacts including Java code, JSP files, DB scripts, WORD files, test cases or even UML models in XMI can be consistently customized for any legal selection of features required in a custom product.

A. TMS core assets instrumented with XVCL

Fig. 4 provides a snapshot of the WFMS core assets in XVCL representation, and Fig. 5 expands some x-frames to highlight the working mechanism of XVCL [2]. The **SPC** specifies which features we need in a custom WFMS product by setting values for XVCL parameters that correspond to selected features. Values of those parameters propagate to x-frames below, navigating configuration and detailed customizations of core assets and features accordingly. **Level 2** x-frames define architecture-level customizations, in terms of configuration of core assets for a custom WFMS product. Some of the coarse-grained feature impacts are also addressed at Level 2. **Level 3** x-frames contain the actual code of core assets and features, instrumented with XVCL commands to enable customization of fine-grained features.

Features we want to select for a custom product are assigned non-empty string values, while features to be de-selected are assigned empty string values. Thus, **SPC** shown in Fig. 5 selects features *IDCard* and *SSO* (related to *Login*), and feature *PayByItem* (related to *Paymode*) for a custom product. It deselects feature *Direct*, *PayByYear* and *PayByYearOrder*.

<**select**> commands mark variation points in x-frames below **SPC**. The value of an XVCL parameter that controls <**select**> identifies an <**option**> to be processed. <**select** PayByItem> in x-frame **OnlinePayment** at Level 2 illustrates a simple variation point affected by one feature only, namely *PayByItem*. If feature *PayByItem* is selected, then the Processor emits feature code to the custom product; otherwise, <**select**> has no effect.

[2] Details on TMS's XVCL solution are available at this link: www.comp.nus.edu.sg/~yinxing/TMS-XVCL-solution.html.

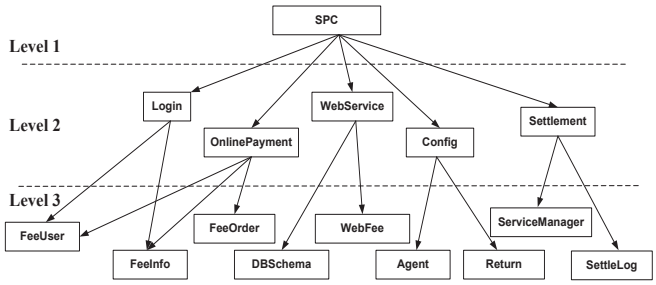

Fig. 4. Overview of WFMS core assets in XVCL

<**select** Login> in x-frame **FeeUser** at Level 3 marks a variation point affected by three features, namely *IDCard*, *SSO* and *Direct*. Notation **@v**, where v is an XVCL parameter, means reference to v's value, as assigned in respective <**set**> command. The value of Login, <**set**> to be a concatenation of the three XVCL parameters corresponding to these features, controls <**select**>, directing processing to the <**option**> corresponding to the particular combination of selected features. Note that <**option** "IDCard+SSO"> is processed whenever the two interacting features *IDCard* and *SSO* are selected. Symbol '+' is a separator. By the multiple features in <**option**>, XVCL can handle the interacted features.

XVCL parameters formally link together customizations of all the core assets affected by selected features, at all the relevant variation points. XVCL parameters set in **SPC** create a bridge between features and WFMS core assets in XVCL.

B. One variation technique instead of many

Our example of Fig. 5 also illustrates how a single variation technique can successfully provide capabilities of many variation techniques. In x-frame **FeeOrder, @PayMode** c = **new @PayMode** replaces configuration files and applications of *Strategy* pattern in the original WFMS core assets in Fig. 1, Fig. 2 and Fig. 3. Here, we need a parameterizable name of the class. Java generics support parametric types, but not class names. In the original WFMS core assets, *Strategy* pattern and configuration parameter stored in a configuration file were used to mitigate the problem (Fig. 2). *Strategy* pattern reads the name of a required class from the configuration file.

In the original WFMS core assets, architecture-level configurations of core assets and coarse-grained features were done by Ant. For example, if we select feature *PayByItem,* Ant's command <**fileset dir>** in Fig. 3 includes file selFeeItem.jsp into the custom product. The same is achieved by **<adapt>** placed under **<select>** in x-frame **OnlinePayment**. Of course, Ant has more capabilities than XVCL's <**adapt**>, but in this context only Ant's asset configuration capabilities are used.

In x-frames **DBSchema** and **FeeUser**, we see how XVCL's parameters and <**select**> replace conditional compilation and commenting out feature code. For example, feature *InitPayMode* affects **DBSchema** and **FeeUser** and is managed by conditional compilation and commenting out technique. Manual modification of the conditional compilation or comments has to been done to include/exclude features. In XVCL on the other hand, variation points are inter-lined and customizations are automated.

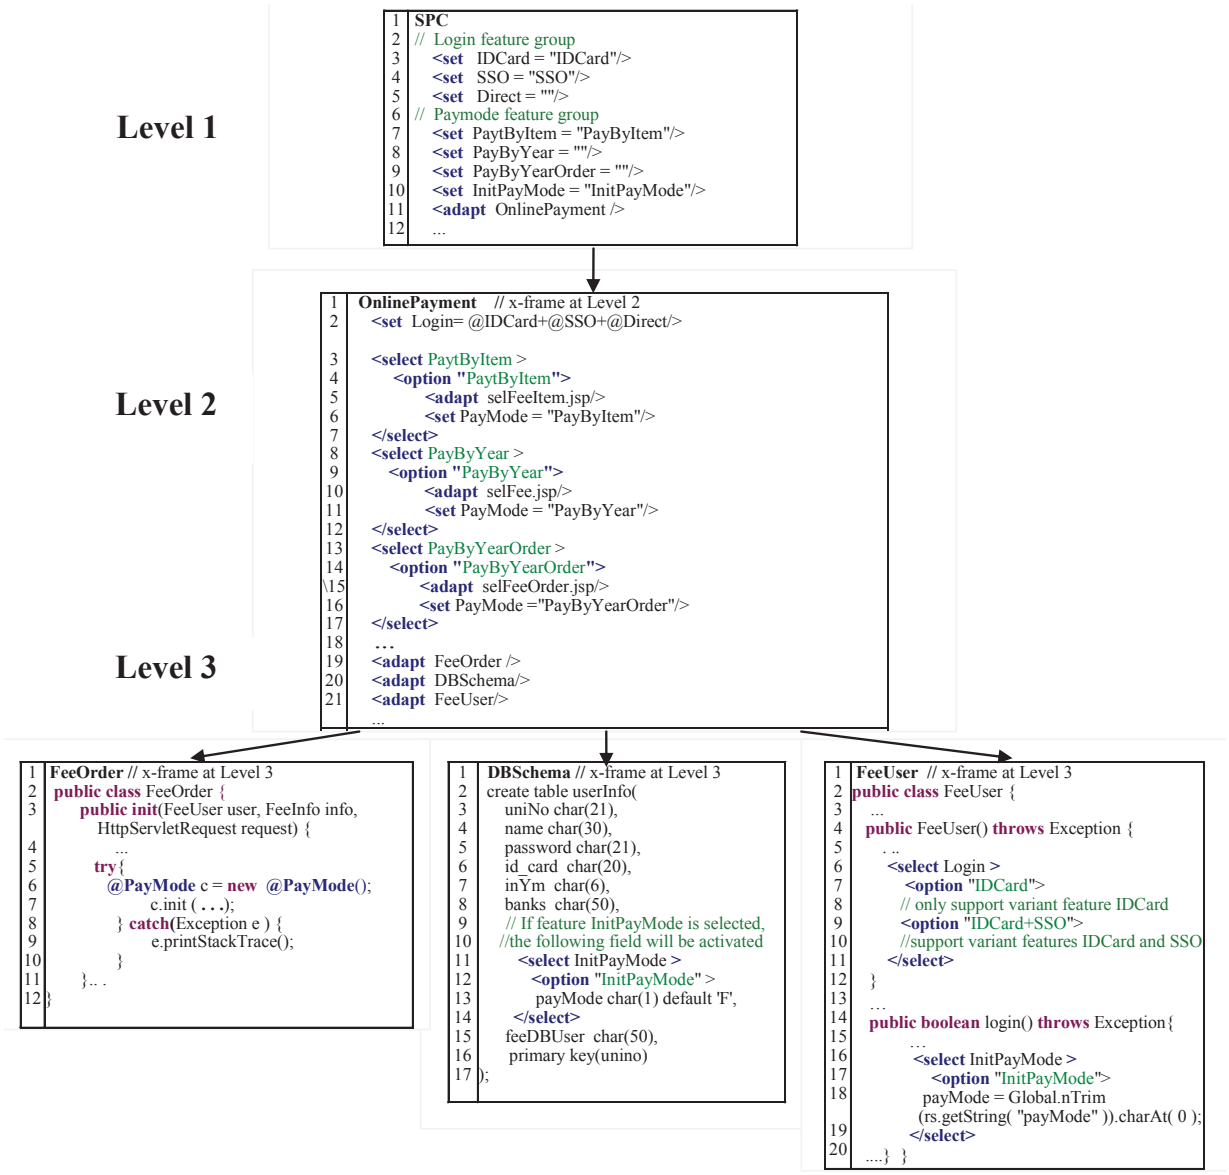

Fig. 5. Detailed view of WFMS core assets in XVCL

IV. Evaluation

What are the implications of replacing multiple variation techniques with a single one on SPL productivity? To answer this question, we conducted lab studies and collected inputs from Fudan Wingsoft Ltd. regarding the original WFMS core assets developed by Wingsoft using multiple variation techniques, and core assets in XVCL. Below, we comment on productivity during domain engineering (i.e., building and evolving core assets), and product derivation.

A. Domain engineering effort

The original WFMS core assets were built by gradual re-engineering of existing WFMSes. Core components and their interfaces were stabilized first, and then variation techniques were used to prepare them for ease of customization, as described in Section II. While it is difficult to precisely determine the effort to build core assets, we obtained some relevant information from Wingsoft engineers who were involved in re-engineering. Selecting suitable variation techniques for various features was not difficult for experienced engineers. Also, each step of applying variation techniques was quite simple. New staff joining the Wingsoft team had little difficulty to understand the variation techniques used in WFMS core assets and their role. However, some problems could be observed during evolution of the WFMS core assets. When multiple variation techniques were used together to implement a variant feature, it might not be clear how to find all the relevant variation points, and understand the exact interplay between variation techniques. Still, given the size of WFMS core assets and relatively small number of features, the solutions adopted by Wingsoft team were considered to be adequate for the purpose.

To get insights into the effort of unifying multiple variation techniques with XVCL, one PhD student and one developer re-engineered the original WFMS core assets into XVCL representation. PhD student was an XVCL expert, and the

developer was a WFMS expert, also participating in maintenance of the original WFMS core assets. It took two weeks for them to replace multiple variation techniques with XVCL in core assets for TMS subsystem. Applying XVCL was greatly simplified, as core assets were already in place, and they preserved most of the variation points. The main task was to work out overall XVCL controls and then to replace multiple variation techniques with XVCL commands at respective variation points.

Evolution of core assets involves adding new features and modifying features. The effort to evolve core assets depends on the number of variation points involved in change, and the complexity of finding, analyzing, changing variation points and tracing the impact of change. While the number of variation points in both solutions is almost the same, we assume that evolution of XVCL solution is easier than evolution of the original solution. This is due to uniform treatment of features, formal links between all the variation points relevant to a given feature, and feature query system [10].

B. Product derivation and maintenance effort

Deriving new products includes reuse of existing features, modifying features, and implementing extra features required by product customers. Similarly, the effort of each such task depends on the number of variation points involved in product customization, and the complexity of finding, analyzing, customizing variation points and tracing the impact of change.

Table I summarizes statistics relevant to product derivation effort. "Managed variation points" means variation points that have to be revised manually when reusing or modifying features. "Managed variation points" is a subset of all the variation points at which one feature affects core assets. For example, among core assets affected by feature *InitPayMode* are Java files and DB schema files. To reuse this feature in the original WFMS-PL, all affected files need to be manually changed. In the XVCL solution, once we <**set**> value of XVCL parameter **InitPayMode** in **SPC** (Fig. 5), all the customizations for feature *InitPayMode* spark from there, can be found by feature queries, and automatically performed by the XVCL Processor. Therefore, feature *InitPayMode* requires only one managed variation point in XVCL solution.

TABLE I. MANAGED VARIATION POINTS

	#variation points	#managed variation points	# files containing managed variation points
Original WFMS core assets	275	126	31
XVCL WFMS core assets	275	40	6

As another example, core assets affected by feature *Settlement* include seven Java files, four JSP scripts, one configuration file, and one file containing DB schema, totally 13 variant points. To reuse feature *Settlement* in the original WFMS-PL, we must customize code at 8 managed variation points handled by conditional compilation, comments and Ant. The location of managed variation points as well as relationship among them is not formally captured, therefore must be communicated via external documentation or re-discovered when needed. In XVCL solution, for the same feature there are also 13 variation points, but only 3 managed variation points (XVCL parameters for **Settlement** and for two dependent features). All the variation points are inter-linked via relevant XVCL parameters <**set**> in **SPC**, and reuse of the feature is automated by the XVCL Processor.

C. Other inputs from Wingsoft

Besides the above comparison study, we also collected some feedback and comments on the XVCL solution from interview with several Wingsoft engineers.

Comments on code readability. Both XVCL representations and the original final-boolean conditional compilation and commenting out applied variation techniques to embed fine-grained feature code in the code of core assets at relevant variation points. Wingsoft engineers reported about 30% of code in class FeeOrder, 20% of code in FeeInfo and 35% of code in FeeUser was managed by final-boolean conditional compilation and commenting out (the respectively similar percentages managed in XVCL representations).

Comments on copyright protection. In the original WFMS core assets, run-time binding variation techniques such as design pattern and configuration parameters are widely used. Therefore, Wingsoft engineers often included unnecessary feature code into a custom product release because of the characteristics of runtime variation binding and also time involved in feature removal. When extra functionality is contained in files that are released in readable form (e.g., JSP or XML configuration files), this practice can sometimes create copyright problems, as other customers may use extra functionality that was not meant for them or not included in their licenses. In XVCL, unwanted features are never included into a custom product, as the job of feature manipulation is consistently and automatically done by the XVCL Processor. Other than protecting copyrights, such precise and flexible control over feature inclusion/exclusion to/from custom products also matters in situations when we need to build highly optimized products, for example embedded software.

D. Evaluation summary and comments on relation work

Overall, it was felt that for small-to-medium systems such as WFMS (around 50KLOC), adopting multiple variation techniques is still practical. Variation techniques used in the original WFMS are simple and known to most of engineers. They came into engineers' mind naturally, could be applied on the fly during core asset design, with minimum disruption of conventional programming. Multiple traditional VTs provide an elementary infrastructure for SPL support. Handled by the experienced engineers, the original WFMS core assets serve well for the derivation of almost 100 product variants.

As the size of core assets and the number of variant features grows, and feature interactions get more complicated, problems may show up. Feature reuse and maintenance may become more complex because of the many variation points at which feature code needs be understood. Manual customizations become time-consuming and error-prone, even for skilled domain engineers. Then, it may be worth to consider migrating to a uniform variation technique such as XVCL.

In XVCL, for a feature reused as-is we need small number of managed variation points, at which we <**set**> XVCL

parameters for that feature and its dependent features (in **SPC**). All the variation points for a given feature are formally linked to XVCL parameter representing that feature. The ability to locate and analyze traces of customizations for each feature helps developers reuse and modify features with less errors and unwanted side-effects as compared to working with the original WFMS core assets. Reuse is automated by the XVCL Processor.

However, the adoption of XVCL is not without pitfalls, some of which XVCL shares with other variation techniques. Much of the code of features still remains tangled with core assets, affecting readability. This is a big problem, but so far alternative approaches based on specification-based variation points such as AOP [13] or FOP [3] failed to provide an effective solution to fine-grained feature management in SPLs [11] [12] .

Industrial tools such as GEARS [4] and pure::variants [14] could certainly manage the WFMS SPL. However, we do not have hands-on experience with those tools or specific studies to provide detailed comparison. GEARS can handle configurable software artifacts – such as source code, test cases and requirement documents. Its capability is similar to the XVCL. Pure::variants captures the problems (*family model*) and the solutions (*variant model,* which records the customized feature models for product variants) separately and independently, to reuse the solutions and the feature models in new projects.

The new emerging academic tool FEATUREHOUSE [1], in virtue of the FST, the direct annotation in artifacts is avoided and the readability is not undermined. The trade-off is that it has to integrate the various adapters and computation rules for the different languages. Since no annotation inside the artifacts for feature code at arbitrary granularity, we find that FEATUREHOUSE has to adopt hook a method to deal with the fine-grained impact of features. Compared with XVCL, FSTCOMPOSER in FEATUREHOUSE is flexible in supporting additional features. It cannot really change an existing fragment. But XVCL is more flexible in what can be variable.

V. CONCLUSION

This study was conducted jointly by Fudan Wingsoft Ltd., and researchers at Fudan University and National University of Singapore (NUS). Our earlier study of a Wingsoft Software Product Line (SPL) revealed that applying multiple variation techniques poorly scale to larger SPLs. In particular, it may become increasingly difficult to find and understand feature code scattered through core assets (so-called fine-grained features), and to coordinate changes at multiple inter-related variation points. Multiple variation techniques also hinder readability, reuse and evolution of core assets heavily affected by fine-grained features.

In this paper, as a remedy to the above problems, we presented an approach based on a single, uniform variation technique of XVCL, capable of managing both fine-grained features, as well as features whose impact requires customizations at the product architecture/component level. We evaluated the XVCL-based product line representation in lab experiments, and in Fudan Wingsoft Ltd, a company that initially used multiple VTs and then applied XVCL.

An SPL in our study was small, with only 39 features. Feature dependencies were few and feature impact on core assets was not very complicated. Still, we could sense some of the above problems. However, as the impact of features on core assets accumulates and gets more complex, understanding and synchronizing multiple, poorly compatible variation techniques may become difficult. Other SPLs may contain much larger code base in core assets, with hundreds or thousands inter-dependent features [6]. We believe that in case of such SPLs, the problems reported in our study are bound to become more severe, and a single variation technique approach even more attractive.

***Abstract*—Software Product Lines Testing has received special attention in recent years, due to its crucial role in quality and also due to the high cost this activity poses. In this effect, to make testing a feasible activity, some improvements are required. This paper presents a process for testing product lines, designed based on the gaps identified by a systematic mapping study, performed in order to understand the current scenario in this research field. An experimental study was performed in order to evaluate the proposed process in terms of understanding the role of a structured testing process in a SPL project.**

Keywords- Software Product Lines; Software Testing; Software Process; Software Reuse.

I. INTRODUCTION

Testing can be considered one of the most effective methods of quality assurance [1]. However, the state of software testing practice is not as advanced in general as software development techniques and, the same holds true for Software Product Lines (SPL) [2]. Although a number of studies can be found in recent literature on SPL Testing, including definition of processes, methodologies, modeling strategies, and other topics, it is not clear how to effectively apply testing in a coordinated, timely and cost-saving manner, together [3][4].

From an industry point of view, the growing SPL adoption points to the need of more efficient and effective testing approaches, since testing is still a difficult, expensive and challenging process, more explicitly due to the presence of variability, which hinders the way software is tested [5].

Such statements are based upon the results of a systematic mapping study performed by the authors in order to understand the current state of the art and practice of this field [3]. This study involved the investigation of 120 research papers, dated from 1993 to 2009, published by the most important vehicles in the computer science field.

The study describes that existing research on SPL testing addresses a diverse range of topics [3]. Special attention goes to the huge lack of *empirical research*, seeing that proposed techniques are mostly novel and have usually not yet been implemented in practice. Although *solution proposals* are very common in the literature, they are usually not process-centered, that can be largely applied to different context and projects. In addition, reported *proposals* do not care about *evaluation research*. Researchers are not also concerned about *experience reports* on their personal expertise using particular approaches. Practitioners in the field should report results on the adoption, in *real projects*, of the techniques proposed and reported in the literature. In addition, authors should express opinions about the desirable direction of SPL Testing research, expressing their experts' viewpoint.

Our findings are in line with a similar study [4], which also surveyed existing research on SPL testing in order to identify useful approaches and needs for future research.

Based on the findings [3], we decided to initially work in the definition of a structured process to support testing in SPL projects. The proposed process is composed of a set of activities, tasks and roles, encompassing the both SPL phases [6]: *core asset development (CAD)* and *product development (PD)*. We believe that such effort can be an initial endeavor to filling out the gaps of existing approaches, enhancing the SPL testing practice.

An empirical evaluation was performed on the basis of the proposed process. It consisted of an experiment, performed on the unit test level of the process. It involved 30 undergraduate students. Statistical techniques were applied to analyze gathered data. Our decision about including only one test level was based on the idea of incremental construction of knowledge about the role of testing procedures for SPL. We believe that solving every step once at a time could raise better results and accordingly we could extract more detailed feedback.

The remainder of this paper is structured as follows: Section II outlines the research field. Section III describes the proposed approach. Section IV presents the evaluation performed. Section V gives an overview about related work and finally Section VI concludes the paper and outlines future work derived from this research.

II. TESTING IN SOFTWARE PRODUCT LINES

Among the aspects that differentiate testing in single systems development (SSD) and SPL, ***variability*** should be mentioned as the most important issue to be handled, since its exploitation can lead to a huge combinatorial explosion of configurations a system can support. It directly reflects in the testing activities, because the large amount of variability in a product line increases the number of possible testing combinations.

Indeed, testing all combinations is almost impossible in practice. This is the main reason for some authors to consider testing as the bottleneck in SPL, since the cost of testing product lines is becoming increasingly more costly than in SSD [7]. High cost makes testing an attractive target for improvements [8].

In this effect, a systematic testing approach can save significant development effort, increase product quality and customer satisfaction, and also lower maintenance costs. Hence, techniques that consider variability issues and coordinate testing activities are desirable.

A systematic approach for testing has to consider the both SPL phases, *CAD* and *PD*, in which in the prior the assets are designed and built considering the possible variable parts to be further reused, in the latter. In PD phase, products are instantiated, on the basis of assets from the core asset base. This strategy can foster reuse of assets. The systematic reuse of assets enables efficiencies in development time and cost. Creating document templates and abstract test cases may serve, for example, as a feasible strategy [8].

It is just as important to mention that the different test levels should be considered. The goals of *unit*, *integration*, *system* and *acceptance* testing levels should be combined with the goals of the SPL phases.

Evidences collected from the studies analyzed and reported in our previous work [3] points out that these mentioned aspects constitute the core elements when considering testing SPL.

III. RIPLE-TE: A PROCESS FOR TESTING SPL

In line with the results of the mapping study, through exploiting the gaps reported in the literature, we have devoted effort towards designing a structured process to support the test discipline in SPL projects. The design is based on the RiPLE - *RiSE Product Line Engineering* - project. This project is an effort[1] of developing a framework to support a set of disciplines that compose the lifecycle of a SPL, namely Scoping, Requirements, Design, Implementation, Testing and Evolution Management. RiPLE-TE is the name given to the test discipline in this framework.

Testing with RiPLE-TE comprises the core assets, product specific assets, and the interactions among these. The process considers particularities of each of these SPL phases.

- In CAD, when assets have to be developed with a special attention to the forthcoming reuse, attention goes to the execution of *unit* and *integration* test levels.

In a first moment testing should be concerned about evaluating assets from its initial development effort. Hence, in RiPLE-TE the initial effort is devoted to *unit testing*. Components are here considered the *units*. Then, in order to ensure that a component may be further reused, it should be tested, under planned conditions. Although coupling and cohesion are considered the cornerstones in modular software development, provided by component-based development, in practice it is usual to work with tightly coupled units. In these cases, after performing unit tests in a component, and ensure that it fulfills what it was specified to, *integration* tests are then performed.

These levels are responsible for detecting different types of faults. While unit testing independently tests methods, classes, and the interaction among these pieces that comprises a component, whereas integration testing is responsible for testing the interaction among components interfaces and the integration between modules.

- In PD, *integration*, *system* and *acceptance* testing is performed, based on the assets previously developed and tested. In special cases *unit* tests can also be performed in PD, as explained next. The purpose of such a division is linked to the role of testing in every phase, as advocated by other approaches, e.g. [8].

Integration testing is the first level to be performed. The point is why to perform it again. Given that the purpose is to avoid repetition and thus consequently reduce the overall testing effort, in CAD it is only performed the integration between tightly coupled units, regardless integrating the whole set of components. It regards the behavior of the core asset base, in which there are several components, attending to a diverse range of variations, that not necessarily integrate with each other, but indeed should be ready for instantiation in PD. This is when integration testing in PD takes place.

In PD, the integration test of the components that will comprise a product is performed, in order to ensure the workability of the interconnected modules as well.

Next, *system testing* is performed. This level is then focused on evaluating the product as a whole, intended to detect system architectural and/or end-to-end defects. At this point, testers evaluate the system against system requirement specification.

Acceptance tests are carried out after system testing, in order to gather customer feedback on the product just instantiated. It is more a demonstration to user that intends to show that the product does what is expected.

As mentioned before, *unit tests* may be performed in PD. It may happen whenever a new requirement or feature that does not belong to the core asset base yet is probably to be included in a specific product. As this new artifact is built, unit tests have to be performed. Then, the remaining levels should also be performed, considering the new artifact. After that, the new "asset" can be included in the core asset base, and be used in next products, thus motivating reuse. This way, we handle the *interactions between CAD and PD*, as previously stated.

RiPLE-TE is indeed not focused on evolution issues, as the probable "propagation" of assets from PD to CAD afore-mentioned. The boundary between testing and evolution is rather supported by another discipline in RiPLE, the RiPLE-EM (Evolution Management) [9].

The main workflow of RiPLE-TE is presented in Figure 1, which represents both SPL phases and associated levels. Feedback is a closure activity common to all these levels.

[1] RiPLE is a RiSE project - http://labs.rise.com.br/

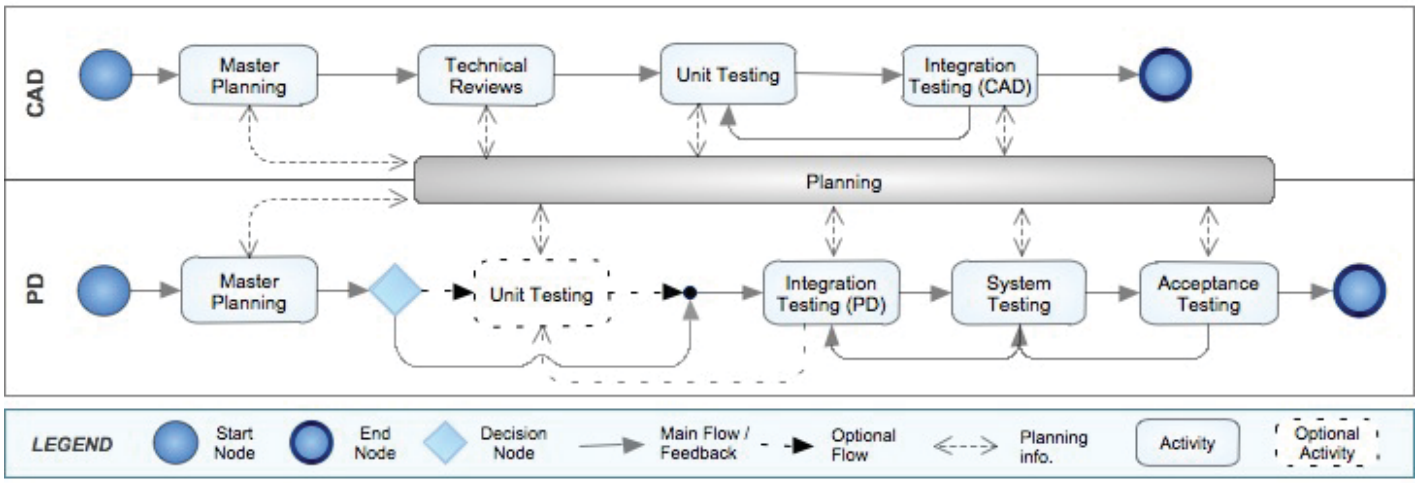

Figure 1. RiPLE-TE CAD and PD Workflow.

This Figure shows the activity *master planning* as the initial point in both CAD and PD. It refers to the development of a *Master Test Plan*, artifact responsible for orchestrating the whole testing activity. This plan is based on [10], and defines: *how testing will be done; who will do it; what will be tested; the coverage criteria;* and *schedule associated with.* As all levels should be planned, not only in the beginning, Figure 1 includes a support activity called planning, linked to all activities, to illustrate the need of performing the activities in a coordinated manner, following a plan that can be continuously updated.

Furthermore, it is desirable that project members can detect and get rid of errors/defects early in the life cycle, even before any code is available [11]. In CAD the activity *technical review* is responsible for reviewing the main assets of a SPL project that directly impacts the testing activities, such as: *Feature Model, Product Map, Requirements (and Use Cases), Feature Dependency Model,* and *the Architectural Document (Design)*. This activity should be performed before starting the tests.

In overall, testing in CAD tries to minimize the PD testing. It can be achieved through preserving variability in core assets. Knowledge produced in the CAD testing can be reused in PD testing, which may reduce the effort of building assets. This will be detailed next.

A. Managing Test Assets Variability within RiPLE-TE

In all activities mentioned from both CAD and PD testing, each level encompasses four main tasks: *planning*, *design*, *execution* and *reporting*. Figure 2 shows the process workflow, which also includes the notion of Change Requests (CR), which is handled by RiPLE-EM. In decision node 1, if any error was found during execution that needs to be supported by a CR, RiPLE-EM discipline is invoked.

The feedback flow represented in the Figure referring to the decision node 2 asks whether the coverage criteria defined in planning was achieved. If yes, then the flow gets to the end node. Otherwise, planning is revisited and the main flow is performed again.

Although the remaining flows are presented as sequentially initiated, this is an iterative and incremental activity, with feasible feedback connections enabling refinements.

Due to limitation constraints in this paper, the complete and detailed list of steps, artifacts, input, outputs, and roles associated can be found at the RiPLE website[2] and also in [12], the M.Sc. dissertation this work is associated with. Our proposal indeed does not introduce new terminologies for testing, but rather tailors existing patterns [10][13].

The management of assets in RiPLE-TE is defined under the idea that every test case created may represent variability. Our previous effort was to define a meta-model in order to capture the relationship among the artifacts created in a SPL project [14]. In the metamodel, the RiPLE-TE works mainly in the relationship of use cases and test cases.

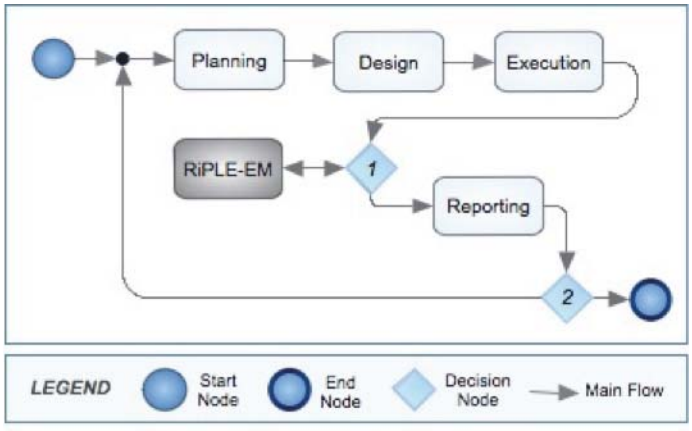

Figure 1. Testing Workflow.

In the test model, test cases are considered the main artifact to be handled. Every use case supports one or more test cases. The use case elaboration expands on the abstract use case

[2] http://riselabs.dcc.ufba.br/riple/

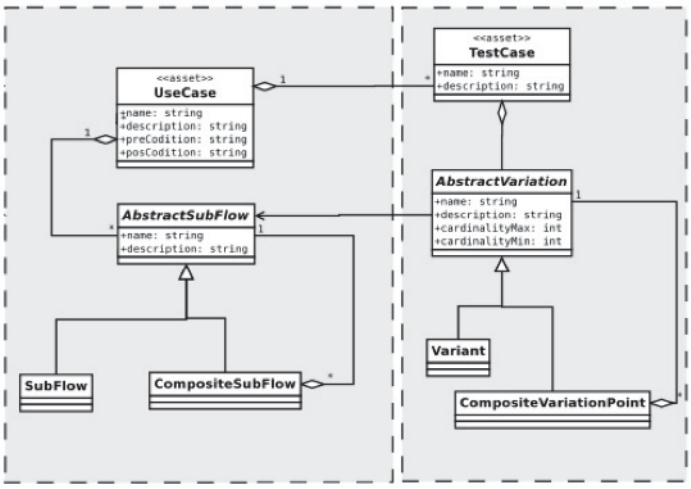

Figure 1. An excerpt of the metamodel [14].

definition, in which variability is represented in the use cases. A use case is composed by the entity *AbstractFlow* that comprises the sub entity *Flow*, which actually represent the use case steps. Every step can be associated with a sub flow that can represent a variation point. Figure 3 shows an excerpt of the metamodel.

Reuse is encouraged in a sense that, both use cases and test cases are composed by fragments. Each fragment represents a recurring set of interactions required to achieve a sub-goal. As each fragment deals with some specific sub-goal, it can be customized and fit variation point needs. This strategy is built on the work described in [15]. Dependencies among fragments in test cases and use case can be tracked.

A tool has been under development that will support the RiPLE-TE, but so far we have only counted on manually performed tasks.

IV. INITIAL EVALUATION

This initial evaluation was focused on trying to understand the role of unit testing in SPL, using the RiPLE-TE, according to the process defined in [16].

A. Definition

Based on the GQM [17], the experimental study goal was to analyze *the RiPLE-TE Process, Unit Test level for the purpose of evaluation with respect to its effectiveness and to identify which professional skills have impact on the test activity results from the point of view of the potential users in the context of a SPL testing project at the University.*

We were intended to answer the following questions:

- ***Q1.*** *Do the quality of detected defect improve when the process is followed?*
- ***Q2.*** *Does the rate of defect detection increase when the process is followed?*
- ***Q3.*** *Does the test coverage rate increase when the process is followed?*
- ***Q4.*** *Which professional skills have influence on the results of the testing activity?*

Since the literature [3][4] does not provide metrics directly associated to SPL testing, we applied known practices from SSD testing, with some adaptations to reflect SPL issues.

- ***M1. Test Case Effectiveness (TCE):*** the ratio of the amount of defects reported (D_{tot}) to the total number of test *cases* (N_{tc}). *TCE* metric validates the effectiveness of functional test cases. This metric refers to *Q2* and *Q4*. Defined as: $TCE = (D_{tot}/N_{tc}) \times 100$.
- ***M2. Quality of Defects Found (QDF):*** the number of valid defects found, normalized to Difficulty (DD) and Severity (SV) *values*. Every defect is valued with a coefficient (*k* and *r*) according to its DD and SV. *M2* refers to *Q1* and *Q4*. Defined as: QDF = k.f(DD) + r.f(SV).
- ***M3.Test Coverage (TC):*** gives the fraction of all features (or requirements/use cases) covered by a selected number of test cases or a complete test suite. Coverage (C_{ov}) was, in this study, generated by the *Eclemma* code coverage tool, and JUnit framework. *M3* refers to *Q3* and *Q4*. Defined as: TC = C_{ov}.

B. Preparation

Design. *One factor with two treatments*. We compared the two treatments against each other [16]. Factor in this experiment was the *RiPLE-TE unit testing process* and treatments were: (1) *Testing with the process*; and (2) *testing without it*. The participants were divided in two groups, in which one performed testing using the process and the second performed in an ad-hoc fashion.

Experiment materials. Objects used in this experiment was as follows: *Consent Form, Background Questionnaire, Test Assets and Component Source Code, RiPLE-TE Documentation - including guidelines and usage samples, Error Reporting Form, Feedback Questionnaire*. A copy of common artifacts was provided: *master test plan, unit test plan template, feature model, project code - components to be tested and specification - requirements and use cases*. *Error reporting forms* were also provided.

All participants signed a **consent form**, as a means of agreeing to join the study, and filled in a questionnaire, with their background information, the **background questionnaire.** They provided information about their experience with software development, SPL, testing, and the tools required by the experiment, and expertise in industrial projects.

There were designed three types of **feedback questionnaire**: (a) addressed to the group that did not use the process; (b) another to the group that applied the RiPLE-TE. The questionnaires were designed to provide information on the use of the approach, through gathering information about the participants' satisfaction; (c) designed to gather feedback on the subjects that did not use the process, regarding their opinion about the possibility of finding more defects, if they had used the process. This was answered after the last training session, when the RiPLE-TE was addressed.

Hypotheses. The Null Hypotheses are stated considering that there is no benefit of using the process (*RP*), if compared to ad-hoc testing (*AH*), in terms of effectiveness. They are:

H_{01}: $\mu TCE_{AH} \leq \mu TCE_{RP}$

H_{02}: $\mu QDF_{AH} \leq \mu QDF_{RP}$

H_{03}: $\mu TC_{AH} \leq \mu TC_{RP}$

Conversely, alternative hypotheses state the opposite values. Due to space constraints, we omitted them.

Variables. Dependent variables were the metrics TCE and QDF. The independent variables were the background information of the participants, due to our intention of evaluating the effectiveness of the proposed approach and to identify which skills could interfere in the results.

Project. It was chosen a SPL project in the domain of conference management. The goal of the project is to develop the *RiSE Chair* product line, targeted at the submission/ management of papers in conferences, journals, and others, including the control over the review life cycle. The RiSE Chair platform was based on commonality and variability among systems such as: *EasyChair*, *CyberChair* and JEMS[3]. The project is composed of 41 features extracted from the scoping analysis of such systems. The code was developed in the J2EE platform, with Spring and Hibernate, implementing variability in 8 core components.

Participants. 30 undergraduate students taking a V&V course, from Computer Science department at Federal University of Bahia, Brazil. This course is targeted at last year undergraduate students. All students had previously enrolled in courses on OOP, Java, and Testing.

C. Execution

The experiment was conducted from November to December in 2009, according to the definition and planning documented. From the amount of components of the developed SPL, we selected one feature, with its variants, and dependencies, to our experiment.

Participants were said for not to implement new features, but rather analyze the components they were given and implement the test cases to evaluate existing assets.

D. Analysis

Test case effectiveness. In terms of valid defects found, in group 1 (G-1) (without run the process), the *mean value* was 6.188 with an *standard deviation (sd)* of 3.187, while in group 2 (G-2) (with the process), the *mean* was 3.857, with a *sd* of 3.505. Regarding designed test cases, in G-1 the *mean* was 10.38 with a *sd* of 5.137 and 8.143 with a *sd* of 3.670 in G-2. By applying the TCE formula, the *mean* in G-1 was 0.725 with a *sd* of 0.540. In G-2 the *mean* was 0.425 with a *sd* of 0.353. *Median* of G-1 was slightly greater than in G-2.

Quality of defects found. What we mean by defect category refers to defects found that, although described in many different ways, they expressed similar problems in the code. We arranged these similar problems into categories. Then, we identified 12 groups of defects, and classified them according to associated Difficulty (DD) and Severity (SV). The classification was done based on a discussion performed with experts, considering their industry expertise. Each group of defect was assigned to a coefficient. As there were no baseline values to these coefficients, we performed PCA calculations [18], to identify such values. These formed the elements to calculate the score of quality. As result, the *mean* in G-1 was 8.868, and a *sd* of 3.896; in G-2 the *mean* was 6.048, and a *sd* of 5.302.

Test Coverage. While in G-1 the *mean* was 0.663 with a *sd* of 0.136, whereas in G-2 the *mean* was 0.630 with a *sd* of 0.364.

Hypothesis Testing. Regarding *TCE*, t-test (unpaired, two-tailed) was applied and resulted in a p-value higher than 0.05, which indicates that the Null Hypothesis H_{01} could not be rejected. H_{02} could not also be rejected, since calculated p-value was higher than 0.05. Thus, we can conclude that there was no gain using the process instead of an *adhoc* fashion, regarding *QDF*. TC_{ov} presented apparent similar values, but when applying t-test in this sample resulted in a very high *p-value*, which lead us to conclude that means are extremely different. In TC_{ov}, then, we could not draw conclusions.

Interpretation. Considering absolute values, the results presented insights that enabled us to infer that unit testing in SPL does not have impressive differences if compared to SSD, since practitioners which did not have experience in SPL projects had slightly better results than others who applied a formalized process. However, the model extracted from the multivariate regression analysis (MRA) [18], which correlated all variables, did not return satisfactory results, in a sense that, much was collected but a very small amount of variables impacted the results.

The insights served as a first step towards defining, and in long-term, refining, a process for testing SPL. Moreover, although the results have presented results very different from expected, in terms of the use of a formalized process for SPL, this experiment served for us to sketch models using MRA, and to define baselines for future experiments.

V. RELATED WORK

In [19] an approach providing a method to derive scenarios to be tested is proposed. It deals with textual use cases as the central development artifact. Use cases are extended with tags, which describe the variability. Test specifications containing variability are derived from these use cases. It handles how to manage variability and how to instantiate test cases for a specific product.

In [20], a method for automatic generation of test cases associated to specific products is provided, from sets of incomplete and generic scenarios associated to a product line. They propose a two-step process, from test requirements to product-specific test cases. From use cases, they structure scenarios to produce reusable test patterns common to an entire product line and represented using the UML. When the final design is available and a product is chosen as test target, test cases for that particular product are synthesized.

In [21], an approach to support the systematic reuse of assets for system and integration testing of SPL is provided. It describes test cases from requirements, by using UML activity diagram to represent all possible use case scenarios for a use case.

These are representative approaches to the field, but they have limitations that prevent their larger application. They do not provide elements of software process, encompassing the

[3] http://submissoes.sbc.org.br/

whole life cycle and the SPL phases. Besides, little is reported regarding validation. Only [21] did it. However, replications would be difficult since no details but rather only the results are described. It does not invalidate the proposed process, but it may be infeasible to implement it in contexts other than what was reported. Hence, more practical evidence is required.

In our proposal, we use the test case generation methods from these approaches, since we considered them as well defined practices, but we also give details that are not provided by them, in terms of activities sequence, inputs and outputs, and so on.

VI. Concluding Remarks and Future Work

In this paper, the RiPLE-TE process for testing SPL has been introduced as a process-centered strategy to coordinate the testing activities. It was designed based upon results gained from a systematic mapping study performed aimed at providing evidences about this research field and sketch a set of open rooms for improvement [3].

The RiPLE-TE process was based on best practices reported in the literature, and focused on a direction that no existing approaches had been concerned about, the coordination of test activities in the whole lifecycle and the SPL phases. This way, our proposal works out as a complementary solution to existing ones.

In addition, based upon the underlying assumption that effective processes are required due to the additional complexity of testing SPL because of assets variability [3], we designed an experiment in order to investigate such assumption through evidences. Hence, our initial evaluation was focused on understanding the role of RiPLE-TE process, unit test level, in a SPL project. This served as an initial step towards clarifying peculiar characteristics of different test levels in a SPL project. A formal basis of experimentation was applied in this work [16].

We have been working towards incrementally building knowledge about the role of testing procedures in SPL. Thus, as future work we are intended to empirically investigate other test levels, based on this proposed process and also making comparisons with approaches that support other levels. Besides, we are also intended to investigate how variability affects test cases and explosion of test cases, and how we manage that and how we organize SPL test cases. Our model for representing test assets and their interaction with other artifacts [14] was a first step towards such understanding.

***Abstract* – The constant changes and the search for new benefits in the software industry make possible the emergence of new research areas. In this context, a trend that has presented important benefits is the area of agile software product lines. Software Product Lines (SPL) and Agile Methods (AM) both search to satisfy the customer, increase quality and decrease time-to-market and costs. The integration between SPL and AM is a challenge, but can increase the benefits that these approaches offer. In this sense, this paper proposes an agile scoping process for SPL.**

Keywords – Scoping, Software Product Lines, Software Process.

I. INTRODUCTION

The main aspect for software development processes adoption, with objects or not, is the idea of reuse. The idea is to build software across the use of existing artifacts or knowledge.

The implications for decreasing development time and costs and quality increase make the reuse approach highly attractive. In this context, one of the reuse approaches with significantly and increasing success is Software Product Lines (SPL) [5].

In order to obtain success in the SPL development, the planning should be made carefully. The planning performed in the initial phase of software product lines development is called *scoping*. Product lines scoping is the phase by which information used in software systems development within a domain is identified, captured and organized with the purpose of making it reusable when building new products [2]. The literature has highlighted the importance and benefits of scoping for the product line success [13][14][15][21].

On the other hand, another success practice in industry is agile methods that encourage strong business involvement in development activities, focus only on the requirements at hand with incremental planning and design. Initial evidences based on the results of ongoing research suggest that agile methods are advantageous, given the right context [3][6]. In spite of the differences, when compared to SPL, AM has the same overall objective: improve software development productivity. In this sense, recently, the community started to investigate if these approaches can be combined and how the agile aspects can be integrated in product lines processes for maximizing the benefits searched by product lines and agile methods [7][10] [11][18][19][20][24]. However, even with the initial efforts, specific areas have been few explored on this perspective, such as scoping. In this sense, this paper presents a scoping process for SPL based on some agile principles.

II. PROCESS OVERVIEW

For more than one decade, the SPL scoping has been investigated [5][8][13]. However, the studies do not address the issue "*how to perform systematic and agile scoping*" which starts a new research direction.

The importance of scoping to be systematic in SPL is based on the idea that it should manage variabilities and commonalities among several applications, factor which increases its complexity compared to traditional software development. Thus, in order to develop a SPL is needed systematic scoping to obtain positive results. On the other hand, as SPL scoping is totally defined up-front, it demands high effort and costs. In this sense, introducing agile aspects in SPL scoping enables to add agility for scoping decreasing effort and costs.

In this context, a systematic and agile scoping process with tasks, guidelines, inputs, outputs and well defined roles, incorporating agile practices in their lifecycle is important to decrease the risks related to product lines and decrease the effort and costs up-front.

Based on this scenario, this work presents RiPLE-SC, an agile scoping process for SPL. It is part of the RiPLE (The RiSE Process for Product Line Engineering), project that is being developed within Reuse in Software Engineering (RiSE) Labs[1] to develop a process covering the full SPL lifecycle.

RiPLE-SC is the first discipline of the RiPLE as can be seen in Figure 1 and has a direct relationship with the process of Requirements Engineering (RE), Risks Management (RM) and Evolution Management (EM) from RiPLE.

The RE activities are responsible for refining the scope, thus, the scope definition is a pre-requisite to start the RiPLE-RE which has the *Product Map* artifact (a matrix of features and products generated by the RiPLE-SC) as a mandatory input. The RM activities are related to the identification and management of the risks related to scoping as well as all the risks identified during the RiPLE execution. If some risk is identified, it is catalogued by the RM and techniques for risk management are applied to mitigate it.

The communication between SC and EM is performed by *Change Requests* and maintenance tasks in the artifacts created during the scoping phase. If some artifact of SC is incomplete

[1] http://labs.rise.com.br.

or inconsistent and it is discovered in some of the phases of the scoping process, the SC requests a change to EM. The EM analyzes the change and when approved, sends a task to SC.

In the composition of RiPLE-SC, there are phases related to tasks, roles and work products (inputs and outputs). The roles defined in the process are: **scoping expert** - responsible to conduct the scoping process, driving the workshops performed in the process; **customer** - it has critical role in the process and their presence is essential for that the product lines products present their real needs; **domain expert** - provides their knowledge on the domains and the products related to it; **market analyst** - provides knowledge on market analysis and can help in the identification of the domains and products more relevant for a determined market segment; **developer** - important for the *assets scoping phase*, where they define estimative related to effort; **architect** - responsible to indicate which features will constitute the reference architecture; and **product line manager** - responsible by providing the organizational goals.

Regarding the phases, they are iterative, incremental and clearly integrated with agile aspects, such as: review meetings to obtain customers' feedback; creation of user stories to obtain the real needs from the customers; pre-scoping meeting to gather the different visions of the stakeholders; and so on. The phases are discussed in details in the next section.

III. PHASES AND GUIDELINES

RiPLE-SC consists of four main phases that are performed in an iterative way to enable frequent feedback: ***(A) Pre-Scoping***, ***(B) Domain Scoping***, ***(C) Product Scoping*** and ***(D) Assets Scoping***. Besides, we believe that during the achievement of theses phases it is very important the use of *reflection meetings*, meetings that should be performed at regular intervals in order to discuss, what is good, what should be improved and what should be performed to improve, adjusting the behavior of the team adequately.

A. Pre-Scoping

This phase is composed of two tasks: *pre-scoping meeting* and *analyze market*. In it, relevant characteristics that will influence the next stages of the scoping process such as project vision, operational and organizational context, stakeholders and roles, business goal and market potential are identified.

1) Pre-Scoping Meeting

This task has as objective to identify general information related to: customer, team and organization. Moreover, this task aims to provide an initial contact between the customer and the project team and exposes the agenda that will drive the application of the process.

The identification of the information necessary from the customer, project team and organization can be obtained with the use of questionnaires and semi-structured interview that drive the *pre-scoping meeting*. The meeting is conducted by the scoping expert through informal conversation with the stakeholders, factor that encourages the customer collaboration in the project and the collaboration inside the team. The active involvement of the customer and the cooperation among all the stakeholders is essential for the success of agile projects [9]. Besides, the communication face-to-face is considered by the Agile Manifesto as the most efficient and effective method of conveying information in a project team.

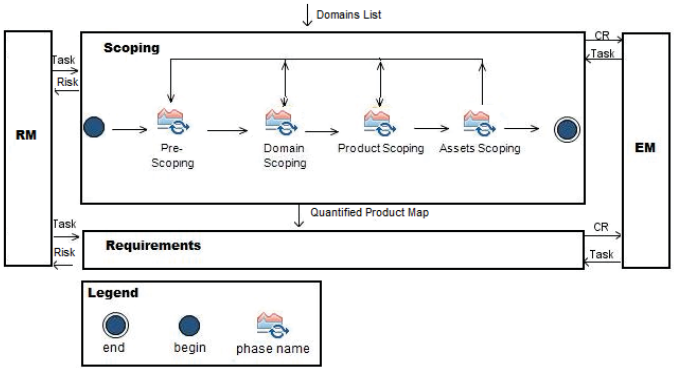

Figure 1. Relationship of the SC with RM, EM and RE.

Four steps should be performed in the *pre-scoping meeting*: *identify organizational context*, *identify operational* context, *analyze stakeholders* and *identify business goals*. For performing these steps, the *pre-scoping meeting* receives as inputs the *stakeholders' information*, which are related to information such as "what" are the expectations of the stakeholders for the SPL, "what is the profile of the project team" and in "which" operational and organizational context the project will be inserted; and a *domains list*, an artifact in which are defined the domains that will be analyzed in the product line. As output is produced, the *SPL vision*, where relevant information for the project, identified in the *pre-scoping meeting*, are documented.

a) Identify Organizational Context

It must capture context aspects of the organization for identifying how the activities performed during the identification of the scope will be influenced. Thus, the following aspects should be considered: **1.** *structure*, it is an aspect that can influence the planning of meetings and workshops. In the context of small organizations, the execution of an agile approach, i.e., focused on workshops integrated by all the projects stakeholders, makes possible the face-to-face communication, the collaboration among the stakeholders and consequently the decrease of documentation. On the other hand, in complex organizations, dates are harder to find and important experts might miss due to other obligations and sometimes it is not possible that all people meet at the same location [13], thus for mitigating these problems, we recommended the use of different ways such as workshops and individual interviews for communication and coordination; and **2.** *maturity*, it directly influences the problem understanding and consequently the agility in which the scoping process is performed. The knowledge of both, process and domain is fundamental for the best scoping result. Therefore, the maturity will determinate the need for trainings on the process and the investigation of documentation about the domains before performing the scoping process.

b) Identify Operational Context

The operational context has impact on the scoping planning, influencing the overall scoping process [13]. They drive decisions that affect all further scoping tasks. These decisions are exposed in the following aspects: **1.** *business constraint*, (e.g. time-to-market and resources) can affect the process lifecycle and the detail level of some assets. Furthermore, it influences on the choice of stakeholders, tools

and in the scope size. In projects where the time and the resources are limited, the team should commit oneself with a smaller scope; and **2.** *process*, the identification of the process used by the organization determines if there is a relationship between it and reuse practices. In cases where the organization presents reuse practices inserted in the current process, the adoption of SPL practices is easier, as well as the understanding of why specifics scoping tasks are performed.

c) Analyze Stakeholders

A stakeholder is someone who has a defined interest in the outcome of the project. In the RiPLE-SC, the choice of the stakeholders and their respective roles is performed according to the profile analysis of each stakeholder in the initial context of the product line.

A product line can start from the scratch, i.e. it can be introduced while some products are already under development, or its core assets can be reengineered from legacy systems. Thus, the initial context influences on the identification of the stakeholders and consequently in the scope definition, because it can present different information sources. In this choice is also considered the maturity of the stakeholders on the domains that will be analyzed in the SPL.

d) Identify Business Goals

In this step, stakeholders' goals are identified. RiPLE-SC considers that scoping is not only an economical activity, but also a social activity and, therefore, should be defined with the participation of each relevant stakeholder group for the SPL, making possible the identification of different views and business goals. In this sense, there are an arbitrary number of business goals for the product line development. However, according to the study on software reuse measurement based on experts performed by the RiSE Labs, the business goals most considered in organization that adopts practices of product lines are, respectively: *reduce costs*, *improve the productivity*, *improve the time-to-market*, *improve the quality*, *increase the company portfolio* and *gain new markets*.

2) Analyze Market

The systematic research and the analysis of external factors such as market segments and potential determine the success of a domain in the market. It involves the gathering of business intelligence, competitive studies and assessments, market segmentation, customer plans, and the integration of this information into a cohesive business strategy and plan [5]. Thus, the task *analyze market* aims to obtain information of the market segments in which the domains are inserted for identifying issues that can determine their success in the marketplace.

This task uses as input the *domains list* that will be analyzed in the product line and the *SPL vision*, producing as output the *business plan*. The *business plan* is a strategic plan that has information about the domains potential in the market, the market segments related, their sales channel and the factors that determine the success of these domains in the marketplace. The market expert performs this task.

B. Domain Scoping

A key question in developing a domain scoping process is: which set of factors can determine the domains and sub-domains of more potential? The answer for this question is to consider dimensions such as: maturity, volatility, market potential, reuse potential, risks, experience, coupling and existing code potential. These dimensions directly impact on the potential of a domain or sub-domain, for example, mature domains make possible easy access to documentation and the existence of reusable code is more probable. In this sense, the domain scoping phase of the RiPLE-SC combines the fundamental aspects for a success domain analysis.

The domain scoping of RiPLE-SC aims to analyze and discuss the domains and sub-domains among the projects members, considering points which aid in the definition of the most relevant ones. Moreover, this phase proposes the knowledge dissemination of the domain and sub-domain among the team, decreasing the need for documentation.

This phase is composed by the task *analyze domains*, which has as inputs: an already prepared list of domains, the *SPL vision*, the *stakeholders' knowledge*, relevant information of each stakeholder about the dimensions discussed, and the *business plan*. It produces as output: the *domains and sub-domains list*, which is composed by the domains and sub-domains of more potential for the SPL

1) Analyze Domains

In the RiPLE-SC, the task *analyze domains* as well as the other tasks of the process is iterative and incremental. Therefore, in each iteration, new information can be searched and thus evidenced the need of inclusion or exclusion of some domain. For example, it is common that in the definition of the products, new domains are identified and thus an analysis of these domains should be performed. It is possible also that with the prioritization of the features, a domain is considered dispensable and excluded.

The domain analysis of the RiPLE-SC uses the workshops culture in its execution, i.e., all steps of the task *analyze domains* are performed in the workshops format, mediated by the scoping expert. The workshops are a fundamental resource from agile methodologies for maintaining the integration in a team. Moreover, it allows that the stakeholders of the project discuss several aspects expressing their viewpoints.

The domain analysis workshops proposed in the RiPLE-SC makes possible the communication face-to-face and the collaborative work between business and technical people. It has as goal to identify the domains and sub-domains more relevant for the product line. In addition, this analysis requires a clear understanding of the stakeholders that integrate the workshops of the domains, because the agility can be negatively influenced when the stakeholders do not have experience with them. Thus, before the beginning of the domain analysis, the participants should explore information on the domains that will be analyzed. This information can be obtained from: project plans, user manuals, modeling, data dictionary, existing applications and knowledge from domain experts.

Four steps should be performed in the task *analyze domains*: *review domains*, *identify sub-domains*, *analyze sub-domains* and *prioritize domains* and *sub-domains*. These steps are discussed in the next sections.

a) Review Domains

In this step, the objective is to discuss general characteristics of the domains, making possible to align the knowledge of the stakeholders regarding them. The review of

each domain is performed in pre-determined timeboxes. The timeboxes are time interval which cannot be exceeded. With them is possible to limit the time of the analysis and maintain the focus on the workshop. In the review, the stakeholders should express their understanding on the domains, enabling them to identify new domains, exclude existent ones or maintain the initial set of domains.

b) Identify Sub-Domains

A domain can be composed by a big number of systems. Furthermore, the identification of "what" is *in* and *out* in a given domain depends on the vision of specialists and stakeholders in general, because each one has their particular interests. Thus, the division of the domains in technical sub-areas (sub-domains) makes possible a deepened analysis of each individual area of the domain, facilitating the choice of the areas where the reuse is adequate and where the economical potential is most suitable.

The sub-domains definition is performed in brainstorms sessions. These brainstorms provide an opportunity for the stakeholders, together, gather information about their needs and expectations regarding to key sub-domains that are of particular concern to them. In this step, is important also that the team is aligned with the customer' needs and the product line as whole. Thus, the knowledge of domain experts and market experts is determinant to drive the team in the choice of which sub-domains are more relevant for SPL and their customers.

c) Analyze Sub-Domains

In this step, each sub-domain is individually discussed by the stakeholders concerning the relevant dimensions previously defined for the analysis. Thus, considering the different visions of the stakeholders, a conclusion about each dimension evaluated in each sub-domain is performed. The following dimensions are considered in the analysis: **1.** *experience*, it indicates the level of knowledge that the participants of the workshop have on the sub-domain; **2.** *risks*, they are identified and analyzed to determine the negative impact on the sub-domain. In the analysis, the risks are prioritized according to the perceptions of the team about their severity; **3.** *volatility*, it determines if the sub-domain changes with the time. **4.** *maturity*, it determines if the sub-domain is stable; **5.** *code potential*, the code existence facilitates the understanding of the sub-domain and aids in the development; **6.** *market potential*, it identifies which sub-domains can obtain greater economical return in the market segments; **7.** *reuse potential*, it determines the possibility of the sub-domains of composing a generic reuse infrastructure; and **8.** *coupling*, it identifies if the sub-domains can be dealt in an independent way. The dimensions considered in the evaluation of the sub-domains were defined with base on relevant aspects identified in [21].

d) Prioritize Sub-Domains

The prioritization is performed based on the results obtained in the sub-domains analysis, the business goals and considerations made by the customers in the task of pre-scoping meeting.

This step is performed by different stakeholders and is possible that the different viewpoints result in conflicts. Thus, it is recommendable an initial search for common interests and the negotiation of the divergent ones. In this case, discussion sessions moderated by the scoping expert can be made, enabling the alignment of the interests for all the team. With these sessions is constructed the final list of domains and sub-domains more relevant for the product line.

C. Product Scoping

In today's competitive business environment, it is extremely important to offer for customers exactly the products that they want. SPL has the potential to enable companies to offer a large variety of products while still being able to manage the complexity caused by this increased number of products. In this sense, the product scoping phase aims to define the product portfolio that optimally satisfies customer demands, characteristic of highest priority in agile process, where the customers' role is critical [22] and at the same time restricts the number of products offered.

In this phase, the products and features associated with them are identified and evaluated with respect to their potential for introduction in the product line. In this identification and evaluation, the market analysis as well as the real needs of the customers are considered.

In order to define the product scoping, five tasks should be performed: *construct user stories*, identify features, *features review meeting, identify products*, *construct product map* and *validate product map*.

1) Construct User Stories

In a product line started from scratch or in its evolution, the utilization of user stories as basis for identification of customers' needs and consequently features of product is very important. It is well known the fact that customers have difficulties of expressing their expectations before using the final product [23]. Thus, user stories should be used in these cases, because in our vision this is the most natural way for customers express their needs. However, in cases where is necessary to construct a product line of pre-existents products, i.e. in cases of reengineering, the construction of user stories is unusual, and the features are identified from the analysis of documents associated to products or through the code.

RiPLE-SC defines user stories as brief descriptions on how customers will use the system [9]. The stories present short names, business value and are written in a short way or graphical description.

Each story can be written in index cards because they are relatively small, easy to move and order [9]. If there is the need to report the progress to others parts of the organization in a traditional format, electronic media can be used.

2) Identify Features

The goal of this task is to determine the features which will be present in the further products of the SPL. It is performed across a workshop whose collaborative participation of the team is essential. This workshop should be moderated by the scoping expert, and all participants are expected to be fully engaged. During the workshop is possible to identify and discuss several issues with base on different perspectives. In this sense, different views of the stakeholders will be confronted and analyzed enabling a better scoping result.

For identifying the features, RiPLE-SC uses as base: **1.** user stories, in this case an evaluation of the user stories by representative stakeholders is essential to determine if the stories are feasible and complete, and thus to identify potential

features for the product line and create competitive products; and/or **2.** the abstraction of the previous knowledge obtained from e.g. books, user manuals, design documents and code.

In the RiPLE-SC process, functional and non-functional features are considered. The functional features are related to aspects as "what" the system has to do. The non-functional features are associated with quality attributes, which the products should address. These attributes will serve as architectural drivers for the product line and present impact on the product line architecture. Therefore, the identification of non-functional features is of extreme relevance for the architecture of the product line.

3) Feature Review Meeting

The feature review meeting is related to feature evaluation and negotiation between the organization (domain expert and marketer) and customers. Domain experts and market experts are indicated for this task because they have high knowledge of the domains, and also know potential market segments and their needs. In this context, it is possible to obtain the customer's feedback enabling they to evaluate the work performed and define if the releases are aligned to their real needs. With the review meeting, new features can be included, excluded or reprioritized in the list.

4) Identify Products

The task *identify products* has as objective to find appropriated products for the product line. This task receives as inputs the market experts' knowledge, the SPL vision, the features list and the business plan. The output of this task is a list that presents the products of more potential for the SPL.

The choice of products for a product line is critical for the organizations, because the market is competitive and requires products diversity, factor that can have negative consequences, such as: increase of costs, complexity and time-to-market, causing decrease of benefits for the product line [12]. Thus, in this choice it is highly important to consider a set of products aligned with the goals of the organization and needs of a specific group of customers or market segment.

5) Construct Product Map

After the identification of the products and their features, these are organized in a product map. In this map, columns and rows are used to represent products and features, respectively. Moreover, in this map, each column is composed of two other columns: the first indicates if the feature is a possible further feature of the product; the second indicates if the feature is required in the product. Thus, it is possible to determine which features will integrate or not each product. In addition, in the product map, each feature is related to a scope as follows: *mandatory*, features that are required by all members of the product line; *optional*, features that are part of some products, i.e., can or cannot be selected by the SPL products; or *out of scoping*, features that are part of only one product.

6) Validate Product Map

The product map validation is performed in meetings with the participation of customers, domain experts and market experts. These meetings have as objectives: **1.** identify if any feature was forgotten or allocated improperly in some product; and **2.** verify the scope defined for the features.

With this task, the product map is consolidated enabling the choice of the assets that will integrate the reuse infrastructure for the SPL.

D. Assets Scoping

The goal of the assets scoping is to determine the appropriate features that should be built for reuse. Thus, the assets scoping establishes the reusability of features relevant for the development of the reference architecture. This phase is based on a quantitative analysis of the benefits of making the feature reusable. In this sense, our process determines the definition of metrics for measuring the benefits that specific feature has for the product line. It aims to optimize the product line according to specific benefits.

It is well known that projects have different visions from different stakeholders and that benefits can differ according to the business goals of them. In this context, we consider Goal Question Metric (GQM) [4] as a way for deriving metrics based on different business goals expected by the stakeholders. The choice of performing assets scoping focused on GQM was influenced by the study performed in [1], where ten experts were surveyed regard some factors related to software reuse measurement and was identified that GQM is the most utilized method for reuse measurement.

This phase is composed by the tasks: *create metrics, apply metrics* and prioritize product map, as next described.

1) Create Metrics

The metrics creation involves two well-defined steps: *refine and operationalizate business goals*, *develop benefit and characterization metrics*.

a) Refine and Operationalizate Business Goals

This task initiates with the step *refine and operationalize business goals*. Initially, the goals, prior produced in the pre-scoping phase, are analyzed and refined. The refinement is made because in the phase of pre-scoping, the goals are identified generically. Thus, the goals are refined according to their relevance for the customers, organization and domains.

After the refinement, it is performed the operationalization of the goals according to four distinct levels: goal, question, characterization metrics and benefits metrics. The operationalization flow starts with the goal level, where the optimized description of the goal is performed following the schema that has the form of <Purpose><Issue><Object> <Context>, such as ***Minimize*** *the* ***effort*** *needed for* ***the development of new applications*** *from the viewpoint of* ***software engineers*** *in* ***the company***.

In the question level, additional aspects are elicited and the goal is defined more preciously. After the aspects have been elicited, the goal is expressed in characterization metrics that will be used in the benefits metrics. The characterization and benefit metrics are next detailed.

b) Develop Benefit and Characterization Metrics

The characterization metrics are used for identifying the need of a specific feature to integrate a product in the product line. The benefit metrics describe the potential of introducing a specific feature into reuse infrastructure considering a defined business goal.

2) Apply Metrics

In this task, the benefit and characterization metrics are applied for the product map in two steps: *apply characterization metrics* and *apply benefit metrics*.

a) Apply Characterization Metrics

In general, this task is performed by the stakeholders who provided the different goals, e.g., the developer can be useful to estimate effort, while the architect can help in the definition of which are the impacts of some features in the reuse infrastructure.

b) Apply Benefit Metrics

After the application of the characterization metrics, the benefits of the assets for the product line are evaluated. In this step, the metrics are applied based on the goals previously considered.

3) Prioritize Product Map

After assigning the values for the benefit metrics, the task prioritize product map is performed. In this task, the features with more potential for the product line are selected.

The product map prioritization is performed in a meeting which involves the customer, manager, marketer and domain expert, where considerations and negotiations are performed.

As RiPLE-SC is intended to satisfy the customer's real needs, their feedback is indispensable for definition of the SPL scope. Thus, the base to perform the prioritization of the product map is the customers' need.

IV. Related Work

In [21], we performed a systematic review on scoping approaches for SPL where relevant approaches were analyzed and clustered. Therefore, in this section, we will make a brief discussion about the main related work.

Helferich et al. [8] focus on Product Portfolio Planning (PPP) based on Quality Function Deployment. Their work demonstrates how QFD-PPP can be used to identify different customer groups and their needs, derive systematically product portfolio (i.e. members of a product line) and derive common and variable product functions.

The scoping customization is inserted in [13]. This work highlights that scoping should be customized for concrete situation and activities, because representative stakeholders, artifacts and execution time for the tasks can change according to several factors, such as: resources, organizations factors, etc.

In the context of agile product lines, one approach proposes agile scoping [24], where the goal is to define a product map, i.e. a matrix that relates products and features using active participation and collaboration among the project stakeholders. During the approach, tasks of Collaboration Engineering and practices of AM are used in parallel.

In our work, we defined a systematic agile scoping process for SPL making possible the incremental scope definition and agility, favoring the up-front costs and effort decrease.

V. Conclusions

During the last decade, several efforts were conducted to achieve effective ways of dealing with the software industry competitive needs. In this context, Agile Product Line Engineering (APLE) is a new research area that aims to join the benefits of product lines and agile methods and which was motivated by the need to rapidly deliver high quality software that meets the changing needs of stakeholders.

In this paper, we explored this combination in the scoping phase. Scoping is the first activity to start a software product line and is considered key for its success. It aims to decide which features are *in* and *out* in the product line. We believe that our work can be used as important base to develop the next generation of scoping approaches covering agile issues. As future work, we intend to evaluate our process in an industrial case study in the medical domain.

Abstract

Software Product Lines (SPL) exploits reuse by identifying, modeling, and systemically reusing software features to develop different but related software systems. Successful reuse of a product line depends greatly on the modularity of the features that characterize the product line. Traditionally, features in SPL are grouped along the dimension of commonality *and* variability. *However, this single-dimension grouping overlooks the crosscutting nature of some features in the system, which negatively impacts the reusability and modularity of the product line architecture. In this paper we address this particular problem by investigating the concept of* **Aspectual Feature** *(AF) as another grouping dimension that can be used in SPLs. To this end, the paper proposes the Aspectual Product Line Engineering (APPLE) approach for identifying, modeling, and implementing AFs to enhance the reuse of SPLs. A tool support for implementing the APPLE approach is also presented and demonstrated through a case study.*

1 Introduction

Software product line (SPL) engineering has emerged as an effective and practical technology to exploit systematic reuse in developing software applications. An SPL can be defined as "*a set of software-intensive systems sharing a common, managed set of features that satisfy the specific needs of a particular market segment or mission and that are developed from a common set of core assets in a particular way*" [1]. A core activity in engineering product lines is the *Domain Engineering* (DE) process used to engineer reusable assets necessary to develop a family of applications within a defined domain [2] [3].

Domain Analysis (DA) [4] is a key activity in DE that focuses on identifying and modeling common and variable features for a set of software systems, and exploiting these features into reusable artifacts that can be used for engineering various related products and applications. This activity is known as *Commonalities and Variabilities* (C&V) analysis. Identifying, modeling, and encoding C&V features play a key role in facilitating the reuse of these features. Dependency, coupling, and cross-cuttings among features may limit their reuse, or at least make reuse more difficult and error prone. Conventional SPL development approaches group features along the dimension of *commonality* and *variability* without considering the interrelationships among these features.

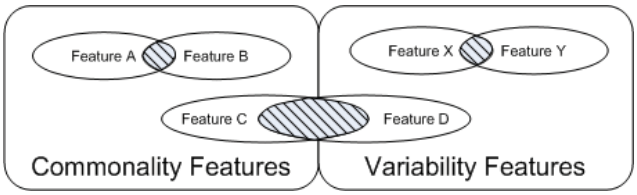

Figure 1. Aspectual Feature Existence

In practice, features do not live in isolation. They typically cross-cut and interact with each other to implement the key functionalities of the system. Figure 1 shows some examples of features that may cross-cut each other within the commonality (A and B) or variability layers (X and Y), or even across the two layers (C and D).

Dealing with cross-cutting features in SPL is not new. In the literature, two research directions were investigated in this context. The first direction focuses on identifying crosscutting features within the variability features (e.g., Features X and Y in Figure 1. [6] [7] [8] [9]. However, this work ignores other types of crosscutting features within the commonality or across the commonality and variability layers. The second research direction focuses on developing

and end-to-end development process to handle crosscutting features in the SPL life-cycle. Example of this direction is the approach reported in [12]. However, this approach is complex as it relies on data-mining and natural language processing to identify crosscutting features.

We argue that identifying cross-cut features is circuital in developing truly reusable software product lines, and there should be a practical approach for identifying various types of such features. Accordingly, in this paper, we investigate the concept of ***Aspectual Feature*** (AF) as another grouping dimension that can be used in conjunction with the traditional *commonality* and *variability* dimension used in most SPL techniques. Recent work reported in [6], [7], [8], and [9] focuses on To this end, we propose a new approach, namely, the ***Aspectual Product Line Engineering (APPLE)*** approach based on the theory of Formal Concept Analysis (FCA) for identifying, modeling, and implementing AFs to enhance the reuse of SPLs. In addition, we present a CASE tool for implementing the APPLE approach and demonstrate its use via a case study.

The rest of the paper is organized as follows. Section 2 presents the proposed APPLE approach and describes its main activities. In Section 3, a case study for applying the APPLE approach is presented. Related work is discussed in Section 4. Conclusions are presented in Section 5.

2 The Proposed Approach

In this section we present the proposed *Aspectual Product Line Engineering* (APPLE) approach, and provide an overview about its main activities and implementation. A brief overview about the Formal Concept Analysis (FCA) theory is first presented.

2.1 Formal Concept Analysis (FCA)

Formal concept analysis (FCA) provides means to identify meaningful groupings of objects that share common attributes as well as provides a theoretical model to analyze hierarchies of these groupings [18]. A formal context $C = (A, O, R)$ in FCA consists of a set of objects O, a set of attributes A, and a binary relation $R \subseteq O \times A$ between objects and attributes, indicating which attributes are possessed by each object. The formal context can be used to generate a set of concepts where a concept C is defined as a pair of sets (X, Y) such that:

$$X = \{o \in O | \forall a \in Y : (o, a) \in R\} \quad (1)$$

$$Y = \{a \in A | \forall o \in X : (o, a) \in R\} \quad (2)$$

Where X is said to be the extent of the concept C and Y is said to be its intent.

The set of all concepts of a formal context and the partial ordering can be represented graphically using a concept lattice. A concept lattice consists of nodes that represent the concepts and edges connecting these nodes. The concept lattice is the basis for further data analysis.

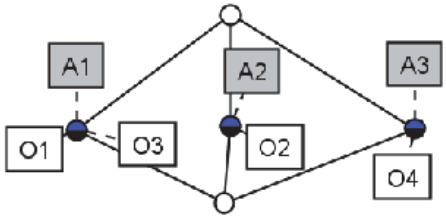

Figure 2. Lattice for the Context of Table 1.

Table 1 shows an example of a simple context. The lattice of this context is illustrated in Figure 2.

2.2 The APPLE Approach

APPLE aims at providing a practical approach for detecting and propagating aspects from analysis to implementation without imposing heavy-weight analysis techniques those are not in the mainstream development process. As we discuss below, in the proposed approach, typical SPL activities such as Use Case analysis and Feature-Oriented Domain Analysis (FODA) are employed. The use of FCA helps to achieve this goal as it is a semi-automated technique that does not require much knowledge from typical analysts and developers.

In the following we present the various steps of the APPLE approach (Figure 3). A summary of the various activities, their input, and outputs are summarized in Table 2.

Step 1: *Domain Analysis:* As with typical SPL development approaches, the first step is to perform functional and domain analysis in order to identify the required functionalities and the common and variable features in the systems under consideration. In this step, the following two parallel activities are performed:

1.1 *UML Domain Analysis:* This activity aims at analyzing the functional and non-functional requirements of the systems within the specified domain. The output of this activity is a set of Use Cases (UCs) describes the requirements of the systems.

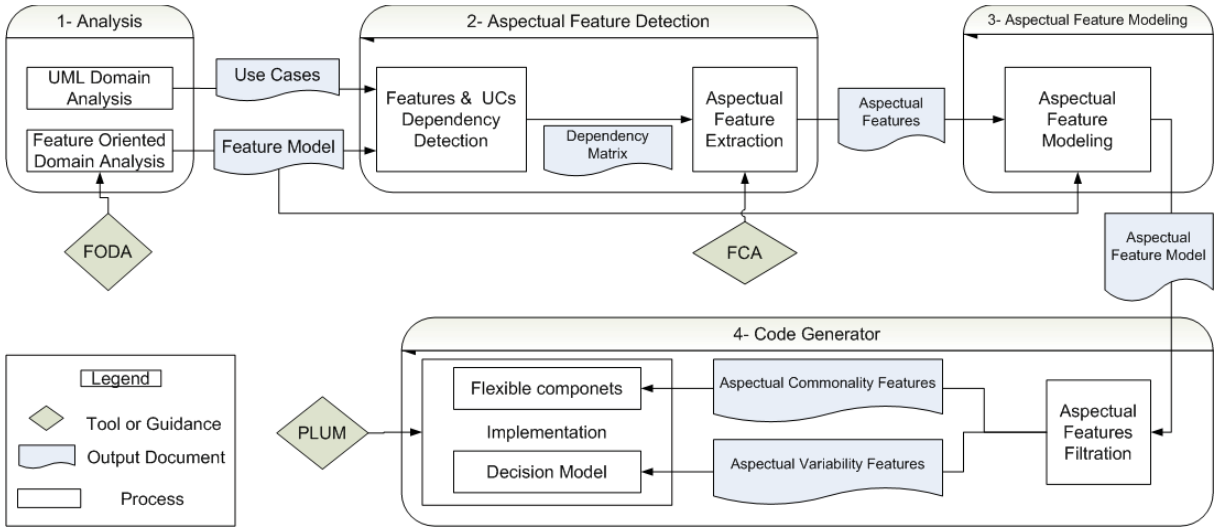

Figure 3. Main Activities In The Proposed APPLE Approach.

1.2 *Feature Oriented Domain Analysis:* In this activity, common and variable features among the systems are identified using the FODA method [5]. Identified features are modeled using conventional feature models (FM) [5].

Step 2: *Aspectual Features Detection:* This step focuses on identifying aspectual features (AFs) based on the UCs and FM developed in Step 1 above. To do so, the following two activities are performed:

2.1 *Features and UCs Dependencies Detection:* In this activity, the relationship between the identified UCs and features are carefully analyzed in order to identify their dependencies. We follow an approach similar to that reported in [8][9]. The result of this activity is a dependency matrix where the rows and columns represent the features and the UCs, respectively.

2.2 *Aspectual Feature Extraction:* The matrix obtained from the previous activity is processed using FCA in order to identify actual Aspectual Features in the systems. A lattice is constructed and its structure is analyzed (via a tool) in order to identify crosscutting and non-crosscutting features.

Step 3: *Aspectual Feature Modeling:* In this step, the conventional feature model constructed in Step 1 is now revised and updated based on the results of Step 2.2 above. The result is a new feature model with a set of features classified along two dimensions. The first dimension differentiates between common and variable features (from the original FM), whereas the second dimension differentiates between crosscutting and non-crosscutting features (based on activity 2.2). It is worth noting that, at this point crosscutting and non-crosscutting features include both common and variable features. This particular point set the APPLE approach from most existing research that focuses only on identifying crosscutting features within variabilities only. The result of this step is an updated FM named Aspectual Feature Model (AFM).

Step 4: *Code Generation:* In this step, the actual implementation of the SPL is performed. In our approach, we adopt the PLUM (Product Line Unified Modeler) as a tool for generating the code for the product line under development [17]. In PLUM, common features are encoded in what is called Flexible Components (FCs), whereas variable features are presented in the so-called Decision Model (DM). DM is used to set the values of the variable features according to the particular product in the SPL family. Accordingly, we handle the common and variable aspectual features differently. That is, common AFs are handled in the FCs, whereas variable AFs are handled in the DM. The following are the two activities used in APPLE to implement AFs:

4.1 *Aspectual Features Filtration:* In this activity, we isolate common and variable aspectual features in order to prepare these features for appropriate implementation.

4.2 *PLUM Implementation*: In this activity the actual code is developed and generated as appropriate. In particular, common AFs are implemented in the FCs using appropriate Aspect-Oriented Pro-

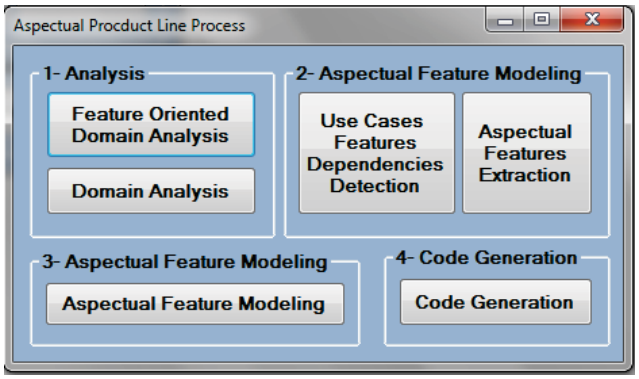

Figure 4. Tool Interface for APPLE.

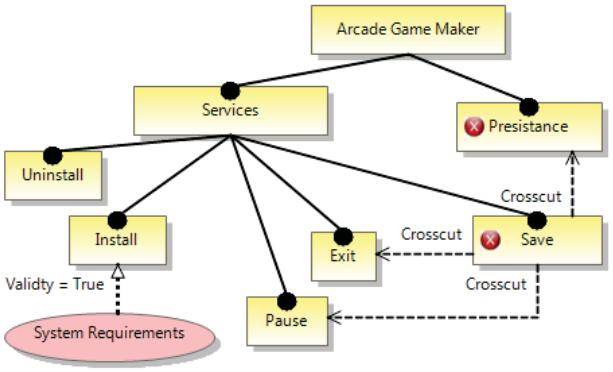

Figure 5. Aspectual Feature Model

gramming (AOP) languages (e.g., AspectJ). Variable AFs are handled in the DM using a sub-class of the Decision Class in PLUM Decision Meta Meta Model.

A CASE tool is developed in order to semi-automated most of the activities in the proposed APPLE approach. The tool supports the four steps shown in Figure 3. The GUI of the developed tool is illustrated in Figure 4. In the lattice generation it extracts and identifies the aspectual features by exploring the scattering and tangling dependencies. Each feature have to be scattered and at least one of the corresponding use cases are tangled to be an aspectual feature. A customization done on the FCA generation to show the aspectual features by analysis of the dependencies and draw hashing on the aspectual features. The tool includes add-in for UC modeling, and Feature Modeling.

The conventional feature model is extended to include the aspectual feature types. Figure 5 shows a sample aspectual feature model with two aspectual features, namely `Save` and `Persistence`.

Aspectual features are marked with an X in the left-hand side as shown in the figure. Each aspectual feature crosscuts

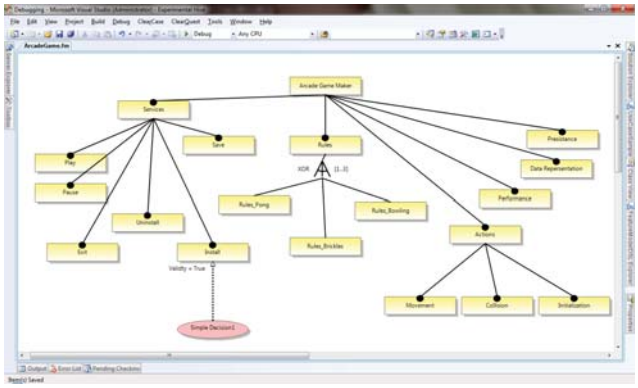

Figure 6. Arcade Game Maker Feature Model.

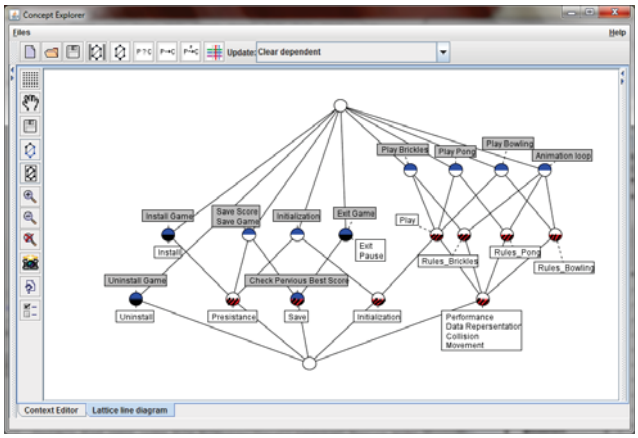

Figure 7. Arcade Game Maker FCA Lattice.

one or more features. The modified aspectual model illustrates this crosscutting nature by dotted line. For example, as shown in Figure 5, the aspectual feature `Save` crosscuts three other features: `Pause`, `Exit`, and `Persistence`.

3 Case Study: The Arcade Game Maker

To demonstrate the APPLE approach, we applied it to the Arcade Game Maker Product Line [8][16]. Arcade Game Maker is a SPL that aims at generating three related, but different games. Each game is a Single-player Game and has some Rules. A Scoring point is obtained by hitting some hurdles. The installer component of the software can install and uninstall the game. The User should be able to interact with the game. Some interactions with the game is to play, save Game and exit. Saving Score is one of the features available in the game. Examples for some functional requirements in this system include: *Play, Pause, install, and Uninstall*. Examples for some non-functional requirements include: *Performance and Persistence*. Most of the func-

Table 2. Summary of Main Activities in the APPLE Approach.

Step	Activities	Input	Output
1- Domain Analysis	UML Domain Analysis	Requirements	Use Cases (UCs)
	Feature Analysis (FODA)	Domain Requirements	Feature Model (FM)
2- Aspectual Features Detection	Features and UCs Dependencies Detection	UCs and FM	FCA Lattice
	Aspectual Feature Extraction	FCA Lattice	Aspectual Features (AFs)
3- Aspectual Feature Modeling	AF Modeling	AFs	Aspectual Feature Model (AFM)
4- Code Generation	Aspectual Features Filtration	AFM	Aspectual Variability and Commonality Features
	PLUM Implementation	Filtered Features	PLUM Code

tional requirements are mandatory and some are related to the particular game that will be generated.

First, the UC and the feature models are constructed using conventional UC analysis and FODA (Figure 6). Next, the dependencies between the identified UCs and features are captured using the technique reported in [8][9]. The results of these analysis steps are used to generate the FCA lattice given in Figure 7. Based on analysis of the generated lattice, an updated Aspectual Feature Model is generated. The identified AFs are filtered and implemented in the FCs and DM of the PLUM tool as discussed above.

4 Related Work

The use of FCA in SPLs is not new. In [13], Niu and Easterbrook reported the use of FCA to examine and refine the functional and quality requirements in software product lines based on the concept of clustering. In [15], Tonella and Ceccato proposed the use of FCA to mine the aspects from the execution traces of the software. These research efforts exploit FCA in SPL at the code level only. In our work; however, we exploit FCA early in the analysis phases.

In [10], Salinas and Suesaowaluk have developed an aspect-oriented approach for SPLs in the context of web applications. They focused on identifying and managing the variabilities from the analysis to the coding phases. In [14], Silva *et al.* , proposed an approach for the mapping between the SPL-AOV graph and the feature model to present a graph that contains both the features and the requirements of the system.

In [8], Conejero and Hernández proposed an approach based on their previous work reported in [9] to identify the effects of crosscutting features. The approach uses matrix operations to identify the relationships between a set of UCs and features by identifying the so-called scattering and tangling matrices. However, they do not show how crosscutting features can be identified from these matrices. The APPLE approach presented in this paper, does not only identify crosscutting features, but it also discovers the relationships between UCs and features without complex manual matrices operations as those used in [8].

Loughran *et al.* proposed in [12] the NAPLES (Natural language Aspect-based Product Line Engineering of Systems) approach. NAPLES aims at providing an end-to-end SPL development approach from requirements to code generation. Similar to the APPLE, NAPLES attempts to analyze aspects in addition to conventional commonality and variability analysis for product lines. In NAPLES, natural language processing and data mining (EA-Miner) techniques are applied to the requirements documents and the textual assets related to the domain of the systems under development in order to identify early aspects, viewpoints, and the commonalities and variabilities. We argue that NAPLES can be complex for use in mainstream SPL development life-cycles. APPLE, on the other hand, makes use of Use Case and FODA, which are more natural to the typical SPL developers.

Table 3 gives a comparison between the proposed APPLE approach and the matrix-based and NAPLES approaches.

5 Conclusions

In this paper, the Aspectual Product Line Engineering (APPLE) approach is proposed to exploit the concept of aspectual features (AFs) for developing modular software product line systems. The key objective of APPLE is to identify, model, and implement the crosscutting features by analyzing the relationships between the requirements and features of the system early in the analysis phase. Based on this analysis, AFs are identified and handled efficiently to facilitate the reuse of the SPL. The APPLE approach is

Table 3. Comparison Between Various SPL Approaches.

Property	Matrix-based Technique [8]	NAPLES [12]	APPLE (This Paper)
Supported Development Phase(s)	Analysis	Analysis Code Generation	Analysis Design and Architecture Code Generation
Aspectual Feature Modeling	No	No	Yes
C & V	No	Yes	Yes
Crosscutting Feature Detection Technique	Matrices	Data Mining	FCA

presented and its activities are described. A CASE tool to semi-automate the various activities of the APPLE approach is also presented and its use is demonstrated through the Arcade Game Maker software case study.

Automating the Detection of Complex Semantic Conflicts between Software Requirements

An empirical study on requirements conflict analysis with semantic technology

Thomas Moser, Dietmar Winkler, Matthias Heindl and Stefan Biffl

***Abstract*—Keeping requirements consistent already at early project stages is a main success factor for software development projects. However, manual requirements conflict analysis takes significant effort and is error-prone. Requirement engineers and other project participants such as technical architects use different terminologies (due to different domain backgrounds) which makes automation of conflict analysis difficult. In this paper we propose semantic approach as foundation for automating requirements conflict analysis and introduce the automated ontology-based reporting approach OntRep. We evaluate the effectiveness of OntRep referring to (a) different types of conflicts and (b) different levels of conflict complexity in a real-world industrial case study. Major results were that OntRep had considerably higher recall and precision of conflict detection for all conflict types compared to a manual approach. Regarding complexity, the comparison with manual results shows that recall and precision of OntRep is considerably higher for complex conflicts.**

Keywords—requirements conflict detection, requirements consistency checking, ontology, case study, empirical evaluation.

I. INTRODUCTION

Modern software and systems engineering projects are complex due to (a) the high number and complexity of requirements (e.g., mutual dependent or contradicting requirements), and (b) geographically distributed project stakeholders with different backgrounds and domain terminologies. A major goal of requirements engineering is to achieve consistent requirements descriptions in order to create a common and agreed understanding on the set of requirements between all project stakeholders. Initial observations at our industry partners showed that establishing consistency of requirements takes significant effort and is error-prone when performed manually. Thus, automation approaches for requirements conflict analysis are needed that (a) increase the effectiveness and quality of analyzing requirements from different stakeholders for symptoms of inconsistency, e.g., contradicting requirements, and (b) reduce the conflict analysis effort. Unfortunately, current automation approaches for conflict analysis suffer from the following challenges and limitations:

- High level of *incompleteness* [2] of conflict detection, leaving complex requirements uncovered.
- *Focus on executable code.* Some approaches need executable code to identify requirements conflicts [2], but in early stages - where conflict analysis is important - executable code may not available.
- *Limitation to syntactical comparison.* Potential conflicts are identified by using trace dependencies between requirements that have been explicitly captured before, e.g. by information retrieval approaches like "keyword matching" [6][7]. These approaches allow syntactical comparison of requirements, but do not cover semantics, even if different terms are used in these requirements definitions.

Thus, using semantic technologies seems to be a promising approach to address these challenges: ontologies provide the means for describing the concepts of a domain and the relationships between these concepts in a way that allows automated reasoning [10]. In this paper, we propose OntRep [4], an automated ontology-based reporting approach for the analysis of complex semantic conflicts between requirements based on ontologies and reasoning mechanisms. The main criteria for the evaluation of OntRep are: correctness and completeness of identified requirements conflicts and the effort to develop a project or domain ontology. OntRep aims at lowering the effort for requirements conflict analysis, while keeping requirements consistency high. Initially, OntRep automatically categorizes requirements into a given set of categories using ontology classes modeled in Protégé and mapping the terms used in the requirements to these classes. Using this foundation, OntRep analyzes the content of the requirements and identifies conflicts between requirements. Therefore, conflict analysis is not only based on traditional keyword-matching-approaches, but also considers different terminologies used for describing semantically equivalent concepts. We empirically evaluate OntRep [4] in a real-life project at our industry partner to investigate performance and quality with respect to (a) different types of conflicts and (b) conflicts on different levels of complexity.

The remainder of the paper is organized as follows: Section 2 summarizes related work on requirements conflict analysis and natural language processing; Section 3 introduces the OntRep approach and motivates research issues. Section 4 describes the performed empirical study. Section 5 presents the results which are discussed in Section 6. Finally, Section 7 concludes and suggests further work.

II. Related Work

This section presents related work on requirements conflict analysis and natural language processing [4].

A. Requirements Conflict Analysis

"Requirements conflict with each other if they make contradicting statements about common software attributes […] Given that there may be up to n^2 conflicts among n requirements […], the number of potential conflicts, […], could be enormous, burdening the engineer with the time-intensive and error-prone task of identifying the true conflicts" [2].

The Trace Analyzer by Egyed and Grünbacher [2] analyzes the footprints of test cases to detect requirements conflicts. If two requirements execute overlapping lines of code, a potential conflict may exist. A prerequisite for the Trace Analyzer is to have executable code, which is often not available in early project phases, when conflict analysis is a major goal. Heitmeyer *et al.* [5] describe a formal analysis technique, called consistency checking, for the automated detection of syntactic errors, such as type errors, non-determinism, missing cases, and circular definitions, in requirements specifications. The approach does not find semantic conflicts.

Information retrieval approaches [6], such as the RETH approach [7] use keyword-matching techniques to identify general requirements interdependencies. These captured interdependencies can be used to identify requirements conflicts. However, these techniques do not allow identifying conflicts or other interdependencies between requirements, if they use different terms for similar concepts. Thus, these approaches are less effective in practice, because they cannot identify the full set of interdependencies between requirements. The extended Bakkus-Naur-Form (EBNF) [12] is a syntax for requirements, which is used to improve the understandability of requirements for humans and machines.

B. Natural Language Processing

Natural language processing (NLP) techniques are useful to extract structure and content of requirements given in natural language for transformation into the structure of an ontology. NLP generally refers to a range of computational techniques for analyzing and representing naturally occurring texts [1]. The core purpose of NLP techniques is to achieve human-like language processing for a range of tasks or applications [8].

Most important NLP models used in this research are part-of-speech (POS) tagging and sentence parsers [1]. POS tagging involves marking up the words in a text as corresponding to a particular part of speech, based on both its definition, as well as its context. In addition, sentence parsers transform text into a data structure, which provides insight into the grammatical structure and implied hierarchy of the input text [1]. Standford parser/tagger[1] and OpenNLP[2] are the core set of NLP tools used in this paper. Furthermore, we use WordNet, a large lexical database in English [9]. Nouns, verbs, adjectives and adverbs are grouped into sets of cognitive synonyms (synsets), each expressing a distinct concept. Synsets are interlinked by means of conceptual-semantic and lexical relations. WordNet is a useful building block for requirements analysis. These NLP technologies can be used for our purpose, namely to improve the effectiveness of requirements management activities like categorization, conflict analysis, and tracing.

III. Analysis of Conflicts with an Ontology

Due to the limitations of requirements analysis approaches that address only links between requirements based on syntactic equality, we explore an approach based on semantic equality: OntRep [4] links similar concepts sharing the same meaning even if their syntactic representations are different. As ontologies are versatile for representing knowledge on requirements and for deriving new links between requirements, we introduce an ontology-based approach for reporting analysis results on a set of requirements. The goal of the ontology-based reporting approach OntRep is making requirements management tasks such as requirements conflict analysis more effective based on the automation of selected steps in these tasks. We focus on complex semantic, which we define as conflicts regarding a set of more than two requirements and constraints, which based on observations at our industry partners are hard to identify manually. In the following subsections, we provide an overview on the approach and motivate research issues.

A. Basis for Requirements Conflict Analysis

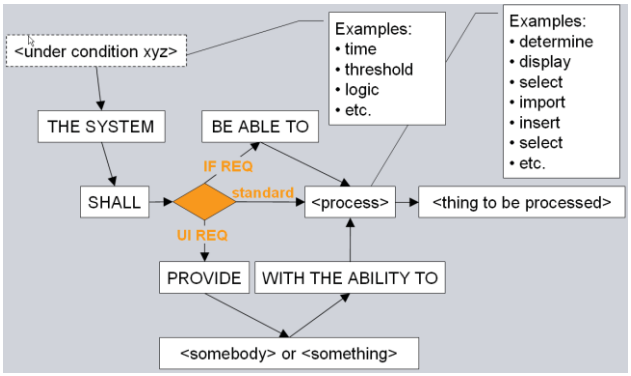

Figure 1. EBNF requirements structure (sentence level) [12].

For formally specified requirement semantics, in our case following an EBNF template (see Figure 1), semantic analysis can identify inconsistencies and conflicts using a set of assertions that should hold true for all available facts. These assertions are based on available requirements, while available facts are based on the environment and properties of the target system. Typically, requirements following this EBNF template specify under which conditions *(under condition)* a target system should provide a certain functionality *(process)* regarding a specific object *(thing to be processed)*, e.g., the system configuration, to a certain entity or role *(somebody or something)*, e.g., to an user or to the administrator. In this paper, we focus on (a) functional requirements (following an EBNF template) and (b) a set of requirements constraints regarding technical, requirement-specific or documentary issues.

We derive three types of conflicts, which can be detected with OntRep:

- *Not well-formed requirements* (conflicts between requirements and EBNF grammar).
- Conflicts between *functional requirements and technical and/or requirement constraints*.
- Conflicts between *two functional requirements*.

B. Automated Conflict Analysis

We developed a prototype tool for the OntRep approach as a plug-in to Trac[3], which can be extended by Python plug-ins.

Phase A: Linking of natural language to semantic concepts. In a first phase, natural language texts (technical constraints, requirements constraints, documentation guidelines and glossary knowledge) have to be linked to semantic concepts as preparation for further analysis and reporting [4]. The following 8 steps are used to build this project knowledge:

1) *Define project-specific concepts* in Protégé. Each concept is defined as an ontology class in Protégé. It is important to define project-relevant "semantic" concepts and not formal ones in order to enable the automated assignment, e.g., "Security". Typically, these concepts can be defined based on a project glossary that contains important project-specific terms.
2) *Provide input data* to be categorized: Constraints, guidelines and glossary knowledge are typically represented as natural language text. For our research we export these natural language texts and import them into OntRep prototype tool.
3) *Remove irrelevant stop-words*, like "and", "any", "but", which cannot be used for assignment. This step is performed automatically using a standard stop-word list[4].
4) Bring all remaining words into their *root form* (e.g., "jumping" to "jump"): this process is called "stemming" based on algorithms like "Porter Stemmer" [11].
5) Get all *synonyms and hyponyms* of the analyzed words in the requirements by using the natural language processing library "WordNet" [9]. For example, "house" is a synonym for "building", "dog" is a hyponym of "animal".
6) *Heuristic-based assignment* of each requirement to the defined concepts depending on the number of hits for (a) synonyms, (b) hyponyms, and (c) substring matches. The heuristic checks if the hits for synonym, hyponym and substring matches meet the given threshold values. If this number is equal or higher than the number of thresholds that must be met, the word will be related to that concept, otherwise not. If several concepts reach these thresholds, the requirement will be assigned to all of these concepts.
7) Save the element as an *individual of the ontology class*, if it is not already in the class. This can only be checked if one or more of the elements attributes have been declared as primary keys (uniquely identifying the element). If the element has already been saved in another class as well (which could be the case), declare that the new element is the same as the already existing one with the "*owl:sameAs*" property.
8) Manually check the *validity and correctness* of the imported fact, both regarding its assignment to the right concepts as well as regarding its meaning.

[3] http://trac.edgewall.org/

[4] http://www.textfixer.com/resources/common-english-words.txt

Phase B: Mapping of Requirements and Semantic Concepts. In the second phase, analysis and reporting approaches build on the mapping of requirements to semantic concepts. For formally specified requirement semantics, in our case following an EBNF template (see Figure 1), semantic analysis can identify inconsistencies and conflicts using a set of assertions that should hold true for all available facts. These assertions are based on the available requirements, while the available facts are based on the environment and properties of the target system (which were imported in the first phase). The following 4 steps describe the semantic requirements conflict analysis:

1) *Import of requirements*. The requirements are represented as tickets in Trac. For our research prototype we export these requirements via CSV from Trac and import them into the OntRep prototype tool.
2) *Parsing of requirements*. If the requirements are formally described using a specified grammar (e.g., EBNF), the information contained in the textual requirement descriptions can be semantically analyzed in order to identify possible inconsistencies and/or conflicts. Based on the specified grammar, certain parts of the requirements are extracted for further usage. In our case, this primarily affects the "thing to be processed" and the "obligation" ("shall" or "shall not") specified in EBNF.
3) *Linking of requirements to semantic concepts*. The "things to be processed" of the specific requirements, which were extracted in the previous step, now are linked to semantic concepts modeled in the first phase of the OntRep approach. If there is no semantic concept available for a specific "thing to be processed", a new semantic concept is created, in order to later identify conflicts between two functional requirements. Additionally, the "obligation" for each requirement is stored to enable requirement conflict detection.
4) *Requirement conflict detection*. After all requirements have been successfully parsed and linked to their related semantic concepts, every semantic concept enables checking for consistency, validity, and correctness of the related requirements using ontology-based reasoning. From the point of view of semantic analysis, we focus on two different kinds of conflicts in this paper, namely on logical inconsistencies between facts, as well as numerical discrepancies of facts. In the following, we present an example for these kinds of conflicts.

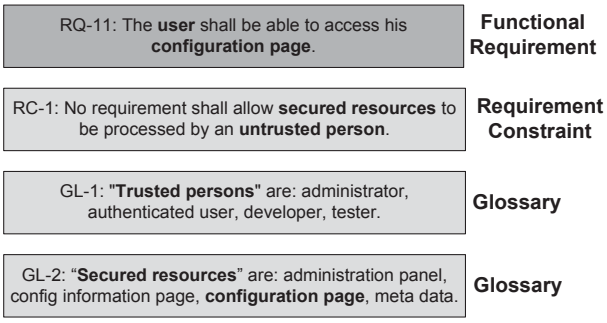

Figure 2. Logical requirement conflicts.

Figure 2 depicts an example for logical conflicts between requirements and constraints. Requirement RQ-11 links the

semantic concept "User" to the semantic concept "Configuration page". Additionally, there exists a requirement constraint specifying that no links may exist between the semantic concepts "Secured Resource" and "Untrusted Person". In the project glossary the semantic concept "Configuration Page" is identified as sub-concept of the "Secure Resource" concept, and the semantic concept "User" as sub-concept of the "Untrusted Person" concept since it is not a sub-concept of the "Trusted Person" concept which is defined as the negation of the "Untrusted Person" concept. Using these facts, the OntRep approach successfully identifies a logical conflict between RQ-11 and RC-1, relying on the facts specified in GL-1 and GL-2.

Figure 3 depicts an example for conflicts between requirements as well as for numerical discrepancies between requirements and constraints. There are three requirements which are linked to the semantic concept "Notification", RQ-12, RQ-17, and RQ-21. RQ-12 and RQ-17 are additionally linked to the semantic concept of "Messages per Second", but with a different parameter value, therefore the OntRep approach successfully identifies a conflict between these two requirements. Additionally, the semantic concept of "Notification" is linked to the semantic concept "SSL Encryption", for which a technical constraint is defined, specifying a link to the semantic concept "Messages per Second" with a parameter value of 3. While this holds true for RQ-17, RQ-12 requires at least a parameter value of 4 for the "Messages per Second" semantic concept; therefore the OntRep approach detects another conflict between RQ-12, RQ-21, and TC-1.

C. Research Issues

The underlying idea of this research is to use advanced semantic technologies, like ontologies and reasoning mechanisms, to increase the effectiveness of the analysis of complex requirements conflicts. Based on our findings in [4], the main research questions of this paper are:

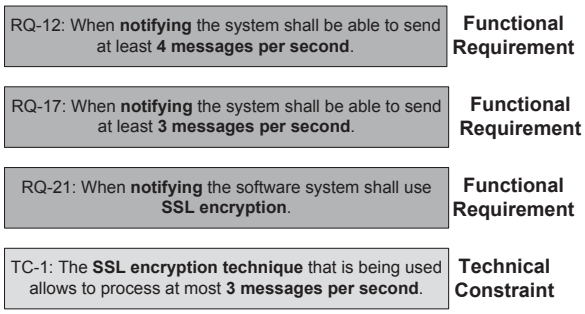

Figure 3. Numerical discrepancies of requirements and constraints.

RQ1) How effective is OntRep in finding different types of conflicts compared to manual analysis by experts? We mentioned 2 kinds of conflicts in section 3.B: numeric discrepancies and logical requirements conflicts. These conflicts may occur between different elements: (a) between requirements, (b) between a requirement and a constraint, and (c) between a requirement and a formal guideline. For these 3 types of typical conflicts we analyze the correctness and completeness of conflicts found with OntRep and compare the results to a manual approach for each conflict type.

RQ2) How effective is OntRep to identify conflicts of different degrees of complexity compared to manual analyses by experts? A conflict may consist of two or more elements, e.g., a conflict may exist between two or three requirements. We define these conflicts as "simple conflicts" because we assume they are easy to identify. On the other hand, we define conflicts consisting of more than 3 elements to be "complex conflicts". These complex conflicts might be more difficult to identify completely, especially when performing conflict analysis manually. We assume that OntRep reaches a higher completeness of complex conflict identification compared to the manual approach. For each complexity level we analyze the correctness and completeness of each identified conflict.

Based on our previous experience with tool support for quality assurance [4], we assume that OntRep can help increasing effectiveness and quality of requirements conflict analysis. Additionally, we also assume that OntRep reduces the effort for requirements conflict analysis.

IV. Study Description

This section summarizes study settings, i.e., goals, design, process, material, and participants, and identifies a set of threats to validity.

Goals. The goal of the pilot study was to analyze the effectiveness and quality of the OntRep conflict analysis approach compared to traditional manual approaches with focus on different types and complexity levels of conflicts.

Study Subject. As described in [4] the case study project is a software development project at our industry partner with the goal to design and implement a web application that serves as a platform for communication and networking between technology experts. This type of project seemed well suitable to apply and evaluate the OntRep prototype, because OntRep has been implemented as Trac plug-in and was easy to integrate with the project's tool infrastructure.

Participants were six project managers for individual conflict detection, randomly assigned to two teams for preparing an agreed team conflict list. One requirement engineering expert, i.e., one of the authors, provided control data for all tasks.

Material. We used a list of requirements (i.e., a spreadsheet) containing 23 functional requirements, 11 constraints (7 technical and 4 business constraints), and 4 formal documentation rules (documentation guidelines). To focus on individual conflict classes, i.e., conflict between requirements (CRR), conflict of a requirement with a constraint (CRC), conflict of a requirement with a formal guideline, i.e., ill-formed requirement (CRG), we seeded an overall number of 22 conflicts according to different conflict types and two complexity levels. Conflicts related to up to 3 elements are rated as simple, conflicts with more than 3 elements involved are considered as complex conflicts. In addition we used a data capturing sheet, guidelines to support the participants in identifying conflicts, and questionnaires to capture the background of participants prior to the study and feedback after afterwards.

Variables & metrics. Independent variables were the number of seeded conflicts, the defect types, and the number of

requirements per defect type. Dependent variables are the number of identified conflicts and for conflict identification. We used recall and precision as study metrics.

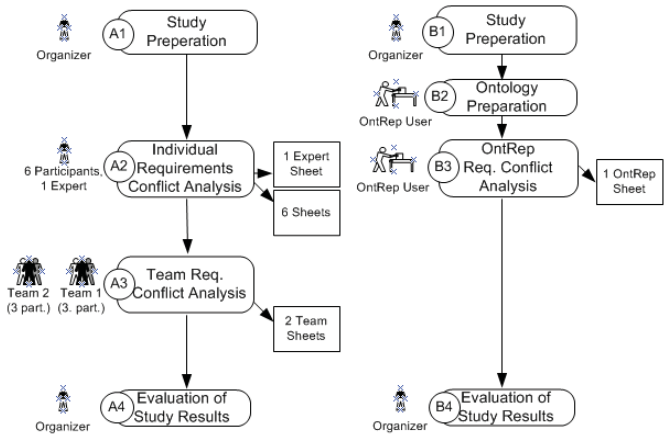

Figure 4.Evaluation Setting: Manual (l), OntRep (r) [4].

Study Design and Study Process. We applied the standard practices of empirical software engineering research according to Freimut *et al.* [3] and Wohlin *et al.* [13] to investigate the performance of OntRep in comparison to manual conflict detection. Figure 4 illustrates the relevant steps for evaluating requirements conflict analysis. This study was part of a larger overall study, reported in [4], where requirements categorization and tracing aspects were addressed in addition to conflict analysis. In context of this paper steps A2, A3, B2, and B3 are important for conflict detection. The other steps are described in [4] as part of the overall study.

A2) *Individual requirements conflict analysis*: The participants read through the task description, i.e., supporting guidelines, and were asked to (a) identify conflicts according to different conflict types and complexity levels and (b) report them within the data capturing sheet. Results of the individual conflict detection step were 6 individual results, provided by project managers and control data provided by one requirements engineering expert, i.e., one of the authors. Furthermore, we captured the individual effort of every participant.

A3) *Team requirements conflict analysis:* Afterwards, the participants harmonized their individual results within 2 randomly assigned groups of 3 team members. Again, the effort needed for this task was captured, resulting in 2 team sheets.

B2) *Ontology preparation:* A tool expert constructed one ontology class in OntRep for each category and then imported the given requirements from Trac as CSV into OntRep.

B3) *OntRep requirements conflict analysis:* Then, we provided the requirements as CSV-input to OntRep. Further, the tool expert had to model the constraints as facts and the formal guidelines as rules in the ontology. We captured the effort for this preparation. Afterwards, automated conflict identification was executed. The results were summarized in a final report.

Finally, we analyzed and evaluated the following results: (a) 6 spreadsheets for conflict analysis from each of the 6 individual participants, (b) 2 team spreadsheets, (c) 1 conflict analysis spreadsheet from a requirement engineering expert, and finally (d) 1 conflict analysis spreadsheet created with the OntRep approach. The results were evaluated with descriptive statistics in Excel and R and are described in the following section. We applied the Mann-Whitney-Test at a significance level of 95% (2-sided) for statistical testing.

Threats to Validity. Following the standard practice of empirical software engineering [13], we identified a set of internal and external threats to validity. We addressed *internal threats to validity* [3] of the study by two measures: a) intensive reviews of the study concept and materials, and b) a test run of the study conducted by a test person in order to make sure that the guidelines, explanations, and task descriptions are understandable for the participants and to estimate the required effort/time frame. Regarding *external validity*, we performed this initial case study in a professional context at a software development company. The participants had medium requirements management know-how and advanced software engineering know-how (captured by background questionnaire prior to the study). In addition, we had an expert in Requirements Engineering as control group. Nevertheless, the small number of participants might hinder the generalization of results. Therefore, we suggest replicating the study in a larger context in future work.

V. RESULTS

The following subsections describe the results of requirements conflict analysis with OntRep.

A. Conflict analysis results by conflict types

The first research question was how effective OntRep is in finding different types of conflicts compared to manual analysis? We defined 3 types of typical conflicts: Conflicts between a requirement and a constraint (CRC), e.g., when a particular requirement requires a response time that is not feasible with the chosen technology (the chosen technology constrains response times); Conflicts between a requirement and a documentation guideline (CRG), e.g. a requirement may conflict with the documentation guideline "all requirements must use the obligation word 'shall'"; Conflicts between requirements (CRR), e.g. the requirements "The system shall update the index at least 30 times per hour" and "The system shall update the index at least 20 times per hour" results in a conflict.

The individual recall and precision results for detecting CRC conflicts manually are low: approx. one third of existing conflicts has been identified and only one third of found conflicts were identified correctly. Group harmonization was quite effective for this type of conflict, because both recall and precision were improved, i.e., the conflicts found by each individual in the group have been merged in a discussion session, which results in a recall of approx. 60%; and some false positives were eliminated, which results in a precision of 50%. The expert performed better than the individuals regarding recall and precision, but the group results regarding recall were better. In this case the discussion of conflicts in the group was valuable.

Comparing the expert's CRC recall value with the CRG and CRR results shows that CRC results are clearly lower than the others. This is probably due to the fact that CRC conflicts were complex only, and thus hard to find, whereas the CRG and CRR conflict bulks consisted of either simple only or both simple and complex.

Mann-Whitney Test at significance level 95% (2-side) did not show any significant differences (p-values >0.098(-)) regarding study groups, i.e., individuals, groups, experts, and OntRep and individual conflict classes, i.e., total, CRC, CRG, and CRR. The main reason is a low number of involved data sets. Note that expert (Exp) and OntRep include one data set and we had 2 groups and an overall number of 6 individuals.

The CRG results are similar to the CRC results: rather low recall and precision values of individual conflict analysis and an improvement by group harmonization. A slight difference is that the expert performed much better than both the individuals and groups. He reached pretty high recall and precision values (more than 80%). The CRR results of the expert are similar to his CRG results, but totally different regarding individual and group results: The individual results were rather good (40% recall and 56% precision, but then worsened by group harmonization (30% recall and 24% precision).

Table 1. Overall Recall and Precision per Conflict Type.

	Total		**CRC**		**CRG**		**CRR**	
	Rec	Prec	Rec	Prec	Rec	Prec	Rec	Prec
Indiv.	32%	46%	29%	31%	30%	66%	40%	56%
Group	48%	49%	57%	49%	50%	68%	30%	24%
Expert	68%	88%	43%	100%	80%	89%	80%	80%
OntRep	100%	100%	100%	100%	100%	100%	100%	100%

Table 1 shows that OntRep has 100% values for both recall and precision for every conflict type. This means that OntRep found all of conflicts (7 CRC, 10 CRG, 5 CRR conflicts and no false positives). Although these results look like rigged for making OntRep look good, we think that the defined conflict types and the seeded conflicts are typical and realistic. Thus, the study is well-balanced and the comparison of OntRep with manual analysis results is valuable and meaningful.

B. Conflict analysis results by complexity

After analyzing the results regarding the different conflict types, we studied how effective OntRep is to identify conflicts of different degrees of complexity compared to a manual analysis. We defined two levels of complexity based on the number of elements involved in a conflict: simple and complex. The threshold number of elements to make a conflict complex is 3. We chose this threshold subjectively, because we think that analyzing 3 elements cognitively is still feasible, but gets more complicated and difficult to analyze conflicts with 4 or more involved elements. We seeded 12 simple and 10 complex conflicts (see Table 2).

In comparison to OntRep, the manual conflict analysis approach resulted in a lower completeness, no matter which type of conflict: the only conflict types for which the manual results come close to the OntRep results are the simple CRG and complex CRR conflicts; and there it is only the expert result that is similar to the OntRep result, the average results of individuals and groups are far away and false positives are introduced. They have been reduced slightly during group harmonization.

Table 2. Conflict identification per conflict type and complexity level.

	Simple Conflicts (12) Ind. / Group / Expert / OntRep (std. dev.)				**Complex** Conflicts (10) Ind. / Group / Expert / OntRep (std. dev.)			
Type **CRC**: To find: **0 simple and 7 complex** conflicts

Not Found	0.0	0.0	0.0	0.0	5.0 (2.1)	3.0 (1.4)	4.0	**0.0**
Type **CRG**: To find**: 10 simple and 0 complex** conflicts								
Fully	2.3 (1.2)	3.0 (0.0)	**8.0**	**10.0**	n/a	n/a	n/a	n/a
Partially	0.7 (1.2)	2.0 (1.4)	0.0	0.0	n/a	n/a	n/a	n/a
Recall (f+p)	30%	50%	80%	100%	n/a	n/a	n/a	n/a
False Pos.	2.7 (3.8)	2.0 (2.8)	1.0	**0.0**	0.7 (1.0)	0.5 (0.7)	0.0	**0.0**
Precision	53%	71%	89%	100%	n/a	n/a	n/a	n/a
Not Found	7.0 (2.0)	5.0 (1.4)	2.0	**0.0**	0.0	0.0	0.0	**0.0**
Type **CRR**: To find: **2 simple and 3 complex** conflicts								
Fully	0.0 (0.0)	**0.0** (0.0)	0.0	**2.0**	0.5 (0.8)	0.5 (0.7)	**2.0**	**3.0**
Partially	0.8 (0.4)	1.0 (0.0)	1.0	0.0	0.7 (0.8)	0.0 (0.0)	1.0	0.0
Recall (f+p)	42%	50%	50%	100%	39%	17%	100%	100%
False Pos.	**2.2** (2.3)	**4.5** (0.7)	1.0	**0.0**	**0.0** (0.0)	**0.0** (0.0)	0.0	**0.0**
Precision	28%	18%	50%	100%	100%	100%	100%	100%
Not Found	1.2 (0.4)	1.0 (0.0)	1.0	**0.0**	1.8 (0.8)	2.5 (0.7)	0.0	**0.0**

Complex CRC conflicts seem to be very hard to identify manually: from 7 existing conflicts only 0.9 conflicts on average have been identified completely, 2 conflicts have been identified partially; i.e. less than 45% of conflicts have been identified manually. On the other hand, false positives have been introduced. We expected that the number of false positives is reduced during group harmonization, but the opposite was the case: the amount of false positives increased from average individual results to the avg. group results. This is due to the complexity of the conflicts and the discussion that was caused by it during group harmonization.

Comparing completeness of simple and complex conflicts shows that the differences between manual and OntRep results increase with the level of complexity: e.g. regarding complex CRC conflicts the difference between manual and automated results is higher than regarding simple CRG conflicts where 8 conflicts have been found manually (as optimum) and 10 conflicts have been found completely with the OntRep.

Comparing correctness of simple and complex conflicts shows that correctness of identified complex conflicts is higher than of simple ones: For example, regarding CRR 2.6 false positives have been introduced for simple conflicts in average. On the other hand, no false positives have been identified for complex conflicts. The OntRep results for all types of conflicts are complete: all 22 conflicts of the defined conflict classes in

the given data were identified, due to the 3 reasons for 100% conflict identification described in section 5. We did not find any significant differences regarding the Mann-Whitney Test at a significance level of 95% (2-side). The necessary efforts for both the manual and automated approach are reported in [4].

VI. Discussion

The results of conflict analysis with OntRep seem convincing for the conflict types. The automated conflict analysis depends on the following factors:

- *Requirements structure*: OntRep analyzes different sections of each requirement to map them to the according concepts and to identify conflicts. Thus, a certain structure (EBNF) is necessary. When documents are used, this syntax is not used so frequently, but the importance of such a grammar increases when requirements databases are used instead of documents, because requirements have to be understandable and clear even without the context that usually exists in a requirements document.
- *Completeness of glossary*: the detection of logical conflicts depends on the terms captured as glossary terms in the ontology. OntRep recognizes conflicts between requirements that use different terms only if these terms are appropriately defined and their dependencies are clear. Usually, there is a project glossary existing in a project that can be imported into the ontology without big effort, so that all relevant terms are available for analysis.
- *Quality of ontology*: another prerequisite is correct modeling of the ontology, which requires expert knowledge. If the user does not specify it correctly, the tool cannot find the conflicts. If a constraint is missing in the ontology, the tool does not find any conflicts linked to that constraint. If a constraint has been specified wrongly, the tool might find conflicts with that constraint it was not intended to be found by the user. So if all facts have been modeled correctly, the tool will find all corresponding conflicts.

Despite the given prerequisites and limitations of OntRep, we think that this study is relevant, because its focus was on (a) evaluating the general technical feasibility of applying semantic technology to automated requirements conflict analysis, and (b) compare the results with the results of a manual approach for a practical-relevant set of conflict types.

VII. Conclusion and Further Work

Keeping requirements consistent is a main success factor for software development projects. That is why conflict analysis activities are important for requirements managers and project managers. However, the manual conduct of these activities takes significant effort and is error-prone, especially with an increasing number of requirements. Another issue is that participants with different domain backgrounds and terminologies have to work together in large distributed projects.

In this paper we proposed semantic technology as foundation for automating requirements conflict analysis and introduced the automated ontology-based reporting approach OntRep based on a project ontology and a reasoning mechanism. We used requirements formulated in EBNF as input to the proposed OntRep approach, which supports automated requirements conflict analysis. We evaluated the effectiveness of the OntRep conflict analysis approach referring to (a) different types of conflicts and (b) different levels of conflict complexity in a real-world industrial case study with 6 project managers in 2 teams. In addition a requirements expert and an OntRep user performed the same tasks to enable comparing the quality of results. Regarding the given conflict types the results of the evaluation are similar: OntRep found all conflicts in the requirements during the empirical study, while manual conflict analysis identified 30 to 80% of the conflicts for each conflict type and produced more false positives.

Further work will focus on the replication of this pilot study in a larger context. In addition, we want to increase the number of requirements and conflicts to be analyzed in order to get (a) more accurate numbers regarding recall and precision of the automated conflict analysis approach (b) more meaningful data regarding efforts of OntRep and manual conflict analysis approach for a higher number of requirements and conflicts.

Acknowledgment

We want to thank Alexander Wagner for the implementation of OntRep. This work has been supported by the Christian Doppler Forschungsgesellschaft and the BMWFJ, Austria.

A Process Oriented Approach to Model Non-Functional Requirements Proposition Extending UML

Aneesh Krishna
Department of Computing, Faculty of Science & Engineering
Curtin University of Technology, WA 6102, Perth, Australia
a.krishna@curtin.edu.au

Abstract

Non-functional requirements (NFRs), sometimes termed quality, or quality of service, attributes or requirements, have been a topic of interest within systems engineering, software engineering, and requirements engineering for a considerable period of time. NFRs have been for too long overlooked during the development of software systems. This has led to numerous cases of failure resulting in over budgeting or cancellation of projects. This paper proposes a method to extend the UML diagrams to model NFRs. A car rental case study is provided to illustrate the use of the proposed method.

1. Introduction

Functional Requirements (FRs) determine what functions a software product should offer. Multiple proposals have been developed to analyze and model them, and are nowadays widely used. For Non-Functional Requirements (NFRs), the problem is more complex and due to that they have been ignored for a long time in the early phases of the software development process. NFRs are defined as constrained on the emergent properties of the overall system. Hence, software products are sometimes refined late in the development process to satisfy NFRs, this as a result leads to over budget or cancelled projects [1]. Software engineers now acknowledge the importance of dealing with NFRs in the early phases of the development process [1]; however, there is lack of credible proposals to be used in the software development. In this paper we propose a solution to integrate the analysis and modelling of NFRs into UML [2], which is the most popular language for modelling purposes in object-oriented paradigm. Our goal is to offer a method to analyze, refine and integrate NFRs in existing diagrams to provide justifications for the design.

Chung et al [1] developed a framework to represent and analyze non-functional requirements. This framework is an interesting one; having potential to fully analyze the dependencies between non-functional requirements. This work uses the concept of 'claim' in the diagram. Claims are linked to interdependency, and provide a rationale to design decision. However, having multiple claims can make diagrams complicated and harder to read. Cysneiros et al [3] first proposed a method to integrate NFRs into ER and UML data models. This strategy uses the notion of lexicon, namely, the Language Extended Lexicon (LEL), as an anchor to integrate NFRs into OO models. The idea of LEL is to register the vocabulary (symbols) of a project, and determine the relations between the symbols. The concept of LEL is not widely accepted/used in software industry. Imposing its usage would hugely increase the workload of the systems analysts. Therefore, another solution is needed to link NFRs to UML diagrams that would have practical usefulness in industry. This work also considers that functional and non-functional aspects should be carried through two independent cycles with convergence points, while efforts should be carried out to merge the two aspects. Cysneiros's proposal can be used to integrate NFRs into any UML diagram, but no support is provided to deal with diagrams other than Class Diagrams. These reasons form the basis for our proposal in this paper.

This paper is structured as follow: Section 2 formally formulates the proposal, providing new notations to deal with NFRs through an example. Finally, Section 3 concludes the paper.

2. Incorporation of NFRs into UML

The proposal considers that NFRs and FRs should not be carried out through two independent cycles, but should be part of a common, global strategy. This decision had a huge impact on the process designed. The process can be visualized in Figure 1.

The main steps of the proposal are the following:

1. First, we determine what the FR and NFRs are.
2. From the FRs, we shall draw the use cases, and then associate the NFRs with the different parts of the system they control. When associating them, two cases may arise: either the NFR is specific to an FR (e.g. 'the authentication must be fast'), or it is global and thus not linked to a single FR (e.g. 'all screens of the system should look similar'). In the first case, the NFR is linked with a use case, else with the entire system.
3. The NFRs will then be refined using the use cases. In this step, the systems analysts will use their experience to find missing NFRs that should be included

in the diagrams. This is quite important, because the stakeholders do not always think about every single NFR (some might seem obvious, other irrelevant at first), or some of them are simply hard to come up with. This should prevent NFR from emerging at later stages of the project.

4. Using the FRs and NFRs that have been extracted, a requirement graph will be drawn. This graph will show the decompositions of the NFRs into subgoals, how to satisfy the sub-goals with operationalizations, and the way all these elements interact with each other. The focus here is solidly on FR that can impact NFRs, so not every FR will be included in this graph.
5. Study the interdependencies between the different requirements, their subgoals and their operationalizations. If necessary, perform trade offs (for example, using uncompressed format is good for performance, but not for space usage), and more generally, refine the requirements graph by studying the impact of each interdependency on the related requirements (see subsection 3.4).
6. Finally, use all the information gathered to draw other UML diagrams. This paper highlights only the application of this to sequence, class and deployment diagrams.

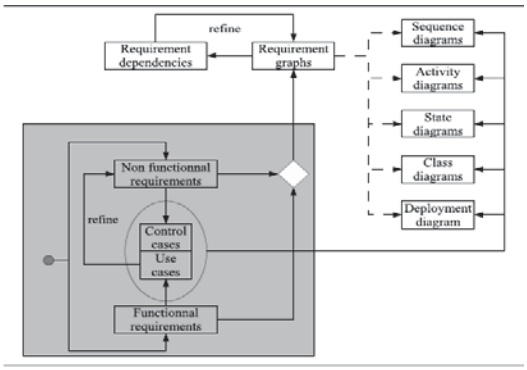

Figure 1: Diagram of the proposed strategy

Use cases controlled by NFRs: Incorporation of NFRs into use case diagrams is done by using a solution similar to [4]. A prerequisite for this is a complete or near complete list of the system requirements. FRs are subsequently used to produce use cases. Each NFR is documented with three pieces of information: the interested stakeholder, the NFR's type and NFR identification code (ID). Representing an NFR in the diagram, these three pieces of information are particularly important. First, we need a non ambiguous way to link a use case to an NFR, which is done by stating the ID of the NFR. Then, including both the stakeholder and the type of the NFR in the representation provides the systems analysts' with useful information without overloading the schema.

The general representation of such a diagram is presented on Figure 2.

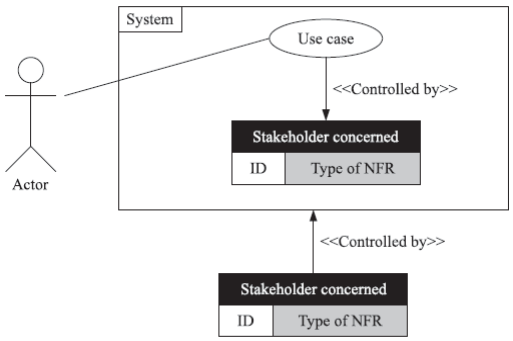

Figure 2: Actors and use cases controlled by NFRs

Construction of the NFRs graph: The aim of this step is to decompose an NFR into sub-softgoals [1]. Then, sub-softgoals that can't be subdivided find alternatives to operationalize it. Therefore, the following process has to be completed for each NFR represented in the use cases/control cases diagram. Add the object that the NFR is related to. Given that the NFR is not linked to a use case in this diagram, it is important to know on what the NFR acts (e.g. if we consider the informal high-level NFR 'Good Performance for accounts', the object is 'Account'). Next, the analyst has to specify the priority of the NFR. This is important to algorithmically determine what subset of the NFRs can actually be satisfied. The mark 1 means that the NFR can easily be ignored, while 5 mean that the NFR has to be satisfied no matter what. With the conclusion of the process, the NFR is renamed 'Formulated NFR' as shown in Figure 3.

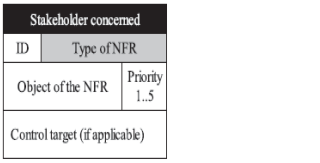

Figure 3: Representation of a high-level NFR

Sub-softgoals are subdivided until the analysts decide that no more decomposition is feasible or interesting. If possible, the analysts must try to avoid dividing a subgoal using only 'helps' contributions. If a softgoal does not have a sub-softgoal (or a group of sub-softgoals) which 'satisfies' it, it will be hard to determine if the higher level softgoal can actually be met. Once no more division is needed, possible operationalizations are associated to each leaf of the constructed graph. To do that, one must think about the most intelligent solutions to respond to the need expressed by a softgoal. All these alternatives will be represented on the graph using a unique ID and linked to the corresponding softgoal using the same connectors than before.

At the end of this phase, the analyst should have a graph

of formulated NFR, each with its own set of sub softgoals and operationalizations. The next step is to study the interactions between graphs and to incorporate the necessary FR.

Studying interdependencies in the requirements diagram: At this point of the process the analysts concentrate on the interdependencies between the different requirements. First all the NFRs graphs which are related are grouped. Obviously, the NFRs controlling the entire system must appear on each diagram. For the others it is quite easy: the NFRs linked to the same use cases, or having the same 'object' (Figure 3) can interact or be in conflict. Once all the related NFRs are on the same diagram, one uses the use case diagram and the associated documentation to add all the related FRs to the diagram. FR can also have an ID.

What remains is the selection of the operationalizations which will be used to design the system. In this work, we don't propose any algorithm (this forms part of the future investigation on this topic) to solve this problem, but such an algorithm should:

- analyze the impact of choosing each operationalization (which requirements are satisfied or helped, which operationalizations or requirements are hurt or broken)
- assure that every FR (and NFR of priority 5) is satisfied (one of its operationalization is chosen)
- give a mark to each alternative subset (using the weight of the contributions and the priority of the NFRs)
- return the highest-ranked solutions

The analyst then chooses the most appropriate subset for the design of the system. The chosen operationalizations are marked with the letter "**C"** in the 'Expected status' box, while the others with the letter "**R",** "Rejected". The 'Expected status' of the Formulated NFRs and softgoals will then be updated according to this choice.

UML diagrams: This section demonstrates how to integrate NFRs and their operationalizations into UML diagrams. The focus is on sequences, deployment and classes, but the techniques can work on other diagrams.

The following links can be used in these diagrams, as shown in Figure 4

- The «implements» link means that the element has been added to the design of the product in order to satisfy the operationalization. If the operationalization is not considered anymore, this element can be removed.
- The «contributes to» link means that an element previously existing in the diagram is used by the operationalization. It is important to highlight such an element: if it has to be modified to comply with its primary function, the systems analysts must study the impact of the change on the realization of the operationalization.
- The «controlled by» link defines that one knows that the implementation has to be guided by a particular NFR but no specific solution has been chosen yet. Most of the time, such a link must come with an annotation.

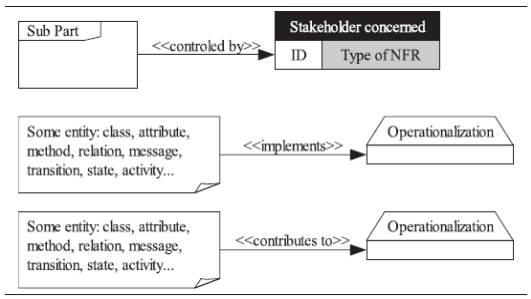

Figure 4: Links to be used in UML diagrams

Sequence Diagram: Once the sequence diagrams are ready, the analysts will incorporate the NFRs into them. Usually, a sequence diagram will be related to one of the use cases that has been designed earlier, and this use case might be related to one or more NFRs. If this is the case, then for each of them, the analyst has to ask himself: where does this NFR impact the sequence diagram, and how? The analyst can choose the level of detail for the diagram as shown on Figure 5. Therefore the analyst can:

- state that a subsequence is «controlled by» an NFR,
- link some specific previously existing messages to a operationalization («contributes to»),
- add new messages (and maybe new classes) to the diagram which «implements» an operationalization.

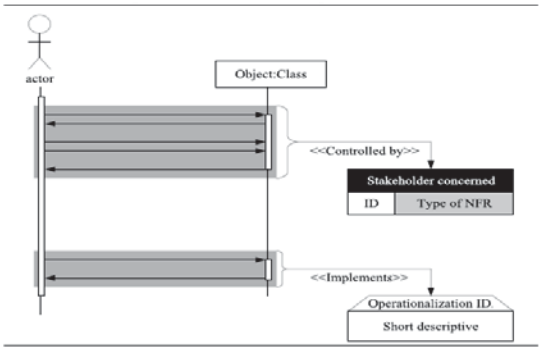

Figure 5: Representation of an operationalization

Class Diagram: The approach to incorporate NFRs into class diagram is quite simple and is shown in Figure 6.

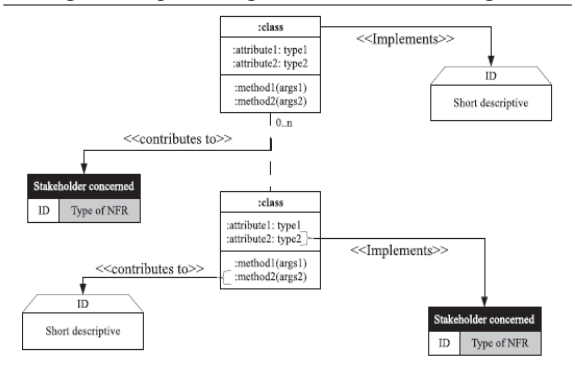

Figure 6: Incorporating NFRs into class diagrams

Verification: Once the NFRs or their operationalizations have been included in every necessary diagram, one has to verify that everything planned on the NFR graphs is actually considered in the design of the product. This justifies the existence of the box 'Current status' at the bottom of the representations of NFRs and operationalizations in the NFR graphs. For each operationalization chosen, one has to check if it appears on diagrams with links of type «implements» or «contributes to». If it is the case, then the operationalization has been 'satisfied', or else it was 'not handle'. Then update the 'current status' of all NFR softgoals that the operationalization links to. After considering the operationalization, if an NFR softgoal that was expected to be 'satisfied' or 'weakly satisfied' is not, it has to be verified if this NFR is linked to any other diagram with relation «controlled by». If so, the NFR has not been forgotten, however, no technical solution has been indicated on the design. If it is the case, it is up to the analyst to decide if this is good enough to mark to softgoal as 'weakly satisfied'/'satisfied' or if the design needs to be refined. These verifications should in fact be done automatically by a framework implementing our proposal. After these verifications, the operationalizations which were chosen but are not satisfied and the NFR softgoals where 'expected status' is different from 'current status' should be highlighted for the analyst to know immediately what is missing.

Car Rental Case Study: This case study demonstrates the application of the method for designing an e-commerce application for online car rentals. The example concentrates on core aspects of such a system with emphasis on business processes that relate to rental and provision of information to customers regarding the company. The complete explanations of the approach (along with case study) can be had by visiting http://www.computing.edu.au/~aneesh/NFR (details withheld due to space limitations).
Use cases enriched with NFRs are shown in Figure 7.

The sequence diagram of the system is depicted in figure 8. The functionality depicted is limited to the searching process for a car.

3 Conclusions and Future Work

This paper presented a novel approach to dealing with Non-Functional Requirements and to model them in UML diagrams. This work constitutes an important contribution given that it allows system analysts to consider NFRs in their models without requiring additional learning of new software. Part of our future plans include the automation of elements of the proposal in order to utilise its full usefulness in industrial settings. We accept that the full proposal is very difficult to automate, as there is a need to provide manual support by systems analysts at certain steps of the approach. However, this is the case with almost all methods proposed so far in this challenging area.

Use Case Driven Extension of ProjectIT-RSL to Support Behavioral Concerns

David de Almeida Ferreira, Alberto Rodrigues da Silva

david.ferreira@inesc-id.pt, alberto.silva@acm.org

***Abstract*—Requirements Engineering is a system engineering discipline of paramount importance. Its primary deliverable is the requirements specification, a document that entails the detailed description of business-specific needs to which the target software system must comply to. Despite the advances brought by modeling techniques, the specification of software systems still consists mostly in manually writing down requirements in natural language. Resorting to natural language to convey requirements has some advantages, such as its expressiveness and the stakeholders proficiency at using it for communication purposes, when compared with semi-formal or formal languages. However, ad-hoc natural language has intrinsic characteristics that make it error-prone, some of which may even hinder the effort of complying with good requirement criteria, regardless the usage of an automated requirements tools. To address this problem, within the scope of the ProjectIT initiative, a requirements specification language named ProjectIT-RSL was developed, based on common linguistic patterns. Despite covering several structural aspects of the software system under specification (e.g., actors, components, entities, properties, and relationships), ProjectIT-RSL still lacks the support for capturing behavioral concerns.**

This paper presents a Use Case Driven extension for ProjectIT-RSL , with the purpose of supporting the specification of functional requirements according to a controlled natural language approach. The proposed solution combines patterns from Use Case textual description best practices with Pseudocode specifications.

***Keywords*-Requirements Engineering; Specification Language; Controlled Natural Language; Use Cases; Pseudocode.**

I. Introduction

The size and complexity of modern large-scale software systems demand for high-levels of abstraction, conceptual reasoning, and validation upfront. Namely, a clear definition of the real business-specific needs is required. Therefore, regardless of the achievements in both industry and academia, the development of software systems is still a rather challenging process. From all system engineering disciplines, it is argued that Requirements Engineering (RE) is one of the most important regarding this issue, since it supports the work of several other disciplines throughout the entire software product life-cycle [1]: it provides useful scope and status information to Project Management upstream and provides a stable basis for development downstream, namely for design and testing.

Typically, the development of a software system begins with Requirements Engineering (RE) [2]. RE deals with the early activities related with the process of discovering the purpose, scope, stakeholders, boundaries, and actors of the system being specified [3]. These early activities can be classified as the *requirements development process*, whereas the activities of evolving accepted requirements (e.g., dealing with change requests, impact analysis, tracing, and status-tracking) can be regarded as the *requirements management process* [4]. In short, RE is concerned with real-world goals for software systems functionality, and also how it can be precisely specified and maintained throughout the software development process [5].

However, often the importance of RE is underestimated, resulting in a large amount of rework: any attempt to start technical work beforehand, without a deep understanding of the target software system's purpose, will certainly jeopardize the project outcome [6].

The main deliverable of RE is an artifact (usually called *requirements document*) that contains the detailed textual description of *what the target system should do*, or *constraints on its behavior* [7]. However, this form of specification (based on natural language) is ambiguous and, in many cases, unverifiable because of the lack of a standard machine-executable representation [7]. The main problem appears during the translation of natural language requirements into a formal or, at least, semi-formal computer model [8]. Despite these complementary approaches, natural language textual specifications are still the most suitable, fast, and preferred manner (by non-technical stakeholders) to contribute and validate requirements specifications [7].

Taking these facts into consideration, within the scope of the ProjectIT initiative [9], [10], a requirements specification language named ProjectIT-RSL [11] was developed. This initiative seeks to address some of the aforementioned problems, since it advocates that the software development process should be focused on higher-level activities (such as Project Management, Requirements Engineering, and Architectural Design), instead of repetitive and error-prone manual activities. Following this mindset, ProjectIT-RSL was designed to increase the rigor of requirements specifications to enable tool support, namely to provide user feedback

This work is supported by FCT (INESC-ID multi-annual funding and PhD Scholarship SFRH/BD/36972/2007) through the PIDDAC Program.

during the specification process and the automatic generation of initial design drafts upon validated requirements.

Despite the concrete results achieved, there are still several open issues, namely the lack of support for the definition of software system behavior. To cope with real-world problems, the controlled natural language approach provided by ProjectIT-RSL needs to cover not only static aspects of the target system (e.g., *domain model* concepts) but also dynamic aspects related with functional requirements.

The remainder of this paper is organized as follows. Section II presents a review of related work regarding the specification of software system behavior. Section III presents the Use Case Driven extension of ProjectIT-RSL and introduce an illustrative example. Finally, Section IV concludes this paper with final thoughts and discussion.

II. Related Work

Historically, the requirements specification process has consisted in creating a natural language description of *what the target system should do* or *constraints about its behavior* [4], [7]. As opposed to constructed, artificial, or any other kind of engineered languages (with specific purposes in mind), the term *natural language* refers to any language commonly used by humans in their daily communication. Its usage to support RE activities has already been studied for a long time [8]. However, this form of specification is both ambiguous and, in many cases, unverifiable because of the lack of a standard machine-executable representation [7].

To mitigate the undesirable effects of natural language, one can impose some restrictions to reduce its complexity while maintaining its naturalness. *Controlled Natural Languages* (CNL) are subsets of natural languages whose grammars and vocabularies have been engineered in order to reduce (or even eliminate) both ambiguity (to improve computational processing) and complexity (to improve readability). CNLs are typically designed for knowledge engineering, not addressing behavioral aspects. A thorough analysis on the state-of-the-art of CNLs is provided in [12]. Attempto Controlled English (ACE) [13] is a good representative of this category of textual languages, because it is a mature general-purpose CNL with a solid toolset and a wide literature body of knowledge[1]. Furthermore, ACE possesses some interesting (and useful) characteristics, namely every ACE sentence is unambiguous, even if people may perceive the sentence as ambiguous in full English [14].

To address functional aspects, namely to specify complex behavior (implementation-independent algorithms and other abstract computations), one can resort to *Pseudocode* [15]. The high-level algorithmic descriptions achieved with Pseudocode could be integrated with the previous CNL approaches to address their weaknesses in terms of behavioral expressivity. However, Pseudocode lacks a widely accepted and well-defined standard (only some guidelines are defined [16]). We considered that *PlusCal* [17], [18] is a suitable representative for this approach. Despite having formal roots, PlusCal was designed having in mind some of the Pseudocode's guidelines (e.g., simplicity), which in turn reflects on *PlusCal*'s design principles and syntax. PlusCal is an algorithm language that can be used to replace Pseudocode, for both sequential and concurrent algorithms [17]. Specifications in PlusCal can be automatically translated into another formal language enabling the verification of formal properties through model-checking.

Additionally, one can resort to semi-formal *graphical* approaches. This category of languages is well represented by *UML*, the general-purpose language endorsed by OMG and considered by many as the *de facto* standard for modeling and documenting object-oriented software. Usually, modelers use Activity and Sequence UML diagrams to specify software system behavior. However, the information conveyed by UML models is usually incomplete, informal, imprecise, and sometimes even inconsistent. These flaws are caused by the diagrams' limitations. These diagrams cannot fully convey the details of a thorough specification.

Also, there are hybrid approaches such as Use Cases: UML Use Case diagrams can be complemented with their textual descriptions counterpart. Use Cases provide a natural approach to organize and describe the overall system functionality through descriptions, in abstract terms, of how actors interact with the system to accomplish their goals [19]. Although they are not suitable to describe functional requirements of all kinds of systems, they are adequate to specify general information systems [19]. Also, since they describe the system functionality from an actor's perspective, they can be easier to read and understand by non-technical stakeholders than more formal or complex notations (formal methods or UML diagrams enhanced with OCL). However, although it might seem a trivial task, the relatively small number of concepts, allied with the lack of a rigid set of structuring rules (or compositional rules, when dealing with Use Case diagrams), makes people often struggle to write (or model) useful and adequate Use Cases.

Finally, there are some combined approaches. Natural Language Processing (NLP) approaches to automatically derive conceptual models from requirements texts are not new [8], and neither is the usage of formal methods to support consistency checking through mapping techniques [20]. Debnath et al. [21] propose a solution to integrate requirements written in natural language into the OMG's Model-Driven Architecture. They defined manual derivation strategies to obtain conceptual models and formal specifications from textual requirements. Their approach follows an OCL-based transformation process to define Computer Independent Model (CIM) models from natural language oriented models. Mala et al. present research regarding Use Cases combined with NLP techniques. They present an ap-

[1] http://attempto.ifi.uzh.ch/site/pubs/

proach for the automatic construction of object-oriented design models in UML from the natural language requirements specification. Unlike others, their approach combines domain modeling, Use Case descriptions (written in a restricted form of natural language), and non-functional taxonomy to derive non-functional requirements prioritization through trade-off analysis. Konrad et al. [24] also attempts to ease the integration of formal specification languages through the process of specifying properties of formal system models in terms of natural language and formally analyzing these properties using existing formal analysis tools. Still regarding natural language approaches, the work of Meziane et al. [8] follows a different approach to mitigate miscommunication problems by generating natural language specifications from UML class diagrams.

Despite this wide range of techniques and approaches, many problems concerning the pragmatic usage of these solutions are still unresolved [25].

III. ProjectIT-RSL Extension

ProjectIT-RSL is a controlled natural language aligned with a metamodel derived from common linguistic patterns [11]. This language was designed to convey information in such manner that a tool can extract requirements models from its textual specifications. ProjectIT-RSL metamodel already provides concepts (e.g., Operation, Activity, and Action) to convey information about software system behavior. However, until now, the concrete realization of the dynamic part of the metamodel in terms of language constructs has not been addressed [10]. Thus, ProjectIT-RSL lacks the means to convey behavioral concerns about the software system under consideration. The specification of complex interaction patterns between actors and the target system is crucial for gaining a thorough understanding of the software system's functionality, namely to perform a more extensive analysis (e.g., consistency checking and model-checking) on requirements specifications written in this controlled natural language. This kind of feedback is crucial to increase stakeholder engagement in RE activities related with verification and validation.

According to the object-oriented paradigm, so far the conceptualizations that ProjectIT-RSL conveys are typically referred to as a *domain model*. This kind of conceptualization describes the various entities, their properties and relations (an example is provided in [26]). The domain model provides a structural view of the domain of interest, which can be complemented by other views focusing dynamic aspects, such as the one presented in this paper.

Considering the original mindset and design principles of ProjectIT-RSL [11], namely the grammar and writing style, we follow the seminal results presented in [27]. Hence, our proposal extends the previous version of ProjectIT-RSL by combining Use Case textual descriptions with Pseudocode.

A. Reusing and Structuring with Use Cases

Besides the metamodel previously mentioned, ProjectIT--RSL specifications also follow another metamodel (depicted in Figure 1) with different concerns. The former is related with the specifications' content, whereas the latter addresses the best practices regarding requirements document's structure. Our proposal in this paper focuses on providing an extension for the *Functional Requirements* section.

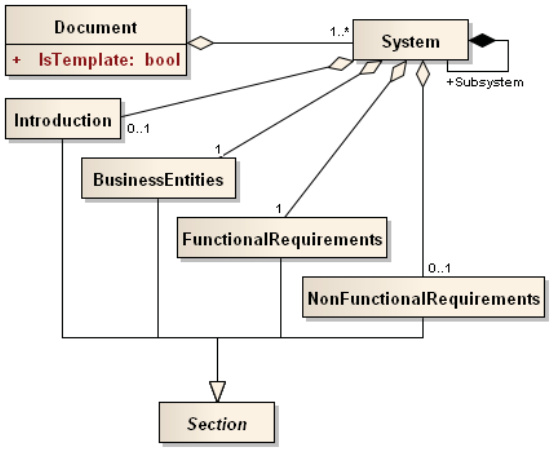

Figure 1. ProjectIT-RSL structural metamodel.

Given the match between our goals in terms of representation of functional requirements and the purpose of Use Cases specifications, we consider that, to avoid "reinventing the wheel", Use Cases are the best underpinning for developing the ProjectIT-RSL extension. Use Cases employ a small set of straightforward concepts that are easily understood by non-technical stakeholders. We also benefit from a well--defined body of knowledge [28]–[30], namely how these specifications can be structured and reused in an easy to understand and industry-standard manner. Finally, bearing in mind the current ProjectIT-RSL support for domain modeling, by adopting Use Cases for conveying functional requirements, we become aligned with the early stages of the well-known ICONIX process [30]. The major pitfall of using Use Cases as a requirements specification technique is the lack of well-defined rules. Nevertheless, this problem can be addressed by providing a Use Case context-free grammar that is aligned with the metamodel presented in Figure 2.

This extension enhances the *Functional Requirements* section by providing a subsection named *Use Cases*, which contains all Use Case specifications of the (sub)system being considered. An illustrative example is presented in Listing 1. This Use Case describes a simple and common interaction with a web application, in which a registered user tries to recover a password. The textual description already provides syntax highlighting according to a context-free grammar aligned with the metamodel presented in Figure 2.

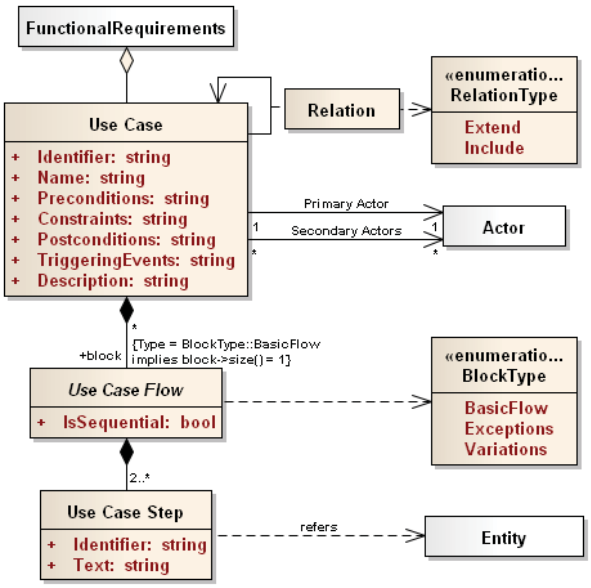

Figure 2. Use Case Driven metamodel.

B. Complex Behavior Specification with Pseudocode

To cope with the description of complex software system behavior, we advocate the usage of Pseudocode-like descriptions. According to our proposal, these Pseudocode--like [15], [16], [31] snippets act as adornments for Use Case steps. They only should be used when a fine-grain level of detail is required, namely to customize the intended action meaning or to entail the detailed specification of a complex behavior (not provided by built-in actions). The verbs used while describing detailed Use Case steps have linguistic properties (such as thematic relations[2]) that allow us to consider them as extension points to which functions in Pseudocode can be hooked up (if the function presents the same number of arguments and constraints as the verb theme). Gottesdiener [19] provides a comprehensive list of suggested verbs for both *informative* Use Cases that provide information to actors (e.g., *find*, *list*, *notify*, *select*, *view*) and *performative* Use Cases that allow actors to handle complex tasks (e.g., *approve*, *authorize*, *choose*, *send*, *submit*, *validate*). By resorting to this hook up mechanism we gain an additional level of flexibility regarding the possibility of providing custom-made functional specifications for the specific needs of the project at hand.

Pseudocode often appears in the literature as a simplified programming language to describe algorithms. Regarding the Pseudocode syntax, we adopt PlusCal's due to its benefits: we do not "reinvent the wheel" by designing a concrete syntax for Pseudocode, and we also automatically ensure compatibility with PlusCal's formal verification tools. PlusCal's documentation [17] already provides a context-free grammar that we reuse within the ProjectIT-RSL extension for specifying Pseudocode-like snippets.

                Anonymous User."
          5.1b "The system terminates the use case."
      EndUseCase
    End Section
  End Section
End System
```

Listing 1. Use Case example: "Recover Password".

Following the example of Listing 1, we can illustrate the usage of Pseudocode to specify the behavior related with the verb *"send"* used within step 5 (*"The system sends an e-mail with new password to the Anonymous User through the Mail Server."*). According to VerbNet, the sentence's main verb (*"send"*) has three roles (arg0 the "sender", arg1 the "sent", and arg2 the "sent-to"). While mapping these roles we notice that step 5 contains additional information provided by a prepositional sentence ("through the Mail Server"). This piece of information will not be considered while hooking up the verb arguments with the built-in actions, unless we introduce a Pseudocode extension. We can specify a custom-made Pseudocode snippet (illustrated in Listing 2) to support this additional verb role (arg3 the "by-means").

```
--algorithm Send

variables maxAttempts = 3, secondsBetweenAttempts = 60

procedure SentToBy( variables sender, message, destination, channel )
  variables count = 0
  while ( count < maxAttempts )
    if ( call SendToChannel( message, destination, channel ) )
      return 'true'
    else
      count := count + 1
      call SleepSeconds( secondsBetweenAttempts )
    end if
  end while
  return 'false'
end procedure

end algorithm
```

Listing 2. "Send-To-By" Pseudocode specification example.

[2]Thematic relation is a linguistic term used to express a syntax–semantic correlation, namely the roles that a noun phrase plays with respect to the action or state described by a sentence's main verb.

C. Parsing of ProjectIT-RSL Extension

This extension of ProjectIT-RSL resorts to different parsing techniques, being the pipeline divided in two different stages. First, we make use of a structural template, derived from Use Case textual description best practices [28]–[30]. This derived template is processed with a context-free grammar similar to those used by programming languages. Next, after the structural information has been parsed, the process follows to the second stage of the pipeline. At this stage we make use of NLP techniques, namely shallow parsing[3] of the pieces of information previously captured according to its context within the structural template. The extracted information, namely from detailed Use Case steps, will populate models aligned with the ProjectIT-RSL metamodel. Pseudocode is used to specify complex behavior not covered by built-in actions associated with the verbs used while describing detailed Use Case steps.

We resort to shallow parsing techniques to address complexity of natural language, which hinders the possibility of building a general-purpose representations of meaning from ad-hoc natural language text [32]. To ease the burden of full parsing, we only look for very specific kinds of information in detailed Use Case steps, namely to populate models according to the *"Actor performs Operation on Entity"* core structure emphasized by the ProjectIT-RSL metamodel. Our shallow parsing approach can be considered as Chunking [32, Ch. 7, p. 261], more specifically a regular expression cascaded chunker. The possibility of adding new parsing rules that express linguistic patterns, namely to extract specific and contextualized pieces of information from detailed Use Case steps, makes the language extensible.

IV. Conclusion

Requirements Engineering is a mature discipline, and throughout the last decades several approaches to improve its processes and artifacts have been proposed. Yet, there are still open issues to address, namely problems regarding communication and requirements quality.

The ProjectIT initiative advocates that a greater attention should be given to the rigor and quality of requirements specifications. Namely, it emphasizes the need for tool support, because most RE techniques are manually applied, thus making them error-prone and less cost-effective when dealing with modern software systems, due to their size and complexity. Since requirements provide the foundation for most of subsequent technical work, these activities would certainly benefit from consistency checking of the requirements specifications. Also, unless suitable tool support is provided, to validate and generate an early design draft from requirements specifications, it will be difficult to seamlessly integrate RE with the Model-Driven Engineering paradigm.

[3] As opposed to full parsing, where one or more complete parsing tree are derived, shallow parsing techniques try to identify and extract information from relations between words.

Considering these facts, this paper presents an extension for the ProjectIT-RSL language, to address its current lack of support for the specification of behavioral aspects. To convey information about the software system behavior with ProjectIT-RSL, namely to specify functional requirements, we propose an integration of well-known techniques, more specifically textual Use Cases with Pseudocode specifications. The former is an industry-standard technique that provides a template for structuring functional requirements, thus reducing the complexity of natural language parsing with well-defined contexts. The latter provides a technology-agnostic approach to express complex behavior (the computations associated with the customized-actions, i.e., the verbs used within Use Case steps). This extension complements the current ProjectIT-RSL support for domain modeling and, although it is process-independent, it can be well supported by processes such as ICONIX or RUP.

As future work, in the short-term we plan to validate the ProjectIT-RSL language with real-world case studies. First, we are going to develop the required tool support by extending the current ProjectIT toolset, namely the parsing algorithms and text editor. In the long run, we plan to use the requirements models entailed within ProjectIT-RSL to infer or verify properties of the target system (e.g., model-checking or theorem proving) in order to ensure the overall quality of its specification.

***Abstract*—This paper presents the application and validation of a UML metamodel developed for the requirements modeling in multi-agent systems projects. In this paper we describe the metamodel and its application into the modeling of an intelligent tutor system called AME-A. We also demonstrate the way we intend to validate this metamodel.**

Keywords-Metamodels; Stereotypes; Agents; Agent Roles; AgentRole_Actors; Internal Use-Cases; AME-A

I. INTRODUCTION

AOSE (Agent-Oriented Software Engineering) is a new area that mixes concepts both from the software engineering and artificial intelligence areas. This new area arose from the multi-agents systems (MAS) development increase and from the new challenges relative to the analysis and project generated by this kind of software. The AOSE seeks to develop methodoologies, techniques, and languages that allow the modeling of the special features presented by the MAS.

UML (Unified Modeling Language) is a standard modeling language adopted by the software engineering area, thus, within the AOSE context, some attempts to create new languages after the UML as adapted to the Multi-agent Systems (MAS) project were made. However, none of the languages studied was concerned about extending or adding new metaclasses to the metamodel that serves as the basis for the use-cases diagram (UCD), for that is mainly employed in the requirements analysis (RA) an essential step for the achievement of a good software project.

Considering the importance of the requirements analysis phase, we developed a UML metamodel for the requirements modeling in MAS projects. In this metamodel we created new metaclasses and stereotypes, thus to allow the employment of the use-cases diagram for this purpose.

In this paper we shall discuss the UML-derived languages for the MAS project we have studied. Next we shall speak about the RA importance, passing on to the definition of metamodels, models, and profiles. After that, we shall describe the developed metamodel and present an application of it. Finally, we shall discuss the validation of the metamodel, when we shall compare the diagrams produced using our metamodel concepts with the diagrams produced by means of the standard UML, thus trying to demonstrate that the UML does not support the modeling of the concepts that our metamodel does.

II. DERIVED LANGUAGES FROM UML FOR THE MULTI-AGENT SYSTEMS PROJECT

Some languages were derived from UML to adapt it to the MAS Project, like AUML [1], AORML [2], AML [3], MAS-ML [4], and the [5] agency metamodel. However, there were found no mechanisms in these languages to model the requirements for the MAS project, nor any concern into making a RA as in the system life cycles described by [6] or in software development methodologies like the UP [7].

One of AUML [1] main contributions was the adaptation of the UML sequence diagram to the agent communication. However, there has been no adaptation of the UCD for it to be applied into the RA. We imagined that, as the AUML is based in UML, the UCD would be applied in its original way; however, were this the case, this diagram could not be used to model the internal requirements of a MAS.

The AORML concentrates on the matter of interaction modeling between agents and how these react to stimuli. With respect to the requirements modeling, [2] proposes, but does not show, the use of the activity diagram for the RA. In [8] the UCD is applied in its original format, identifying only external requirements; no adaptation of this diagram was attempted to model agent roles, goals, perceptions, actions or plans.

The AML represents agents and the roles played by them and it allows to dynamically model role changes. AML further represents the agents' perceptions and actions. [3] mentions it is possible to apply mental states so as to enrich the use case modeling by means of the requirements modeling based on goals; however we did not find examples of how that could be done. Besides, no metaclasses were created to model requirements in MAS as proposed in our work.

MAS-ML [4] represents agents, their environments, the resources the agents can manipulate, the organizations of the system and the roles that can be played by the agents, as well as their beliefs, goals, and plans. However, the language is not concerned about the matter of the requirements analysis and no attempt was made to adapt the UCD to this end.

The metamodel in [5] represents roles, organizations, environments, beliefs, goals, and plans, as well as the agents communication. However, this metamodel does not focus on the requirements modeling and no attempt was made to adapt the UCD for this function.

III. Requirements Analysis

According to [9], about half of the factors associated with successful projects is related to requirements and the project success is directly bound to its quality. Now [10] states that the incorrect requirements definition is one of the mainly factors contributing for the failure of a project. And, according to [11], the requirements elicitation, analysis and documentation in complex systems is a crucial and non-trivial task. Finally, according to [6], use-cases (UC) are of special interest in the requirements engineering, since they were demonstrated as valuable to elicit, document, and analyze requirements.

Within this context, several authors recommend the UML UCD for the requirements modeling, like [6], [9] and [11]. The objective of this diagram, as can be seen in [12] is that of identifying the actors that might interact with the system, the functionalities offered by the software and which actors will be allowed to use which functionalities. Being a standard language widely accepted and used, with great flexibility for adaptation to new dominions we believe that UML notation use can easen understanding by developers. Thus we developed a UML metamodel in which we created new metaclasses and stereotypes with the goal of allowing the employment of the UCD for the requirements modeling in the MAS project.

IV. UML, Metamodels, Models and Stereotypes

UML is a visual language for specifying, constructing, and documenting system artifacts. It is a general-purpose modeling language that can be applied to all application domains [13], The UML specification is defined by using a metamodeling approach. When metamodeling, a distinction is established between metamodels and models. A metamodel defines a semantics for the way of modeling elements within a model. A model captures a vision of a physical system, it is an abstraction of the software with a purpose that determines what must be included and what is irrelevant.

A stereotype is a limited type of metaclass that can only be used in conjunction with one of the metaclasses it is extending. A stereotype allows to define how a metaclass can be extended, assigning to it new characteristics and/or constraints. When a new metaclass is derived from a previous metaclass and uses the stereotype named, “stereotype”, this new metaclass allows to model instances of the original metaclass containing a stereotype with the new metaclass name, making possible to model stereotyped elements in a model with characteristics that differentiate them from the original elements.

V. The Proposed UML Metamodel

Considering that UML is a widely accepted language and that MAS has its own characteristics and that none of the studied languages that extended the UML to the MAS project focused on the RA issue, we created a metamodel containing new metaclasses and stereotypes prepared to identify the requirements of this kind of system.

Initially, we tried to create a UML profile to adapt the UCD, but we realized that only extending the metaclasses used by this diagram would not be enough. Previous versions of the original profile have been published in [14], [15] and [16]; nonetheless, we evolved it into a real metamodel, adding new metaclasses and stereotypes and adapting it to the work by [17]; besides, in the previous publications we did not speak about how we intend to validate this metamodel.

Initially, we tried to use the Actor metaclass to model agent roles, because, according to [12], this metaclass represents a kind of role played by an entity that interacts with the system, but is external to it. However, the agents are not external to the system, they are inserted within the system and, as they are independent, proactive, and able to interact with the software according to their goals, the roles of these agents must be represented as actors. Therefore, as states [18], it is necessary to adapt this concept, since agents are internal to the system, and if we intend to represent agent roles as actors, these actors must be represented internally, inside the system boundaries.

The representation of agents/roles as UML actors can also be seen in [19], where agents represent active objects and are modeled within the system as actors with square heads. However, [18] only suggests that the actor concept should be adapted, all the while [19] did not create a UML metamodel. In our work we explicitly created new metaclasses to allow for an adequate requirements modeling to be employed in the MAS.

All the same, according to [13], it is not possible to take away any constraints once applied to a metamodel in a profile. Thusly, instead of extending the Actor metaclass, we created a new metaclass from the same metaclass as was created the metaclass Actor, as can be seen in the Fig. 1, thus creating the metaclass AgentRole_Actor. In this new metaclass we copied all the characteristics of the metaclass Actor, suppressing only the constraint that an actor must be external to the system.

From this new metaclass we derived the Reactive and Cognitive_AgentRole metaclasses. We applied the stereotype named, “stereotype”, to both metaclasses, which means that these metaclasses will be applied as stereotypes upon AgentRole actors and will assign them special characteristics.

We specialized still further the Cognitive_AgentRole metaclass by deriving the PS, UAM and SMI_AgentRole metaclasses. They were created after the work of [17], who suggested the use of specialist agents Problem Solving (PS), that must own knowledge about the problem the application will help to solve; Users and Agents Modeling (UAM), that must own the knowledge about the users and agents modeling in order to make cognitive models; and Social Mediated Interactions (SMI), that must own knowledge about how to mediate social interactions between the user and the system.

According to [12], UC can be used to specify the system's external requirements. A UC is the specification of a set of actions performed by software, generating an observable result and producing some value for one or more actors. We intended to represent actions, perceptions, goals, and plans as UC, but the UseCase metaclass semantic states that UC represents external requirements, thus, with the objective of adapting the UC concept for the MAS modeling, we derived a new metaclass from the same metaclass as the UseCase metaclass had been derived, calling it InternalUseCase (IUC) and then we created relationships for this metaclass, equal to those existing between the Classifier metaclass and the UseCase metaclass.

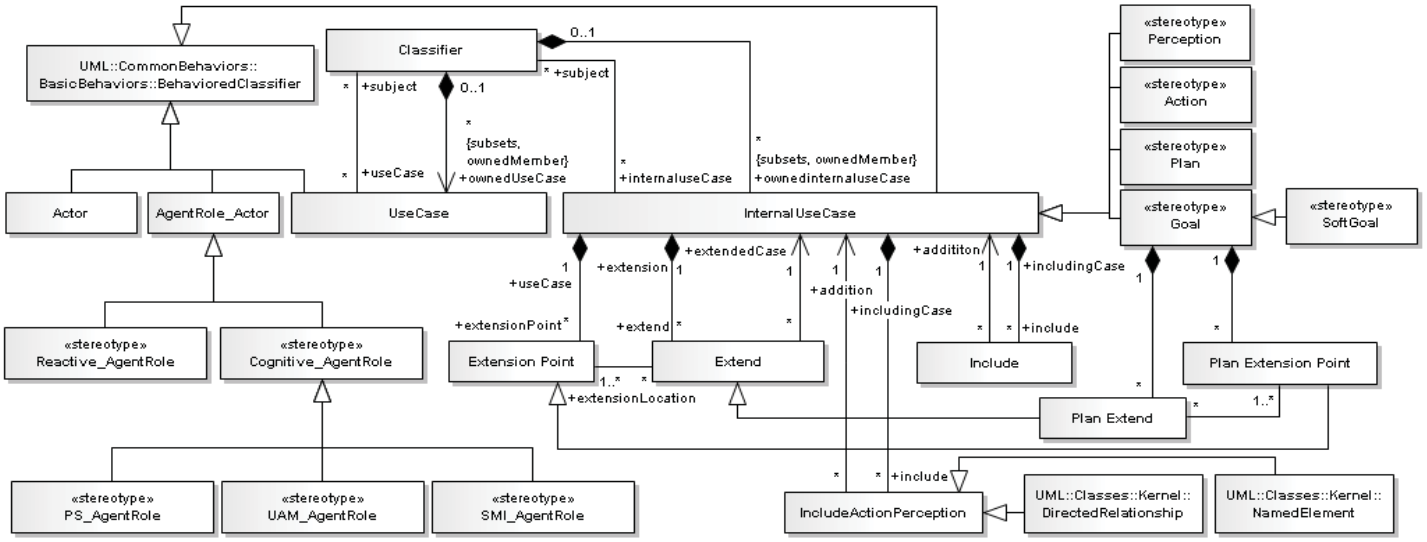

Figure 1. UML Metamodel for Requirements Modeling in the Multi-Agent Systems Project

All IUCs are internal to the system and cannot be seen or used by external entities. From the InternalUseCase metaclass, we extended some metaclasses to attribute special characteristics to the IUCs. These extended metaclasses will be employed as stereotypes. Thus, we created the Perception and Action metaclasses to model IUCs that contain the necessary steps for an agent to perceive an event or perform an action.

A third metaclass was derived from the InternalUseCase metaclass, to represent goals. An IUC employing the Goal sterotype will contain a description of an agent's desire and the possible conditions for that desire to become an intention. A somewhat similar proposal to represent goals as use cases can be seen in [19]. However, besides creating the IUC concept, we went even further, when we considered that, in the same way a goal represents a desire that will not necessarily became an intention, the steps for its execution should be detailed in one or more IUCs other than the IUC that represents the goal.

So, in a situation where an IUC employing the Goal stereotype was used, we would detail in this IUC only those perceptions and conditions necessary for that goal to become an intention. Considering that a goal can eventually own more than a plan and that these plans only will be executed under certain conditions, we decided to derive a fourth metaclass named Plan, to identify the plans associated to the goals.

According to [12], an extend is a relationship that specifies how and when a behavior defined in the extended use case can be inserted into the behavior of the extending use case. If the extension condition is true, the extended use case behavior will be also performed. Considering that a plan is only triggered after a condition is satisfied, we extended the Plan Extend metaclass from the Extend metaclass and associated it with the Goal metaclass. We proceeded this way to differentiate normal extension associations from plan extension associations.

We also derived the Plan Extension Point metaclass from the Extension Point metaclass. According to [12], an extension point identifies a point in the use case behavior that can be extended by the behavior of another use case. We derived this metaclass to establish a difference between plan extension points and normal extension points.

Finally, we derived the IncludeActionPerception metaclass from the same metaclasses that the Include metaclass was derived. We made it because the semantics of the Include metaclass says that it is intended to be used when there are common parts of the behavior of two or more use cases. Though agent roles can share perceptions and actions it is not a rule, so we choose to create a new metaclass in which we copied the same characteristics of the Include metaclass but we taked off these constraint.

VI. A CASE STUDY - THE AME-A PROJECT

The AME-A architecture [20] is composed by a hybrid society of agents that cooperate into aiding students' learning. The environment interacts with human agents that can be both the teacher or the students and has several reactive and cognitive agent roles. Previous versions of this case study were published in [15] and [16]; however, in these publications we used old versions of the current metamodel that did not support the types of agent roles proposed by [17]

The teacher can create a learning activity or evaluate the students with the aid of the agent who assumes the Teacher's Tools agent role. The student can choose between performing an unmonitored or a monitored learning session. In the first, he only interacts with the agent who takes the Unsupervised Learning agent role that only presents the content to be learned.

The monitored learning activity is the system main focus, in which it aims to maximize the student learning by means of the aid of five cognitive agent roles, to wit: Student Modeling (SM), Methodology and Teaching Plan (MTP), Learning Orientation (LO), Learning Analysis (LA) and Knowledge Application Orienting (KAO). The first models the student profile in a dynamic way, while the second chooses the methodology and teaching plan that are more adequated to the

student profile every time it changes or whenever the student performance is lower than the expected level; the LO agent role selects the contents to be taught and the way how these will be presented according to the methodology; the LA agent role checks on the student performance throughout the session and the KAO agent role applies a evaluation after the session ends.

Considering that teacher and student are both roles assumed by external human agents, we modeled them as normal actors outside the system boundaries and we associated to that actor who represents the teacher the functionalities "Create learning activity" and "Evaluate students", represented by normal use cases. In these functionalities there is also an interaction with the agent role, Teacher Tools, that being a reactive agent role, was modeled as an AgentRole_Actor with the sterotype "Reactive AgentRole" and put within the system boundaries, since it is inserted in the system.

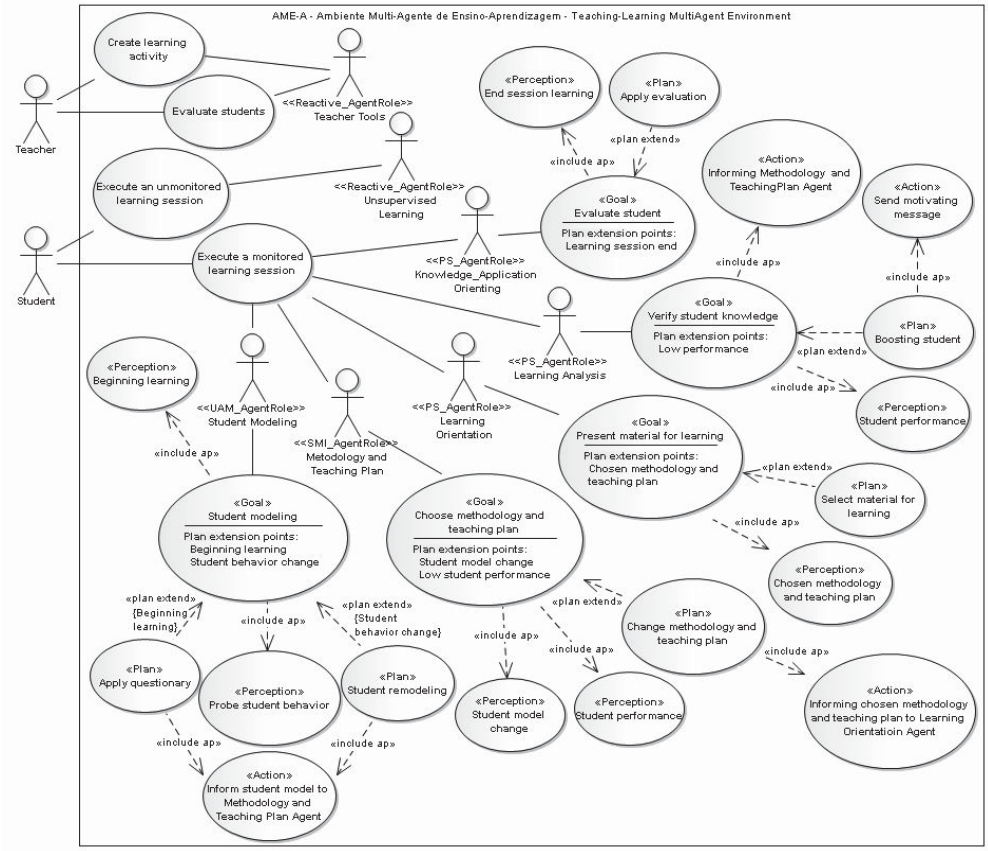

Figure 2. The AMEA Use-Cases Diagram

The actor student was associated to the functionalities, "Execute an unmonitored learning session" and "Execute a monitored learning session"', represented as normal use cases. In the first functionality there is also an interaction with the agent role, Unsupervised Learning, that was represented as an AgentRole_Actor with the stereotype "Reactive_AgentRole".

The functionality, "Execute monitored learning session" involves the five cognitive agent roles, that were classified as PS, UAM and SMI actors, as is demonstrated by their stereotypes in the figure 2. Thus, the SM actor received the UAM_AgentRole stereotype, since it is responsible for the modeling of the students that interact with the system. On its turn the MTP actor received the SMI_AgentRole stereotype, since it is responsible for establishing which methodology will be used with each student. All the other actors received the PS_AgentRole stereotype, because they own knowledge about the problem the application intends to solve.

The SM agent role has for its goal to model the student in a dynamic way. The agent who plays this role needs to perceive when the learning session is beginning and, in this case, trigger the plan, "Apply questionary", to determine the student profile. He also needs to perceive when the student behavior changes, thereby to trigger the plan to remodel the student profile.

We associated the SM agent role to an IUC with the Goal stereotype representing the goal to which the agent who plays this role has to model the student profile. Note that this goal has two inclusion actionperception (IAP) associations (<<include ap>>) with two IUCs that represent the perceptions the agent needs to own to determine whether it is necessary to trigger any of the plans associated with the goal. Thus, to achieve its goal, the SM agent role has to perform mandatorily these perceptions. So, we used an IUC with the Perception stereotype to represent the perception of the learning session beginning and other IUC with the same stereotype to represent the perception of the student behavior.

In the IUC that represents the goal, there are two Plan Extension Points that represent those points in the goal behavior where the plan associated to it can be extended and

besides establish also the conditions for those plans to be performed. So, in the moment the agent perceives the learning session is beginning, it will trigger the plan to apply a questionnaire to the student, represented by an IUC with the stereotype Plan; and, if the agent perceives a change in the student behavior, it will forthwith trigger the plan to remodel the student, equally represented by an IUC with the Plan stereotype. Both IUCs that represent the plans are associated with the IUC Goal by means of plan extend associations, i. e., these IUCs only will be performed when the conditions detailed by the Plan extension points are satisfied. Both plans own an action which is also represented by an IUC with the Action stereotype, and it represents the sending of the student model to the agent who plays the MTP agent role.

On its turn, the MTP agent role has for its goal to choose the methodology and the teaching plan most adequate to the student; to do this, it needs to perceive when the student model changes. This goal is associated to a plan, "Change Learning Methodology and Teaching Plan", that will be triggered whenever the student's model changes or every time the student's performance is proven to be poor. The execution of this plan includes the sending of a message to the agent who plays the LO agent role, to inform the latter that the methodology has been changed.

To model these requirements we associated an IUC with the Goal stereotype with the agent role in order to represent its goal. Next, we associated, by means of IAP associations, two IUCs with the Perception stereotype, to represent the student model change and the student performance perceptions. After that, we created a plan extend association to link the IUC with the Plan stereotype, that represents the plan to change the methodology and the teaching plan, with the IUC Goal. This plan will be triggered only when the student model changes or when the student performance is poor, as is shown by the Plan extension points of the IUC, Goal. Finally, if the plan is triggered, it will be necessary to communicate to the agent who plays the LO agent role the methodology change; as this is done by means of a communication between agents, we identified it as an action and we associated it to the plan by means of an IAP association.

The LO agent role has for its goal to present learning contents for the student and for its perception the choice of the methodology and teaching plan. When the methodology and the teaching plan are perceived, the agent who takes the LO agent role executes the plan "Select material for learning". To model these requirements we represented the goal, the perception, and the plan as IUCs containing respectively the stereotypes, Goal, Perception and Plan. As the plan will only be triggered when the choice of a methodology is perceived, there is an IAP association between the goal and the perception, forcing the agent to verify whether it occurs. There is also an extension association between the goal and the plan, since the plan only will be triggered if the condition is satisfied.

The LA agent role has for its goal to check the knowledge acquired by the student, represented by an IUC containing the Goal stereotype. To execute this goal, the agent who takes this role must perceive the student's performance; this perception is represented by an IUC containing the Perception stereotype. Besides, the agent who assumes the LA agent role must inform this performance to the agent who takes the MTP agent role, which is represented as an IUC containing the Action stereotype. If the student performance is considerated low, then the plan, "Boosting student", is triggered, equally represented as an IUC with the Plan stereotype. This plan has for action to send motivation messages to the student; we identified this as an IUC containing the Action stereotype and we connected this to the plan by means of an IAP association.

Finally, the KAO agent role, has for its goal to evaluate the student after the session ends. Thus, it needs to perceive that the learning session has ended so as to know when to trigger the plan, "Apply evaluation".

VII. VALIDATING THE PROPOSED METAMODEL

With relation to the validation, we compared the models created by means of this metamodel with the models created from the UML original UCD, trying to demonstrate that the proposed metamodel allows the modeling of concepts not supported by the standard UCD. Following this idea, we produced a UCD for the AME-A system using only the standard UML and comparing it with the diagram produced by means of our metamodel, as can be seen in the next figure.

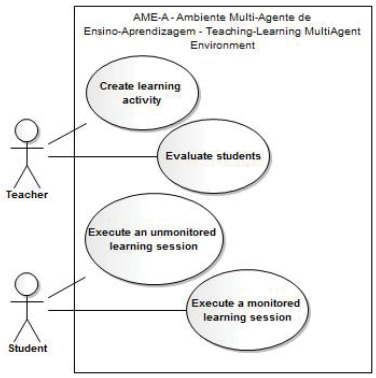

Figure 3. Use-Cases Diagram Using the Standard UML

We did not consider possible to model the goals, plans, perceptions, or actions of these roles, because they are internal functionalities to which the external users do not have access. Besides, the standard UML simply does not have mechanisms to represent goals, plans, perceptions, or actions in a UCD.

Alternatively, using the standard UML, we could try to make the use case "Execute monitored learning session", to encompass the steps of the use cases, "Student modeling", "Choose methodology and teaching plan", "Present material for learning", "Verify student knowledge", and "Evaluate student". What could be done in this specific situation, would be to associate the use cases that represent the plans to the use case, "Execute a monitored learning session", by means of extend associations, establishing the conditions for those use cases to be performed, as demonstrated in the figure 4.

By this approach we tried to use the standard UML in order to achieve the same objective reached by the use of the proposed metamodel. As can be perceived we kept suppressing the representation of agents, as these are internal to the system

and an actor represents entities external to the system.

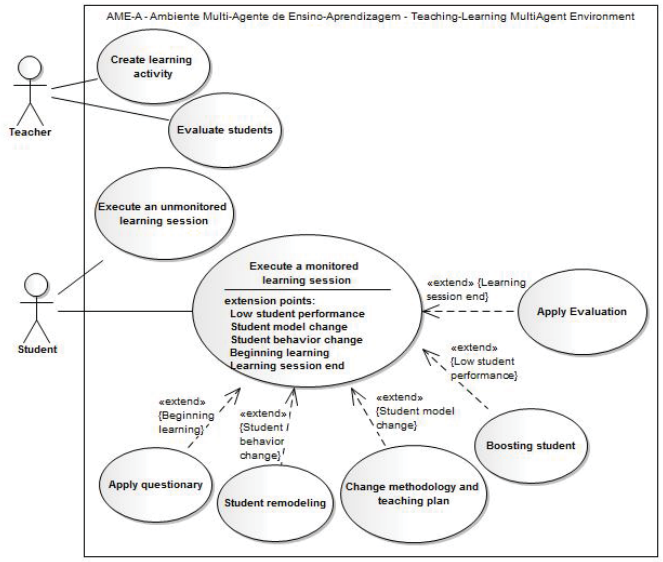

Figure 4. An alternate for the AME-A modeling using extend associations

We tried to associate to the use case, "Execute a monitored learning session", the use cases originally used to represent the plans that should be performed by the agents. Thus, we attributed the plan extension points of the Goal internal use cases to the use case, "Execute a monitored learning session", thus trying to demonstrate under which conditions each "plan" could be performed.

However, these functionalities were not conceived as services to be performed in the "traditional" way by the software but to be divided among cognitive agents, i. e., they are functions separated from the "Execute a monitored learning session" functionality, that represents a service offered to the student, where he will choose, for instance, the learning session theme, but thereafter there will be an interaction with the agents, when those will assume a series of tasks to aid the student and to do it they will need to perceive events, take decisions, and perform actions with respect to which attitudes should be performed. It is not possible to render explicit these kinds of functionalities by using the standard UML.

It is important to note that in reality the use cases associated by means of extensions are not functionalities that the student actor has access to; these functionalities should be performed by agents according to their goals. We further highlight that it is not possible to represent the goals of an agent nor the plans associated to each goal using the standard UML. Likewise, the UML does not support the perception and action representation nor it is able to represent internal agents as actors.

VIII. CONCLUSIONS

We presented a UML metamodel developed for the requirements analysis for the multiagent systems project. This metamodel allows to represent agent roles, besides modeling the perceptions and actions the roles should own, as well as the goals of these roles, together with the plans to achieve them and the conditions for these plans to be performed. We demonstrated the applicability of this metamodel by means of the AME-A intelligent tutor system modeling.

The metamodel in question fills a gap not focused by other approaches that extended the UML language for the MAS project, since none of the studied languages was concerned with addressing the requirements analysis question, a phase of extreme importance for the success of a software project.

With respect to the metamodel validation, we compared the models created by means of this profile with models created from the UML original use-cases diagram; we thus tried to demonstrate that the new proposed metamodel allows to model the concepts not supported by the standard use-cases diagram.

***Abstract*—As video games evolve into richer and more sophisticated products, the software driving those games become more complex. One of the research areas offered by Software Engineering to cope with this complexity, while reducing risks and improving software quality, is Software Architecture. The purpose of this paper is to present an overview of possibly all work having investigated, established and used software architectures for the development of video games. For this, a Systematic Mapping was conducted. The achieved results show an increasing, however still mild, interest in the exploration of software architectures for the development of video games, and lays out lines of research that can be explored.**

Keywords- Software Architecture; Game Development; Video Game; Computer Game; Systematic Mapping

I. Introduction

Developing video games has evolved from a one-man job into highly complex projects, executed by large groups of highly specialized professionals [4] over the period of years. This reflects the fact that the video games industry is the fastest growing one in the entertainment market [17], with titles (i.e., individual games) selling millions of copies in the week immediately following each release date [5]. Both the growing complexity and the diversity of target platforms require efforts from the development team to improve software quality and reduce project risks, as well as minimize the cost of a product and make sure it meets today's market standards.

One of the Software Engineering disciplines that can address these efforts is Software Architecture [18], commonly associated with software quality and maintainability. From the first work of Kruchten on iterative software development with a focus on software architecture [10], a number of works has recognized the value of considering software architectures explicitly in system development processes [2], [19]. As already stated by Shaw and Clements [15], software architectures have attained the status of truly successful disciplines. Software architectures play a major role in determining system quality — performance, maintainability, and reliability, for instance — since they form the backbone of any successful software-intensive system [18].

According to Garlan [8] and the SEI [16], a Software Architecture consists of a component structure, the relations between components, and the rules governing the design and evolution of software systems. A well-defined software architecture can improve system reliability, enable the integration of third-party libraries and COTS(Commercial, Off-The-Shelf) components, and promote component reuse, reducing producion costs between projects. Because of this, numerous application domains have been the subject of software architecture studies, and so should video games. It is, therefore, interesting to search for previous works associating software architectures with video game development.

Evidence-Based Software Engineering (EBSE), which is inspired in the medical area and has contributed considerably to software engineering practices, gives us the Systematic Mapping technique. It offers a systematic method for mapping a given research topic in order to obtain a comprehensive overview of the area[13].

This paper's main objective is, through the conduction of a Systematic Mapping Study, to identify possibly all research works investigating the use of software architecture in video game development. While few such publications currently exist, results point out that interest in the area is growing and reveal interesting specific topics that haven't been explored.

This paper is organized as follows. In Section II we present a brief overview on the Systematic Mapping technique. In Section III we present the conducted Systematic Mapping. In Section IV we discuss about achieved results. Finally, in Section V we summarize our contributions and discuss perspectives for further work.

II. A Brief Overview of Systematic Mapping

When a research field reaches its maturity, there is almost always a noticeable increase in the number of reports and results which are made available. At some point in the study of new areas, researchers usually conduct bibliographical reviews (almost always informal ones) to identify publications corresponding to their specific subjects. These reviews are not, however, done systematically, nor is any support given to prevent bias from occurring during the selection of publications set to be analyzed. It is important to have mechanisms to summarize and provide overviews of an area or topic of interest [13].

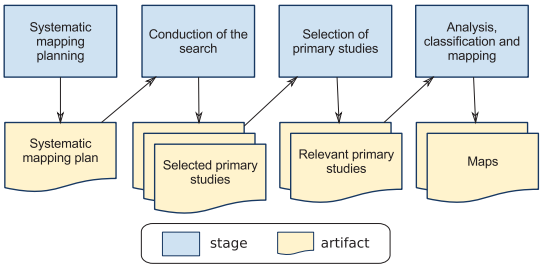

Fig. 1. Systematic mapping process (Adapted from [13])

For this, EBSE has proposed the use of the Systematic Mapping technique [3], [13]. In this context, any individual evidence (e.g., a case study or an experimental study divulged in a publication or paper) which contributes to a systematic mapping is called a *primary study*, while the result of a systematic mapping is a *secondary study*. Systematic mapping aims at providing an overview of a research field, assessing the quantity and types of primary studies existing in the area of interest [13]. In short, systematic mapping is carried out by planning, conduction of search and screening of primary studies by use of inclusion and exclusion criteria [3]. A systematic mapping also includes data extraction and analysis through the identification of categories and classification of primary studies within these categories. As a result, this technique provides maps (i.e., tables and charts) containing condensed information on the area of interest.

III. Conducted Systematic Mapping

This systematic mapping aims at identifying studies describing the use of software architectures in the development of video games, and it was conducted between May and June, 2010, using the process shown in Fig. 1. It is, in short, composed by four stages: (i) systematic mapping planning; (ii) conduction of the search; (iii) selection of the primary studies; and (iv) analysis, classification and mapping. These steps are explained in further detail in the next sections, which present the conducted systematic mapping and explain its execution.

A. Systematic Mapping Planning

This plan consists of formulating the research questions, selecting the sources of primary studies and establishing the inclusion and exclusion criteria.

1) **Research Questions (RQ)**: These questions are structured according to the objective of the systematic mapping. In this case, their purpose is the identification of a panorama featuring both software architectures and video game development. The research questions for our systematic mapping are:
   - RQ1: Which software architecture topics have been studied for the development of video games?
   - RQ2: Who are authors researching the use of software architectures for the development of video games?
   - RQ3: Which software architecture topics for video game development have been given more attention?
   - RQ4: Which video game subsystems have been targeted in software architecture research?
2) **Selection of Sources**: As the sources of primary studies, the databases indexing the most important publications in software engineering were selected: IEEE Xplore[1], ACM Digital Library[2] Springer Link[3], Scopus[4], Science Direct[5] and ISI Web of Knowledge [6]. Only papers written in English were considered in the systematic mapping, since English is the most widely adopted language in the publication of scientific papers.
3) **Establishment of Selection Criteria**: The definition of Inclusion Criteria (IC) and Exclusion Criteria (EC) is another important element in the planning of systematic mapping. These criteria make it possible to include primary studies that are relevant for the research questions and to exclude studies that do not answer them. The inclusion criteria in our systematic mapping are:
   - IC1: The study describes the investigation of a software architecture for video games;
   - IC2: The study describes the investigation of a reference architecture for video games;
   - IC3: The study describes the investigation of a framework for video games;

   The exclusion criteria established are:
   - EC1: The study is not in English;
   - EC2: The study does not have an abstract;
   - EC3: The study is in abstract-only format.
   - EC4: The study does not describe the investigation of a software architecture.
   - EC5: The study does not describe an investigation about video game development.
   - EC6: The study is a copy or older version of another considered study.

B. Conduction of the Search

At this stage, the search for primary studies is conducted according to the previously established plan, i.e., by searching for all primary studies matching a search string in the databases selected as sources. This can be done automatically if the sources provide an efficient search engine. For this, useful keywords are selected and search strings are created.

1) **Keywords**: To keep studies within the systematic mapping's scope, the keywords must be simple and well-chosen. They must be sufficiently simple to produce an adequate number of results, but also rigorous enough to avoid the inclusion of undesired studies. The keywords

[1]http://ieeexplore.ieee.org/
[2]http://portal.acm.org/
[3]http://www.springerlink.com/
[4]http://www.scopus.com/
[5]http://www.sciencedirect.com/
[6]http://www.isiknowledge.com/

chosen for this systematic mapping, separated by area, are shown in Table I.

TABLE I
KEYWORDS SEPARATED BY AREA

Area	Keyword
Software Architecture	"software architecture"
Video Games	"video game", "computer game"

2) **Search Strings**: Using the keywords, the search string is built with AND/OR operators in a way that it represents the correct search parameters. The search string used in our systematic mapping was:
("software architecture" OR "software architectures") AND
(("video game" OR "video games") OR ("computer game"
OR "computer games"))
This search string was accepted by all selected databases, so no custom strings were necessary. With the Springer Link search engine, application of filters after the search was required. The following two filters were used: (i) in "*Subject*" the filter "*Computer Science*"; and in "*Subject*" the filter "*Software Engineering*". With the ISI Web of Knowledge database, the string was used in "topic or title".

This stage resulted in a total of 276 primary studies: 70 from ACM digital library, 12 from IEEE Xplore, 77 from Springer Link, 95 from Science Direct, 6 from Scopus and 16 from ISI Web of Knowledge.

C. Selection of Primary Studies

At this stage, the inclusion and exclusion criteria were employed to select the relevant primary studies.

Table II summarizes the number of primary studies obtained after applying the inclusion and exclusion criteria. To give the databases a fair comparison, this table does not take **EC6** (which excludes duplicated studies) into account. From a total of 276 primary studies previously identified, 33 studies (i.e. 12 %) were considered relevant and thus selected. ISI Web of Knowledge, Scopus and IEEE Xplore were very useful sources for this study: They had high inclusion rates, even though the number of returned studies was low. Ten of the studies returned by Springer Link were included and, despite the low inclusion rate, it should also be considered relevant. Most of the excluded studies didn't cover software architectures or video games at all.

TABLE II
PARTIAL AND TOTAL AMOUNTS OF PRIMARY STUDIES INCLUDED AND EXCLUDED, EXCEPT BY **EC6**

	incl	excl	total	% incl
IEEE Xplore	4	8	12	33.3%
ACM Digital Library	3	67	70	4.3%
Springer Link	10	67	77	13%
Science Direct	4	91	95	4.2%
Scopus	3	3	6	50%
ISI Web of Knowledge	9	7	16	56.3%
total	33	243	276	12%

For the remainder of the Systematic Mapping, **EC6** is also applied, excluding duplicated results from the relevant primary studies. If there were two revisions of the same primary study, the oldest was discarded. The updated relevant primary studies are shown in Table III.

TABLE III
PARTIAL AND TOTAL AMOUNTS OF PRIMARY STUDIES INCLUDED AND EXCLUDED, INCLUDING BY **EC6**

	included	excluded	total	% included
total	31	245	276	11.2%

D. Analysis, Classification and Mapping

While the previous section presented a quantitative analysis of the systematic mapping, this section categorizes the primary studies. For this, two tasks were conducted: (i) search by keywords; and (ii) grouping of the primary studies into categories. To start with, primary studies had their titles, keywords and abstracts carefully read. Following this procedure, terms that seemed to be more relevant were selected as keywords, and these keywords are divided into categories. For this systematic mapping, there was an interest in identifying relationships between software architecture and the development of video games. Thus, four categories, each with a group of keywords, were created:

Category 1: Video game subsystems: This category shows which video game subsystems software achitectures have been proposed for. Fig. 2 illustrates these subsystems and their relationships in a common game system. The subsystems considered here are the result of empirical observation, both by the authors and by the game development community [12]. The keywords for this category are:

- *graphics*: Studies that describe the subsystem in charge of graphics rendering and display;
- *audio*: Studies that describe the subsystem in charge of audio, e.g., music and sound effects;
- *input*: Studies that describe the subsystem in charge of capturing user input from devices, e.g., controllers, mouse and camera;
- *network*: Studies that describe the subsystem in charge of network communications;
- *physics*: Studies that describe the subsystem in charge of physics simulations. This may include the use of a dedicated physics processor or GPU (Graphics Processing Unit) processing;
- *AI*: Studies that describe the subsystem in charge of Artificial Intelligence processing. This may include scripting, strategic/behavioural (i.e., how entities decide what actions to execute) and tactical (i.e., how entities decide how to execute actions) logic, some of which may be title-specific;
- *control*: Studies that describe the subsystem in charge of orchestrating the execution of the other subsystems. It includes the game loop and other title-specific logic; and
- *hardware*: Studies that describe an abstraction layer between the other subsystems and hardware.

Category 2: Software architecture topics: This category shows which topics of the software architecture domain have been more applied in the development of video games. Keywords in this category are:

- *product line*: Studies that present Software Product Lines (SPLs) for the development of video games. SPLs were born as an approach to develop a diversity of software products and software-intensive systems at lower costs, in shorter time, and with higher quality [14];
- *reference architecture*: Studies that propose reference architectures for the development of video game software. Reference architectures have emerged as an element that aggregates knowledge of a specific domain by means of activities and their relations. They can promote reuse of design expertise by achieving solid, well-recognized understanding of a specific domain[1];
- *framework*: Studies that describe software frameworks, which are, in short, abstracted application layers containing common code that provide generic functionality for a domain [6];
- *design pattern*: Studies that describe the use of Software Design Patterns in the development of video games. Design patterns represent reusable solutions to recurring problems in software design [7];
- *aspect*: Studies that describe the use of Aspect-Oriented Programming (AOP) for the development of video game software. AOP has arisen as a new technology to support a better SoC (Separation of Concerns) and more adequately reflects the way developers think about the system [9]. Essentially, AOP introduces a unit of modular implementation — the aspect — which has been typically used to encapsulate crosscutting concerns in software systems (i.e., concerns that are spread across or tangled with other concerns). Modularity, maintainability, and ease to write software can be achieved with AOP [11];
- *COTS*: Studies that describe the use of COTS components that can be used as libraries, tools or building blocks for the development of video games; and
- *quality*: Studies that explore the use of software architectures aiming at improving the quality of video game software.

Category 3: Research environment: This category shows whether the studies come from the industry or the academia. Keywords in this category are:

- *academia*: Studies that were conducted and published by the academia; and
- *industry*: Studies that were conducted and published by the game industry.

Category 4: Evaluation and use level: This category shows how mature the presented software architecture is and how, if at all, it was used.

- *in use*: Studies presenting the use of software architectures that were or are in use in a video game product.
- *prototype*: Studies presenting the use of software architectures that were validated through the implementation of a prototype.
- *study only*: Studies that propose software architectures for the video game domain and that presented the use of neither a prototype nor a product.

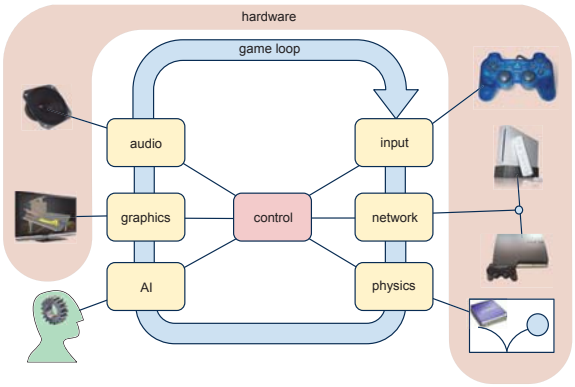

Fig. 2. Game loop and subsystems in a common game system (adapted from [12])

Following the creation of those four categories, the primary studies were classified according to topics within them. It is important to notice that a study may fit into more than one topic per category, or not be classifiable based on the reading of its abstract, title and study keywords. Additional categories for target platform and game genre were considered but ultimately omitted for brevity and because only a few studies could be classified by those categories.

After the conclusion of these groupings, several maps were built, partitioning the relevant primary studies by categories and by year, and the most relevant of those maps are presented and discussed.

Fig. 3 shows the result for the category "Video game subsystems", organized by year of publication. The map shows an increasing interest in researching software architectures for video games, with the substantial rise in 2009 hinting at a larger number of future studies. A constant amount of AI research over time can also be identified, as well as an increasing interest in the control, graphics, input and network subsystems. The augmented interest in the control subsystem can be linked to the newer multi-processed target systems. The appearance of the input and network subsystems can also be explained by the emergence of new technologies, such as non-conventional input systems (e.g., motion and biometric sensors) for the first, and ubiquitous networks for the latter. It is observable, therefore, that there is a tendency towards the use of software architectures to improve each of the subsystems that make up a video game. Considering how software architectures can affect the quality of software products, however, more research work can greatly contribute towards architecturally organizing the video game subsystems and improving the maturity of future video game software.

Figure 4 shows the category "Software architecture topics", by year of publication. This map shows an increase in research in the last few years, and gives us a recurring software archi-

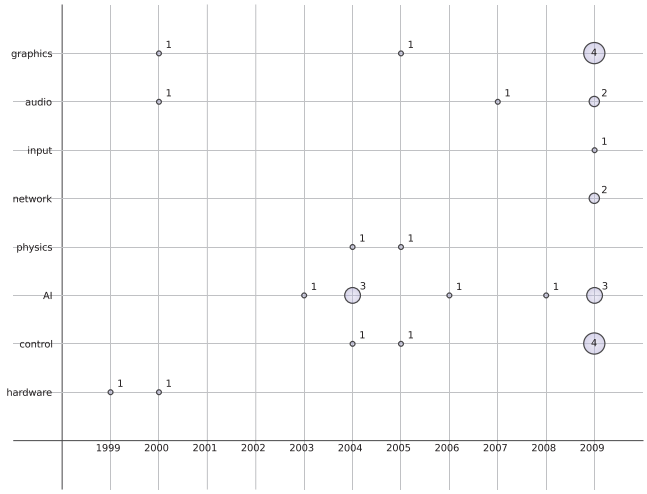

Fig. 3. Map for the category “Video game subsystems”, by year

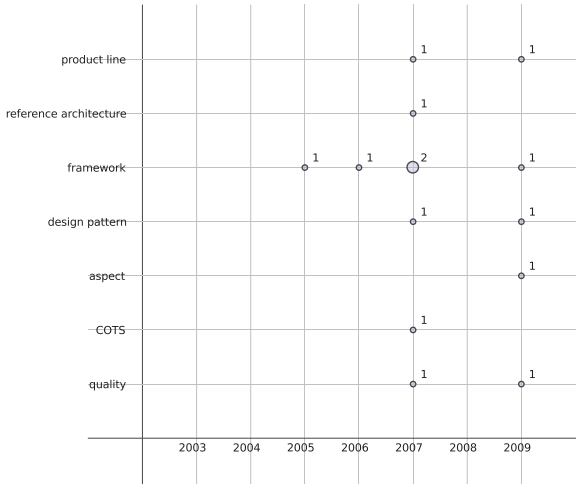

Fig. 4. Map for the category “Software architecture topics”, by year

tecture topic: Frameworks, which are straightforward enough to define and develop, and help streamline the development of video games by keeping all the common problems between different titles treated and solved in a single software package. All topics do, however, remain fairly unexplored in the context of video game development, especially aspect-oriented architectures, COTS usage and reference architectures. The study of validated architectural solutions to problems specific to a game platform or genre, for example, could give birth to reference architectures for that particular platform or genre, which could drastically reduce development time and improve product quality. The study of aspect-oriented architectures for video game development, on the other hand, could help developers model cross-cutting concerns. There is a need for discussions evaluating the use of aspects in game development, be it positively, e.g., identifying important cross-cutting concerns, or negatively, e.g., in respect to program performance or the lack of justifiable reason for the use of aspects.

Fig. 5 condenses two maps. The first crosses two categories, “Research environment” and “Video game subsystems”, and shows that the great majority of studies comes from the

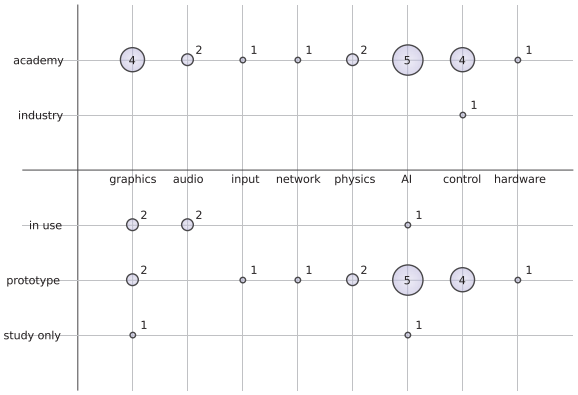

Fig. 5. Map for the categories “Research environment” and “Evaluation and use level”, by “Video game subsystems”

academia. These academic studies focus mainly on the AI, control and graphics subsystems. We have found the lack of publications originated in the industry disturbing, since game developers and software engineers alike could greatly benefit from the knowledge of how real-world problems are solved in production environments. A deeper, more detailed look into the knowledge created by the industry could greatly improve our perception of how video games evolve and how they influence computing and engineering in general, as well as contribute new ideas on how to solve complex architectural problems in software.

The second map in Fig. 5 crosses the categories “Evaluation and use level” and “Video game subsystems”, showing that most investigations involve the development of prototypes. The studies resulting in “in-use” products are about the AI, audio and graphics subsystems, and studies that result neither in prototypes nor in products are related to the AI and graphics subsystems. Although the evaluation by prototype is better than no evaluation at all, the small number of “in-use” studies can be a symptom that either the solutions proposed are not practical, or that the studies are not being taken seriously enough.

In regards to **RQ2**, which asks who are the authors researching the use of software architectures in video game development, no author appeared in more than one of the relevant primary studies. Therefore, it is observed that there is a lack of research groups investigating and publishing work about software architectures in the context of video game development.

IV. Discussion

The use of systematic mapping to elicit previous and current research on the use of software architectures for video game development has uncovered evidence of the growing interest in this subject. This section includes the discussion of a few issues, before a presentation of limitations and lessons learned.

During Section III, all research questions established for our systematic mapping were successfully answered. This suggests that the general knowledge of software architectures in video game development has been mapped. It is also believed that

the results presented in this work are representative of the whole video game development domain, since the systematic mapping technique provides mechanisms and results that allow us to make such statement.

Considering the information gathered throughout this work, it is possible to identify interesting and important research lines that can be investigated in future work.

Current software engineering trends point towards the use of design patterns, COTS components, product line engineering, reference and aspect-oriented architectures to further reduce production costs, project risks and help build products with better quality. These topics do, however, deserve more attention from the game development community if a consensus on their value for developing video games is to be reached.

From the video game perspective, there is room for research in software architectures for all subsystems, in special the control, graphics, input and network subsystems, which have been increasing in popularity.

Also, the game development community can strongly benefit from a detailed description of industry practices that are tested and already known to be successful in real-world applications.

Regarding the limitations of this work, other categories could be established and, consequently, different related maps could be drawn. Also, new research questions could be asked, targeting specific research topics.

V. Conclusions

This work's main contribution is the presentation of an encompassing view of the application of software architectures in the development of video games. To establish this view, a set of steps provided by the Systematic Mapping technique was systematically applied. It is believed that this overview can contribute to the video game development area, shedding light on the existing domain and presenting new oportunities for investigation.

It is widely accepted that software architectures play a major role in determining system quality. More work bridging software architecture and video game development can reduce the gap between these two areas and both improve the quality of video games and bring new architectural styles and solutions to the software architecture domain.

Motivated by the promising results, we intend — as future work — to conduct Systematic Mapping studies involving more specific topics. Thus, our research group strives towards the achievement of an even better understanding of the intersection between software architectures and video game development.

***Abstract*—In the software architecture design, architects usually adopt many classic architectural patterns. However, such important design decisions often fail to be effectively captured in practice. The problem called "architecture erosion" may happen easily. During the design iterations, the latest design may accidentally violate the constraints implied by existing architectural patterns. During the evolution of system, the improper modification may conflict with the original design.**

In this paper, we present an approach for detecting architecture erosion, by capturing the most important design decisions about the adopted architectural patterns. Architects can use a collection of predefined and frequently-used architectural patterns in their design. Our supporting tool can capture what and how the architectural patterns are used, and then generate a set of corresponding OCL code automatically. With these specifications, we can both verify the architecture in design phase and validate the run-time architecture to detect architecture erosion. Finally, we use an illustrative example to demonstrate the feasibility of this approach.

keywords: architectural pattern, architecture erosion, design decision

I. Introduction

Nowadays as the size and complexity of software systems increase, software architecture plays an important role in software development [1]. It is important not just in the development phase, but in every aspect of software development, from the initial conceptualization of the system through requirements to the system's deployment. [2]–[4]. Nevertheless, in current architecture centric development process, the problem called "*architecture erosion"*(or "*decay"*) [5] frequently happens in many projects. On one hand, it is common to see the architecture design of a system and its implementation diverged to a certain extend. On the other hand, when architecture undergoes several evolutions for changed or new added requirements, architecture erosions may also happen.

The key cause of architecture erosion is the loss of the important "*design decisions*" [5], which are taken during the architectural design and embedded in the resulting software architecture implicitly. To address this problem, design decision became an emerging research trend in recent years and it drew increasingly attention in architecture community [6]. Many useful approaches and methods have been proposed. Such as, Archium [7], AREL [8], ArchDesigner [9], AQUA [10], and our own ABC/DD [11]. Most of them provide different methods to capture kinds of design decisions. However, as pointed by van Vliet et al., there are too many design decisions but not all of them are that important [2], and it is expensive to document design decisions. Therefore, we hope to only capture the minimal set of the really important ones.

Adopting architectural patterns[1] is one kind of the most important decision. Architectural pattern expresses a fundamental structural organization or schema for software architecture design [14], and in fact it is incorporated in most software architectures. Since 1994 when Shaw and Garlan classified architectural patterns in their seminal book [15], a number of patterns have been applied in many modern systems. Many are used frequently. For instance, pipe-filter, black-board, multi-layers, model-view-controller, client-server, and so on.

However, architectural pattern does not become the focus in most design decision approaches. In practice, adopted architectural patterns are usually hidden in architecture design without an explicit notation. When these design decisions are lost, it will take time to identify those used patterns. Thus, they might be distorted unintentionally by other patterns or improper modifications Even worse, once those patterns have been programmed, they disappear in the code. It is more difficult to ensure whether they are implemented faithfully.

To address this problem, we present an approach to detect architecture erosion, by capturing the most important design decisions about the adopted architectural patterns. Architects can use a collection of predefined and frequently-used architectural patterns in their design. Our supporting tool can capture what and how the architectural patterns are used, and then generate a set of corresponding OCL code automatically. With these specifications, we can both verify the architecture in design phase and validate the run-time architecture to detect architecture erosion.

The rest of the paper is organized as follows: Section II describes the motivative example; Section III presents our proposed approach of capturing architectural pattern, as well as the process of our approach; then Section IV provides an illustrated example using this approach; and related work are discussed in Section V; in the final Section VI, we discuss some limitations of our approach and future work.

* Corresponding Author

[1] we use the term "architectural pattern" as synonym for "architecture style" as suggested by Hofmeister et al. [12] and Bass et al. [13]

II. Motivative Example

Multi-layer architecture (also referred as *n-layers architecture*) is one of the most common used architectural pattern. When adopting multi-layer pattern, the architect needs to break up a system into several layers which logically grouping components that offers a cohesive set of services. Each layer provides a set of services to the layer above and uses the services of the layer below. The most widespread use of multi-layer pattern is *three-layer architecture* as shown in Fig.1(a). It separates presentation, application processing, and the data management components into three independent layers.

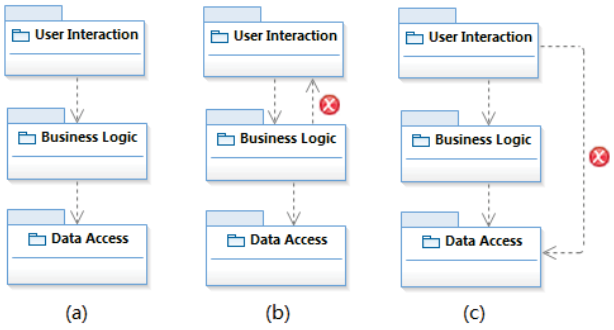

Fig. 1. Multi-layer architectural pattern

Two topological constraints are imposed when adopted multi-layer pattern. Firstly, components in one layer cannot use services provided by the upper layer. Secondly, components cannot use services across the layer. The dashed line marked with error in Fig.1 (b) and (c) illustrate the two violations respectively.

Nevertheless in practice, throughout the entire software life cycle there are some situations in which architecture erosion may occur.

(a) Patterns in Architecture Design

Within one architecture, often several architectural patterns can coexist in the same design. Previously used patterns may conflict with the subsequently used patterns during architecture design iterations.

For example, multi-layer pattern in Fig.1 (a) was adopted already, then *Model-View-Controller (MVC)* pattern was adopted later. The architect wants to separate the components of *model, view*, and *controller* into different layers. Then the interaction between these components maybe conflict with multi-layer pattern, if it is not designed properly.

(b) Patterns in Implementation

The best architecture is worthless if the code does not follow it [1]. However, it is hard to guarantee each design introduced by architects can be faithfully transformed to program source code.

For example, the layered architecture design in Fig.1 can be violated accidentally. A report of a real project said that the key developer of the GUI directly accessed the database without modifying architecture design just like Fig.1 (c) [16]. Even the popular open-source IDE – Eclipse, which adopts multi-layer pattern, has similar layers violations, as discussed in [17].

Similar violations also can happen during the evolution phase of systems. Without an explicit representation of architectural pattern, people often modify the system without a fully understanding of the system. If it evolves in a way that conflicts with the original design, the architectural pattern may be broken.

III. Proposed Approach

A. Software Architecture Meta Model

Based on our previous underlying meta-model for architecture design [11], we extend it to support architectural pattern, as shown in Fig.2.

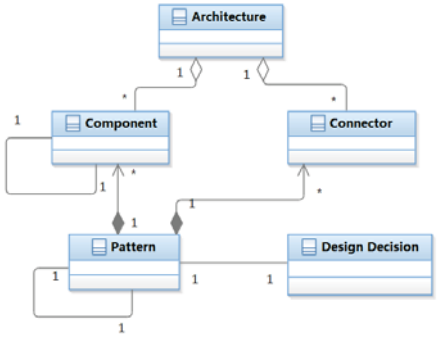

Fig. 2. The Core Meta-Model of the Approach

B. Predefined Architectural Pattern

In order to provide a handily cataloged architectural pattern repository of ready-to-use, we must clearly define what constitute a pattern in advance. According to existing literature, mainly [3], [14], [15], [18], we use the minimal set of constituent elements to characterize an architectural pattern:

(1) Structure

Each architectural pattern has a structure which is constituted by several subsystems. The name of each subsystem provides a vocabulary of design solution. For example, pipe, filter, blackboard, client, server. We use a package diagram to illustrate the structure of a pattern.

(2) Structural Constraints

The constraints define how elements can be integrated to form this pattern and determine allowed interaction between subsystems, e.g., as discussed in the motivative example, components in multi-layers architectural pattern, should not access the components across the layer, as Fig.1 (c). We use natural language to describe these constrains, and use a set of templates of OCL code to precisely describe them.

(3) Known Quality Attributes Impact

Most architectural pattern will affect the quality attributes. Applying a given architectural pattern may make it easier or harder to implement certain quality attributes. Based on existing literature, we collect known impact on quality attributes. Table.1 lists some of the most representative ones.

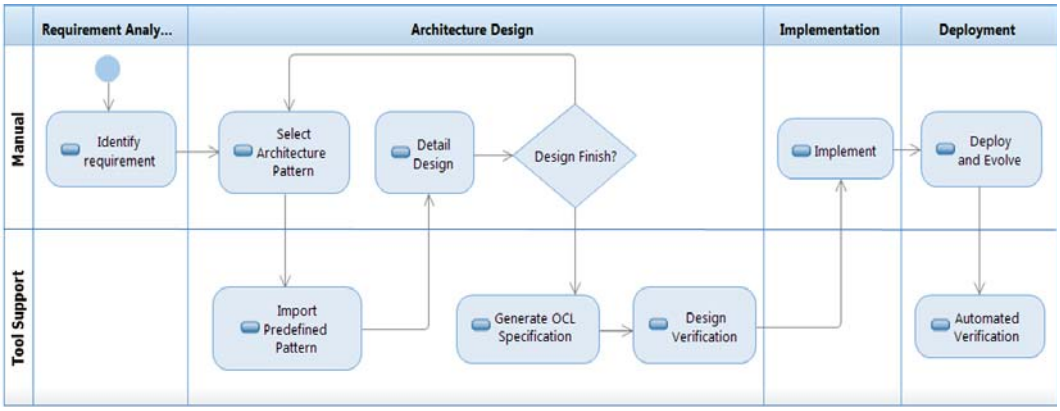

Fig. 3. Process diagram of the approach

C. Process of Proposed Approach

The process of our approach is depicted in Fig.3. There are in all four segments horizontally representing four phases of the software life cycle, including *requirement analysis, architecture design, implementation, deployment/evolution*. In the vertical direction, the diagram is divided into two compartments: the upper one contains manual activities, while the lower one contains the activities finished by our tool.

(a) Requirement Analysis Phase

In the first phase, architects must organize all the architectural significant requirements (ASR) of software system, including both functional and non-functional requirements.

(b) Architecture Design Phase

(b.1) Select Architectural Pattern

By examining the predefined architectural patterns, architects should select a suitable one as a starting point according to identified non-functional requirement and the known quality attributes impact.

(b.2) Import Predefined Architectural Pattern

With the help of our modeling tool, adopting a specific architectural pattern is simple. All that the architect needs to do is to click on the selection from the palette of patterns, then drag and drop to the editing area. By doing this, our tool will automatically place a skeleton of this pattern. For example, Fig.4 shows the case that MVC pattern is adopted. The rounded rectangles labeled with the name of each subsystem are explicit notations of the adopted architectural patterns.

The action of adopting a pattern is an important design decision and it will be captured by our tool automatically in chronological order.

(b.3) Detailed Design

After importing the architectural pattern, architect then can

Pattern Name	Pattern Structure	Pattern Element	Structural Constraints	Quality Attributes
Pipe and Filter		A set of Pipes	Pipe is connected with a filter End with a pipe not a filter	+ modifiability + portability + scalability – performance
Model-View-Controller		Model, View, Controller	Components in View and Model should not directly access All the connections should be managed by Controller	+ scalability + extensibility + reusability + evolvability – performance
Layers		Layer	If component resides in layer i , then it can only access the components reside in layer i and i-1.	+ portability + extensibility + reusability – performance – evolvability – reconfigurability
Client-Server		Client, Server	Client should only access the server Client can not access other clients	+ scalability + evolvability – reusability

Table.1. Predefined Architectural Patterns

continue the detailed design within the generated skeleton of pattern. Concrete components and connectors can be filled into the skeleton. The explicit skeleton makes the boundary of architectural pattern more clearly and prevents an ad-hoc architecture design.

(b.4) Generate Architectural Pattern Specification

When the architecture design is finished, the supporting tool will generate a set of OCL code to specify every constraints imposed by existing architectural patterns.

In our predefined architectural pattern repository, pattern constraints are denoted as several templates of OCL code. When generating the executive OCL code, parameters in those templates will be substituted by concrete components and connectors in pattern.

For example, in the *Model-View-Controller* architectural pattern, one constraint is that components of *Model* cannot directly access components of *View*, and all the connections should be managed by components of *Controller*. We denote this constraint as a template of code as shown in Fig.5. The parameters denoted as c_1 to c_3 and r_1 to r_3 represent components and connector respectively, and they will be substituted by concrete components, such as "OnlineShop", "Compare" components in Fig.4.

The reason why we use OCL is because it is a precise language that provides constraint expressions on any MOF model or meta-model [19]. The meta-model that we used is conformed to MOF, therefore we chose OCL to specify pattern constraints.

context MVC_Pattern:
invariant
$c_1.name$ = "controller" ***and*** $c_2.name$
= "view" **and** $c_3.name$ = "model"
and component :: $AllInstances() \rightarrow includes(c_1)$ **and** $r_1.source$
$= c_1$ **and** $r_1.target = c_2$
and connector :: $AllInstances() \rightarrow exists(r_3 | r_3.source =$
c_2 **and** $r_3.target = c_3)$

Fig. 5. Template of OCL Code for MVC Pattern Constraints

(c) Detect Architecture Erosion

In our approach, the generated OCL code can be used to detect architecture erosion in two situations, as discussed in section II. Firstly, we can take a static verification to detect whether there are some conflicts among existing architectural patterns. When a conflict is detected, the tool will warn the architect and highlight the components and connector that are improperly designed in the architectural model.

When system has been implemented and deployed, we can leverage the ability of reflecting the runtime system's architecture [20] to reflect the real architecture. By executing the OCL codes against this architecture, we can judge whether the system still conforms to its original design. When architecture erosion is detected, ABC tool also will prompt a warning and highlight the problematic components and connectors.

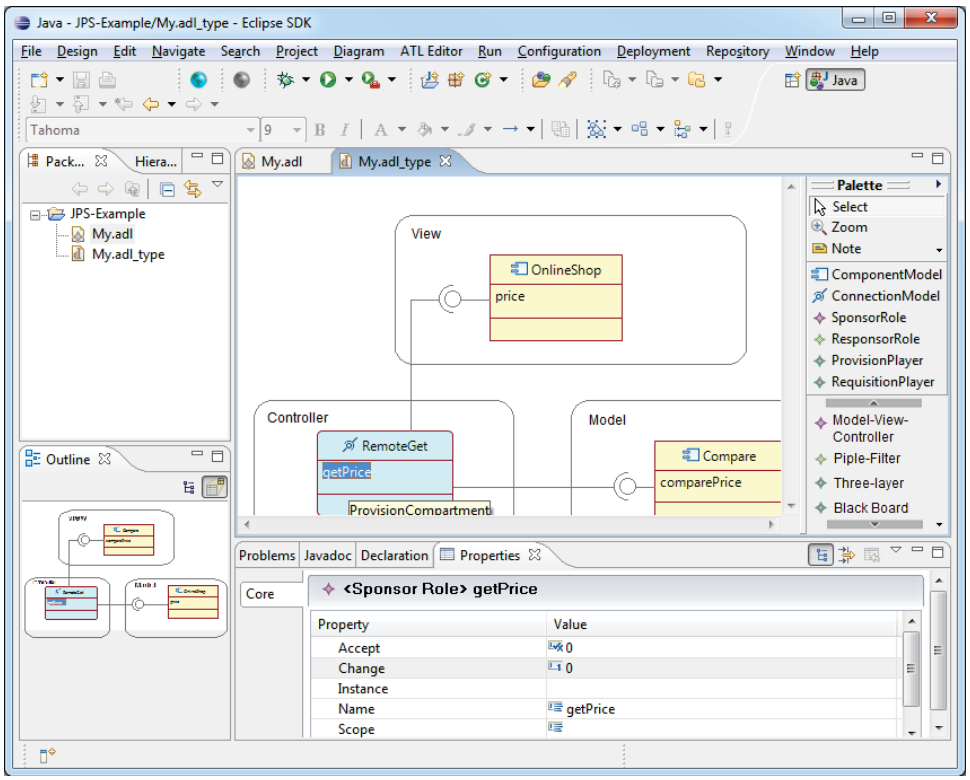

Fig. 4. Screenshot of Supporting Tool

D. Tool Support

Based on our previous architecture modeling tool, ABC (Architecture-Based Component Composition) Tool [21], which we developed as an new plug-in to support the proposed approach. This tool implements an integrated environment that provides support for designing architecture, adopting predefined architectural pattern, capturing design decision and detecting architecture erosion.

ABC Tool is developed as a suite of Eclipse Plug-ins. We mainly use three open source frameworks: EMF (Eclipse Modeling Framework) to model our architecture model, architectural pattern, design decision; and use GMF (Graphical Modeling Framework) to provide visual design ability; and use Eclipse-OCL to parse and execute generated constraints.

IV. Illustrative Example

A. A Simple On-line Voting System

In this section, we use a simple case to illustrate our approach. This is a project selected from a software architecture course for graduate students. Requirements of this on-line voting system includes: (1) provide a user interface for each kind of user; (2) when login, user can view each candidate's information, (3) user can vote for a selected candidate; (4) each user can only vote at most three times; and (5) this system should have high portability.

B. Using the Proposed Approach

One group of students' architecture is presented in Fig.6. In this architecture, there are three adopted architectural patterns. The first one is three-layer pattern; and within the middle layer, there is the second pattern: pipe-and-filter; and the third one is model-view-controller which is scattered in three layers. In total, there are eight components and seven connectors.

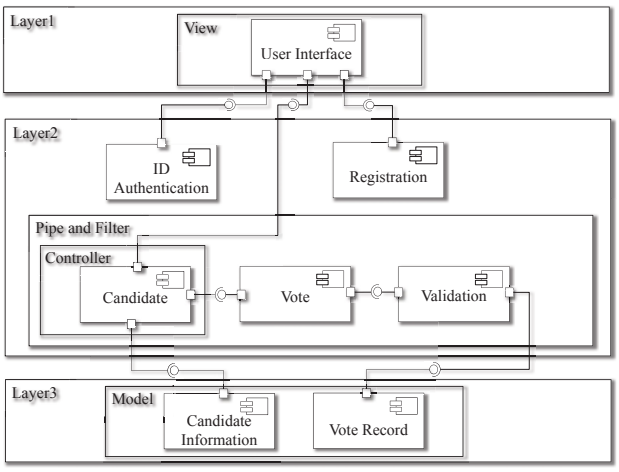

Fig. 6. Architecture of On-line Voting System

In the help of ABC Tool, this group of students used our proposed approach and finished this project. By reviewing this project, we find that ABC Tool detected 2 structural problems in their architecture design and 2 implementation problems during the runtime stage. That is to say, there are 4 potential architecture erosion. We list them in Table.2.

	Architecture Design	Run-time Architecture
Three-Layer	Connect "User Interface" to "Vote Record"	1) "User Interface" directly invokes "Candidate Information" 2) "User Interface" directly invokes "Vote Record"
Pipe-Filter	null	null
Model-View-Controller	Connect "Candidate Information" to "User Interface"	null

Table.2. Detected Architecture Erosion

For example, during the architecture design stage, architect connected "User Interface" to "Vote Record" which broke the constraint of multi-layer pattern; the tool also detected an improper design that connected "User Interface" to "Candidate Information", which violated the constraint of model-view-controller pattern.

V. Related Work

A. Software Architectural Pattern

There are three major approaches used for modeling architectural patterns, including ADL(Architecture Description Language), UML and formal Method.

Most of ADLs are introduced by academia and aim at representing software architectures in general [22]. Some of them directly support architectural pattern description and also leverage formal or semi-formal approaches for the formalization of pattern specifications. For example, ACME [23] uses first-order logic language, Armani, to formally specify architectural pattern. Likewise, Wright ADL uses CSP and ArchWare uses (π-calculus), etc.

UML aims at providing a generic modeling language. There are also some researchers tried to use UML to describe software architectures [24] and architectural patterns [25].

Some researchers proposed to use pure formal methods to describe architectural pattern. For example, [26] uses graph grammars to formal specify pattern. Similarly, [27] also uses some formal methods to analysis architectural pattern. Another comprehensive work [18] presents a semi-formal way using architectural primitives to model architectural patterns. Their work provided a solid foundation for our work.

B. Software Architecture Design Decision

In recent years, there are lots of valuable work in design decision area. Such as Archium, AREL, AQUA, ArchDesigner, ABC/DD, and so on. The most related one is SEURAT [28] that supports the software architects in selecting architectural patterns, design patterns, and idioms for use in architecture. It also captures the rationale for each pattern and the rationale and store them in the pattern library. Compared to our work, although SEURAT records the decisions of adopted pattern and corresponding rationale, it did not provide a visual modeling environment and did not support verification.

VI. Conclusion and Future work

In this paper, we have proposed an architectural pattern-based approach to capture important architecture design decisions. By predefining a collection of architectural patterns, architects can directly select and apply them in their architecture design. Meanwhile our ABC tool can capture these important design decisions, i.e., adopted architectural patterns, and generate a set of OCL code to specify the constraints imposed by those patterns. Then, we can detect architecture erosion in both conceptual design and runtime by executing the generated OCL code.

This paper presented our preliminary work. So far, we have already identified a number of areas that call for further improvements and some of them have become our ongoing work.

The first limitation is that we do not support variants of architectural pattern. Some patterns have several variants to adapt to a specific problem. For example, in the multi-layer pattern, sometimes components in a high layer do need to use components in a very low layer. Such intentional violation of layers constraints is called "*layer bridging*". Similarly, there are many patterns have variants, so we need to improve this problems.

The second limitation is that we do not provide an extension mechanism for architects to add some new architectural patterns. All the predefined patterns in our tool are hard-coded. This problem limits the extendibility of our approach. Since our tool support is based on the Eclipse platform, we plan to take advantages of the meta-modeling capabilities of EMF to support this.

The third limitation is our approach is unavailable to support specifying behavioral aspect of architectural pattern. We plan to extend this work to detect critical behavioral design decisions and their trade-offs.

As part of our future work, we also plan to evaluate the feasibility of our approach with quantitative experiment in a more complex system in real world.

Abstract

Over the last decade, we have seen an increasing interest in the event-driven architecture (EDA) approach. EDA allows the transmission of events among loosely coupled and highly-distributed software components, which is totally adequate to peer-to-peer based applications mainly considering features of scalability and flexibility. In this paper, we present the initial steps towards the design and implementation of a peer-to-peer based EDA, which is intended to reduce the coupling between application layers, and achieve a better distribution of responsibilities between the architecture elements and the environment. Our flexible EDA framework, proposed in this work, inherits important features such as scalability, decentralization and fault-tolerance from the peer-to-peer domain. For a preliminary evaluation of our approach, two experiments using the EDA framework were conducted in different domain applications.

1. Introduction

Event-driven architecture (EDA) is a style of software architecture based on real time flows promoting the production, detection, consumption of, and reaction to events [8]. This architectural pattern may be applied by the design and implementation of applications and systems, which transmit events among loosely coupled and highly-distributed software components and services.

In EDA, events processing may follow three different styles: simple, stream and complex [8]. In simple processing, when a meaningful event happens it initiates downstream actions. Stream processing deals with multiple streams of event data aiming at identifying the meaningful events within those streams. Complex event processing evaluates a confluence of events and then takes action. The events, which may be meaningful or ordinary, may cross event types and occur over a long period of time.

Peer-to-peer (P2P) networks offer an appropriate paradigm for developing efficient distributed systems and applications. In a P2P network, all processes involved in a work or activity have similar roles, interacting cooperatively as peers with no distinction between client and server computers or the infrastructure where they perform [13]. P2P applications are composed by a great number of processes executing on a distributed peer way. The communication pattern among processes is a key point which depends on the application necessities.

Important aspects of P2P applications must be fulfilled through software development frameworks encompassing loose coupling, scalability, decentralization and fault-tolerance skills. The convergence of EDA and P2P is a natural outcome of the recent evolution of distributed systems, since many of the challenging standards issues are closely related. This convergence creates best practices that enable interoperability between networking systems for P2P applications. Therefore, a flexible EDA is essential to improve communication, allowing the exchange of objects between processes in a natural way.

In this work, we propose a flexible EDA for peer-to-peer based applications, keeping the principles of modularity, loose-coupling, well-distribution and P2P technology independence. We implemented a basic version of the proposed EDA, which accommodates the simple event processing style. We evaluate our proposal using two different domain applications, so as to explore distribution through parallelization of the applications tasks. Our results show the easy integration with P2P technologies, while seamlessly preserving EDA principles.

The rest of the paper is organized as follows. The proposed EDA is presented in Section 2, focusing on the architecture (Section 2.1), with the implementation aspects (Section 2.2) and the developed interfaces (Section 2.2.1). The description and the results of the experiments carried out are described in Section 3. Related work is presented in Section 4. Finally, Section 5 concludes the paper and presents our future research directions as well.

2. Our Proposed EDA

The main principle adopted during the definition of the proposed EDA is to divide the development of applications in different layers, providing communication among them through the use of an event bus module and their respective interfaces. This principle allows flexibility, loosely coupling between application layers, better distribution of responsibilities between the architecture elements and the environment, maintaining functionality even when using mobile devices through a TCP network and personal computers in a P2P approach. Together with the P2P applications, other important skills are maintained e.g. scalability, decentralization and fault-tolerance.

The rest of this section presents the proposed EDA architecture, including implementation aspects with the defined interfaces and P2P technologies.

2.1. The Architecture

Our proposed EDA presents four layers: Application, Environment, Network Adapter and Event Bus, as presented in Figure 1. The Application layer is the upper platform layer, which allows the development of different P2P applications, using our EDA framework as a middleware of development.

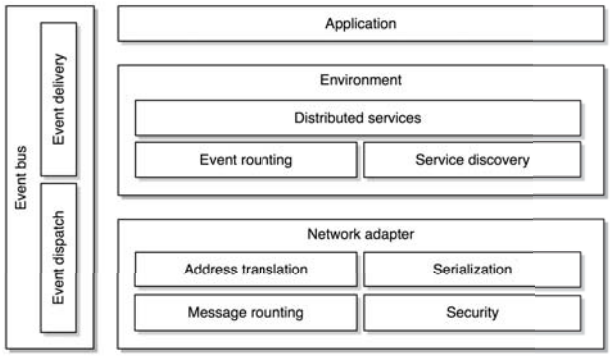

Figure 1. The four-layered architecture.

The Environment layer is composed by the Distributed Services, the Event Routing and the Service Discovery modules. The Environment layer abstracts the modules, allowing the communication and localization of services to be done in a transparent way. In other words, the application issues events in the Environment, which is responsible to notify listeners, without direct communication and connection among different services. In this way, the applications do not know if they are in the same or in different machines. This abstraction feature would help the development of different applications, including software agents, allowing their interaction without the communication bottleneck and independent of the network topology being used.

Apart from offering the described abstraction feature, the Environment layer has an Event Routing and a Service Discovery modules to publish and locate services in a distributed way. Services like distributed database, agent transport, integration of mobile devices can be developed and coupled to the environment transforming it in a more integrated framework. Lots of applications using for example multiagent approach with heavy data, information and knowledge requirements such as bioinformatics, forensics, automated reasoners on the Web may benefit from the features above mentioned.

The Network Adapter is responsible for integrating the Environment to the underlying network, acting as an interface between the P2P middleware and the other EDA framework layers. This layer is composed by the Address Translation, Serialization, Message Routing and Security modules. The integration among the chosen P2P middleware and our EDA framework is done by assigning a unique identifier of each addressable component of the platform, which is represented by the UUID (Universally Unique IDentifier) object of Java API. The P2P middleware implementation uses a table in order to translate these identifiers into other address type, e.g. IP address or P2P network node. In this way, another P2P implementation, such as Chord [17] or Tapestry [10], can be couped to our proposed EDA without modifying other modules.

We should note that, if the chosen P2P middleware has the necessary features of address translation, message routing, serialization and security, then it is not necessary to implement the Network Adapter layer. But, in case it is necessary, it receives the events from the upper platform layers, serializes as a message in the network and sends to the application. Whenever the adapter receives a message, it unserializes as an event, which is sent to the event bus module so that the upper platform layers receive the communication.

Finally, the Event Bus layer is responsible for the Event Dispatch and Event Delivery modules. An event flow starts with the event being generated and culminates with the execution of any downstream activity. The processing of this flow can be described in logical layers. The four logical layers are: event generators, event channel, event processing, downstream event-driven activity [8]. The event processing flow used in our work includes the event generator, event channel, event processing and downstream event-driven activities. The flexibility at each logical layer is the power of event, since the way events are created, how they are transmitted, received and processed is transparent to the P2P applications developed over our proposed EDA.

2.2. Implementation Aspects

The methodology used to define the EDA was based in design patterns with the objective to support its implementation. In order to keep the principles of modularity and loose coupling of event-driven architecture we applied six design patterns, which were the most suitable to the principles of the proposed EDA: $AbstractFactory$, $Singleton$, $Observer$, $Decorator$, $Command$ and $Mediator$ [5]. To validate the proposed EDA, we implemented a prototype in Java at the Computer Science Department of University of Brasília. The prototype has 67 classes and 3,600 lines of documented code.

All the communication in the proposed EDA is done by events, which reduces the object coupling, allowing flexibility and scalability to the architecture. In this sense, the communication has two important elements: the event and the listener, which always come in pairs, since the event carries the object message content and the listener defines which object has to listen specific event.

The Event Bus layer is responsible for the events dispatch and delivery in the platform, which is implemented through three design patterns: $Singleton$, $Observer$ and $Mediator$. $Singleton$ guarantees only one Event Bus instance, while $Observer$ records all listeners and notify them of sent events. The Event Bus layer is also the object mediator in the communication of the platform according to the $Mediator$ pattern. The Event Bus interface is described in Section 2.2.1.

The possibility to execute commands between objects through the Event Bus layer allows the method call between different distributed components in the P2P network. Using $Command$ design pattern we have implemented two special events: $CommandEvent$ and $ResponseEvent$, which inherit from the $Event$ abstract class. Though these events work just like the others, their expected behavior is different. All object that receives a $CommandEvent$ may execute the command and send the results by the $ResponseEvent$. All objects that send a command may wait for an answer during a limited time, and in case the answer does not come, a timeout event is send to the object to notify the expiration time. A method $getId()$ is used in the $Event$ class to identify events.

2.2.1 Interfaces

In order to allow the flexibility and the loosely coupled features of our architecture, considering the application, environment, network and event processing, along with the EDA layers intercommunication, we have developed some interfaces. We present the major interfaces implemented: (i) $Platform$ – interface where all layers and modules are integrated; (ii) $EventManager$ – the event interface that handles the event processing; (iii) $Environment$ – the environment interface to deal with services discovery and distribution; (iv) $NetworkAdapter$ – network interface to deal with the P2P processes.

The $Platform$ interface is the core of our EDA framework. It defines the management of the platform configurations and disaggregates all components (layers and modules) into implementation interfaces, allowing uncoupling and flexibility. This interface follows the $AbstractFactory$ design pattern. Therefore, every component can be reimplemented and replaced without affecting the operation of the other components. The $Platform$ component is also a $Singleton$, which helps and unifies the access of objects among all $Platform$ components, helping the unitary and integration tests.

The $EventManager$ is one of the most important developed interfaces that implements the Event Bus layer, presented in Figure 2. Note that the $EventManager$ interface has two methods: $addlListener()$ – responsible to register listeners and $fireEvent()$ – responsible to communicate an event to a group of listeners. The $EventManager$ interface keeps the reference of all the registered listeners. Whenever the event bus receives an event, it extracts all the objects that inherit the class obtained from the method $getAssociatedListener()$ and notify them in a separate thread. The $EventManager$ implements the $Mediator$ design pattern. Suppose ObjectA wants to communicate to ObjectB, then ObjectA creates a $ConcreteEvent(string)$ and send it to $EventManager$ using the $fireEvent()$ method. The $EventManager$ that has ObjectB registered in the listeners list, communicates the event to ObjectB using $onEvent()$ method.

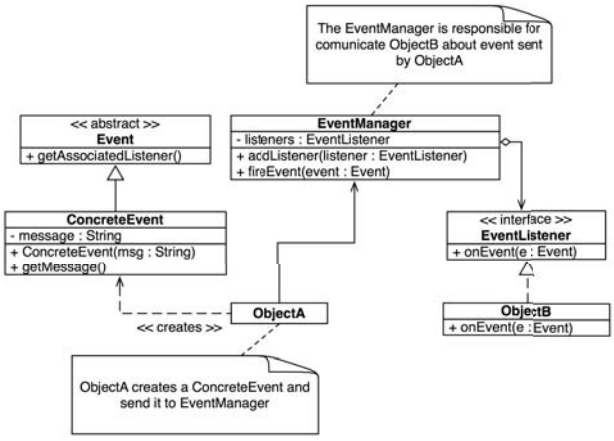

Figure 2. Implementation of the $EventManager$ interface.

The $Environment$ interface defines the environ-

ment in the EDA framework, which has two methods: $requestService()$ and $destroyService()$. The $requestService()$ is responsible to publish and get an instance of the published service.

$NetworkAdapter$ interface deals with the P2P processes. The $NetworkAdapter$ contains two send methods, one to send simple events and the second to send commands and the respective temporary listener to the network. Related to the P2P approach some middlewares were studied to integrate our framework. Important aspects of scalability, fault-tolerance and self-organization were considered, including Chord [17], Can [9], Tapestry [10] and Pastry [12].

We could have used any of the above mentioned P2P middlewares. However, we chose Pastry together with Scribe [2] considering their comprehensiveness. Pastry uses routing mechanisms to achieve great scalability, while Scribe depends on Pastry to route messages to the destinations. Scribe [2] is a typical pub-sub system built on top of Pastry, which leverages its scalability, routing efficiency and self-organization capabilities [15]. The event processing, including dispatch, delivery and routing of events, and the service discovery in our EDA is executed over the Pastry and Scribe mechanisms, making use of the benefits provided by such combination. In this sense, the $NetworkAdapter$ interface is responsible for encapsulating an event through the $PastryEvent$ and send to Pastry.

3. Experiments and Evaluation

During this research project two experiments using the EDA framework prototype were conducted: the turtle and the bioinformatics projects. The objective to use two experiments is to evaluate our framework.

3.1. The Turtle Project

The turtle project is the simple sum of harmonic series, which apparently converge to a number, but is proved mathematically that it varies very slowly. Equation 1 presents the sum of first n elements of the series.

$$H_n = \sum_{k=1}^{n} \frac{1}{k} \quad (1)$$

Table 1 presents the relationship between the lowest number of terms required for the sum of the series is equal to or greater than a specific number. Note that to reach a total value of 1,000 this amounts to 10^{434} terms which is a computational challenge to calculate the sum of the harmonic series term by term, in an iterative fashion.

Our solution was to build a distributed application using the "divide and conquer" and software agents approaches, using the facilities that the EDA framework offers. We

Table 1. Number of n terms sum.

k	least $n \mid H_n \geq k$
1	1
2	4
3	11
5	83
10	12,367
20	272,400,600
100	$\approx 1.51 * 10^{43}$
1,000	$\approx 1.10 * 10^{434}$

used blocks, with the start and size information, and distribute the blocks throughout the network to perform a partial calculation. To implement the distributed solution, two distinct roles become evident: (i) a central figure, to control the distribution of blocks in the network and the receipt of partial calculations; and (ii) a task force, specialized in the processing of the blocks. Each role is implemented by one particular agent, the $BossAgent$ and the $TraineeAgent$ (respectively) both agents have a parent in common, $AbstractAgent$, and inherit their behavior. The $AbstractAgent$ seeks the event services and discovery of services and adds to the platform using the $environment$ interface (Section 2.2.1).

The $BossAgent$ has an internal data structure to track which blocks are being calculated at the time and a variable that stores the next block, starting with the value 1. The block size is fixed, but can be changed before starting the agent. When the $BossAgent$ receives a block request from the $TraineeAgent$, it sends the next block to be processed and waits for the partial sum. Every 5 seconds, the $BossAgent$ uses a log tool to print the partial sum and the number of blocks processed in a file. Once created the agents, the application is started automatically via the exchange of events.

The computational platform used in this test bed (experiment) had eight computers with the same configuration: Pentium 4, 2.66 GHz, 1GB of RAM, and Ethernet 10/100 MB/s. The number of blocks processed with one computer is 209, with two computers is 418, with four computers is 827 and with eight computers is 1,612, considering the total execution time of 00:04:58. Note that the growth in the number of processed blocks is linear as presented in Figure 3.

3.2. The Bioinformatics Projects

P2P model is being used for applications that requires great amount of computer resources, since it offers some direct solution to modularity and scaling properties in large scale distributed systems. In this context, P2P approach is very important to bioinformatics. Thus, we have conducted

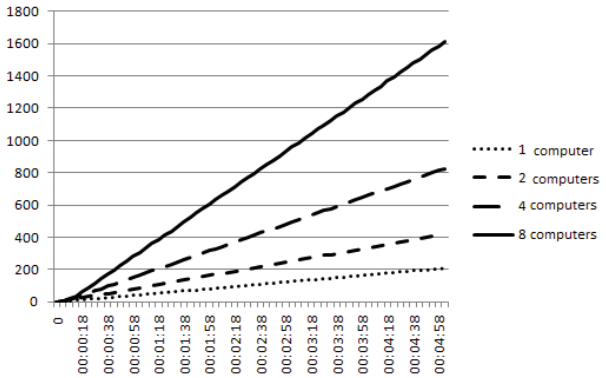

Figure 3. The number of blocks processed over time.

this experiment to illustrate the use of our EDA prototype in this area.

In this project we executed a particular bioinformatics application, BLAST, which is a family of algorithms for searching similarities between two biological sequences, widely used in genome projects [1]. We used real data of $Escherichiacoli$ or $E.coli$ bacteria, which is very known to bioinformatics community. The objective of the experiment is to apply BLAST algorithm to $E.coli$ sequences in order to validate EDA aspects of distribution, parallelism, and fault-tolerance. Although the $E.coli$ sequences is not expressive enough to justify high-throughput processing, our intention is to evaluate the abstraction of EDA proposal from the application perspective in different domains.

To implement the distributed solution, we used the same approach of the turtle project, presented in Section 3.1, according to the simple event processing style. The computational platform used in this test bed (experiment) had eight machines with the same configuration: Intel(R) Core(TM)2 Duo CPU E7500, 2.93GHz, 2GB of RAM and Ethernet 10/100 MB/s. Table 2 presents the execution time to process distributed BLAST over 6,400 $E.coli$ sequences. Note that the growth in time is linear, just like the turtle project presented in Figure 3.

3.3. Experimental Evaluation

Considering the fact that both experiments were carried out in different domains, extra effort was not necessary in the EDA layers. The modularity of our EDA framework was guaranteed by the defined layers and the modules. The provided interfaces (e.g., $Environment$, $EventManager$) assured the flexibility of our EDA framework, since it could encapsulate the application in both experiments, without generating extra implementation efforts to the application development. Other computer intensive P2P applications may use our EDA in a similar way.

Table 2. Time execution to process 6,400 sequences.

Number of Computers	Execution Time
1	00:24:44
2	00:12:25
4	00:06:16
8	00:03:07

In addition, our architecture promotes a high level of abstraction of the underlying P2P technology used, preserving flexibility. The EDA framework could benefit from the scalability and decentralization guaranteed by the P2P middleware. In this work, we have analyzed basic fault-tolerance features of our framework through the use of Scribe, which implements the services of the Network Adapter layers. The analysis consisted in repeatedly disabling the root node during our test beds. The *rendez-vous* point was reassumed without harming the processes computation.

As a preliminary evaluation of our approach the conducted test beds were satisfactory, but further experiments are necessary for a comprehensive evaluation, specially considering scalability and fault-tolerance features. The modularity and the extensibility of our framework may allow the use of other implementations for the security and reliability of the P2P processes at runtime, such as the work proposed by Spanoudakis [16] in the context of mobile P2P systems.

4. Related Work

Our proposed EDA functionally keeps the same principles presented in the EDA architecture, but the elements are organized in a different way, since our focus lies on P2P applications [8]. Pastry was chosen in this work due to its advantages over previous P2P frameworks as JXTA [19]. JXTA modular design and building blocks makes it relatively quick and simple to prototype P2P systems like document sharing and instant messaging in a timely fashion. Nevertheless, its design choices had severe impact on its scalability and reliability. JXTA is defined by a six layer XML based protocol stack that makes its implementations complex, heavyweight and slow [6].

Quite a few research work have focused on event-driven systems [3, 4, 7]. The EDA pattern has been usually associated to SOA, since they are complimentary, as SOA focuses on the decomposition of business functions and EDA focuses on business events [14]. Our approach to EDA is com-

prehensive since the development of P2P applications can be related to services through the decomposition of business functions.

Much research has been done to propose systems over structured P2P networks [18]. There are many applications developed using a P2P approach in various domains, particularly in bioinformatics [11]. However, as far as we are concerned, we could not find research work that integrates EDA approach to P2P networks with focus on a flexible architecture suitable for a multitude of various application domains.

5. Conclusion and Future Work

In conclusion, this work proposed a flexible EDA for P2P based applications. We implemented a basic version of the proposed EDA, which accommodates simple event processing style. We evaluate our proposal using two different domain applications exploring distribution of the P2P network. Our results an easy integration with P2P technologies, while exploring the features provided by the underlying P2P middleware used. Our preliminary results show that our EDA framework could be used seamlessly in two different domains.

As future work, we intend to expand the basic version of our current EDA implementation in order to deal with complex event processing style. Particularly, extend the implementation to deal with various and distinct event types simultaneously. For example, applications in web domain with events of different source types, video, text and image. We also plan to evaluate our framework for its flexibility using different P2P middlewares for validation purposes.

Another important future work is concerned to the extension of the current EDA core in order to transform the application module to encapsulate agents approach. In this direction, computer-intensive applications that may take advantage of multi-agent approach, through the use of rationality and distributed resources can take advantage of our EDA approach.

***Abstract*—Software architects principally leverage successful architectural design practices systematized in terms of architectural styles and tactics. While architectural tactics focus on particular non-functional properties, styles are typical solutions that generally coverage several aspects. The problem is that we do not yet have a formal account of how styles and tactics interact in a way that is sufficient to enable automated synthesis of architectures from application models and the combination of architectural styles and tactics specifications. The contribution of this paper is an extension of our previous work on formal *architectural maps* that makes this fundamental relationship clear, and a demonstration that it enables automated formal derivation of architectures.**

***Keywords*-Software Architecture; Architectural Styles; Architectural Tactics; Architectural Maps; Alloy Language.**

I. Introduction

Software engineering researchers and practitioners have recognized software architecture as a promising means of managing the complexity of software systems [20], [22]. Other studies have further shown its significant role in achieving systems' non-functional properties [7], [13]. Developing a sound and appropriate architecture, however, remains a significant and intellectually challenging activity.

Notwithstanding the growing body of research and significant progress in architecture-based software development, the success of architecture construction still mainly depends on the experience of software architects [14]. As software systems unrelentingly grow in complexity and size, designing such systems manually in this way becomes more costly and labor-intensive, and, once completed, hard to change. Moreover, failure to meet the requirements, which might be later discovered, causes the need to backtrack, which is expensive especially in the case of architectural decisions.

To address this issue, we proposed a model-based approach to automated synthesis of architectural descriptions from formal, abstract application models and separate choices of architectural style specifications [3]. While our previous work deals with issues of architectural structure, it does not address support for non-functional properties.

Architectural tactics [5] have emerged as architectural decisions that codify and record best practice knowledge for achieving a desired quality attribute. However, despite years of research and practice, we have little formal account of how styles and tactics interact. Furthermore, the reusability of architectural tactics is hampered by a number of factors, among which is the absence of formalization, as they are typically represented as a set of documents. In fact, unlike architectural styles, characteristics of an architectural tactic are not understood in such a formal manner, making it difficult for architects to make informed choices.

In this paper, we present a novel approach based on our formal notion of *architectural maps* that makes this fundamental relationship clear. In particular, we show the feasibility of incorporating the notion of tactics with that of styles to enhance the specification of architectural maps, which provides the capability of formally applying refinement tactics to improve quality attributes.

This paper makes three principal contributions in this area. First, we formalize and automate architectural tactics by means of constraint predicates parameterized by choices of *application type* and *architectural style*. Second, we show that our ideas for formal and reusable representation of tactics parameterized in this way can be realized in practice. More specifically, starting with an application model and using the formal definition of the architectural maps as well as the architectural tactics provided in this work, it is possible to arrive to the set of compliant architectural descriptions. Third, we have developed the technique as an extension of our tool for model-based development of software architecture, *Monarch* [1], which leverages Alloy as the basis for the specification of mappings' semantics and the automatic analyzer [15].

The rest of the paper is organized as follows. Section II explains the background context of our work. While Section III presents our approach for incorporation of architectural tactics into the formal synthesis of software architecture, Section IV demonstrates that it can be realized in practice. In Section V, we report on experiences applying our approach and tool set and provide a discussion. Section VI briefly surveys related work. Section VII finally concludes.

II. Background: Architectural Maps

In this section, we provide an overview of the notion of *architectural maps*, introduced and formalized in our previous work [3] based on the idea that choices of architectural style are made separately from choices of essential application properties, and that architects in essence implement a mapping that takes an application model and an architectural style to an architectural model. Knowledge of this mapping is crucial to expertise in software design. Given an application description of some type, the experienced designer knows both what architectural style to pick, and how to map an application description of the given type to an architectural model in the chosen style. In some sense an architectural map embodies knowledge of how to realize different types of applications in different architectural styles.

Figure 1, which is an extension of our previous work, represents the fundamental elements of our model on the basis of the architectural maps and their relationships: s, an *architectural style* specification; $\{a_i\}$, a set of architectural models; a binary relation, *conforms,* on the cross product, that encodes the conformance of the set of architectural models, $\{a_i\}$, to an architectural style, s; t, an *application type* specification; m, an application model; an analogous binary relation, *conforms* encoding the conformance of a given application model, m, to a given application type, t; and a relation, *refines,* encoding the notion that a set of application-specific architectural models, $\{a_i\}$, refines, or implements, the application model, m. Finally, we have $map_{(t,s)}$, which takes an application model, m of type t, and an architectural style, s, to the set of architectural models, $\{a_i\}$, such that $refines(a_i, m)$ and $conforms(a_i, s)$.

More recently, we have shown that the proposed separation of concerns supports a model-based development and tools approach to architectural-style-independent application modeling, and architecture synthesis with style as a separate design variable [4].

III. Approach

Above and beyond providing a proof of concept of the feasibility of the proposed formal *architectural maps* in an automated way, previous works revealed deficiencies in current specifications of architectural styles. That is, applying architectural maps leads not to a single plausible architecture, but to a set of architectures, where not any instances in that set necessarily satisfies all required non-functional properties. In fact, as can be seen in the diagram, one more optimizing search step is required within that space to find the subset of plausible instances especially with respect to quality attributes. This is mainly because style specifications to which application models were being mapped are still underspecified, and in turn their corresponding architectural maps leave overly large architectural spaces.

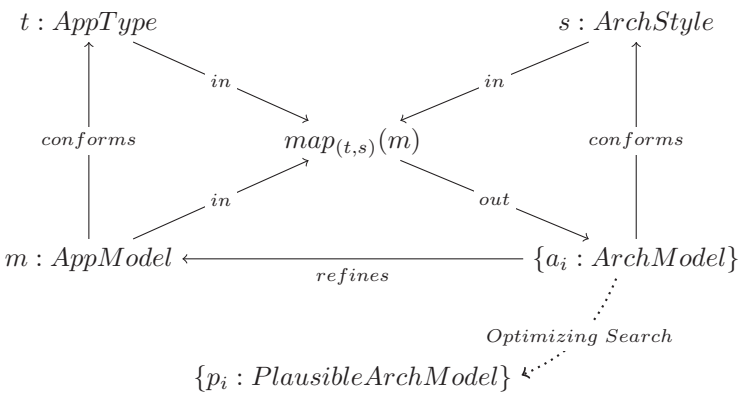

Figure 1. Key entities and relations involved in the notion of *architectural maps.*

As such, the systematic process of getting from an application model to an architecture involves two steps: (1) constraining the formal architectural space; (2) performing optimizing search over the derived space for properties of interest. The more we can do in the mapping, the less we have to do in the search. Therefore, to achieve a practical automated design tool for software architecture, there is a pressing need to formally specify relationships between architectural design decisions and quality attributes [7].

Architectural tactics are architectural decisions concentrating on non-functional properties that shape the system's architecture but in a smaller extent compared to the style decisions [5]. Several architectural tactics have been proposed for various quality attributes such as reliability, performance and modifiability. As architectural styles have extensive use in the architectural modeling, relating styles to tactics provides a basis for making rational design decisions [5]. That is, tactics can systematically be leveraged to adapt styles for the purpose of improving their properties with respect to particular quality attributes. As such, the structure of the tactic must fit within the rules implied by the style. To effectively apply architectural tactics along with the styles the architect needs to realize their side effects and how they relate each other [14].

This paper develops the notion that architectural tactics are not independent of, but rather are parameterized by, choices of application type and architectural style, and it is possible to represent tactics parameterized in this way in a formal and reusable form. Architectural styles and tactics then can be considered as complementary techniques, subsequently allowing for the automated reuse of architectural best practices. Indeed, the effect of a tactic refines and extends the architectural map.

$$map_{(AppType,ArchStyle)} \xleftarrow{extends} tactic_{(AppType,ArchStyle)}$$

In our approach, one expresses an application model as an instance of an *application type,* then selects an *architectural style* in which to synthesize an architecture for the application. The combination of application type and architectural style selects a mapping from applications of that type into architectural instances in that style. The decision to use a particular tactic in mapping an application model to an architecture then involves the explicit inclusion of such a reusable tactic specification along with a more generic architectural map. Applying this compound map to the application model yields a family of correct-by-construction architectural descriptions for the given application in the given style supporting the given tactics. In the next section, we show that our ideas can be reduced to practice.

IV. Automation

To demonstrate the viability of implementing tools that support automated formal synthesis of software architectures complying with the rules implied by choice architectural styles and tactics, we present a proof of concept leveraging the Alloy language for formalization and the Alloy Analyzer for automation.

Alloy is a lightweight specification language based on the first-order relational logic [15]. *Signature* is an essential construct of the Alloy language that represents the basic type of elements and the relationships between them. *Facts* can be used to define constraints over model instances. Alloy further provides *Predicates* to be used in defining parameterized reusable constraints always evaluated to be either true or false. A *Function* similar to a predicate can be invoked by instantiating its parameters, but what it returns is either a true/false or a relational value instead.

Its SAT-based analyzer makes automatic analysis of Alloy models possible. The Alloy Analyzer can be used either to find satisfying solutions with respect to the constraints of a given model, or to find any possible counterexample violating constraints in a given model. The former is used in our approach to compute architectural models.

Five pieces of Alloy specifications are conjoined in the process of synthesizing compliant architectural models: (1) an *application type* represented in an Alloy module; (2) an *architectural style* specification module; (3) an *application model,* comprising an instance of an application type, again represented in an Alloy module; (4) an *architectural map* specifying the relationships required to hold between an application of the given type and an architecture in the given style, represented in an Alloy predicate; and (5) a *tactic predicate* specified for a given pair of an application type and an architectural style to incorporate a given tactic into the software architecture. The Alloy Analyzer computes satisfying solutions to the compound specification, leading to the synthesized architectures.

V. Evaluation

Our claim we make in this paper is that it is feasible to represent architectural tactics parameterized by choices of application type and architectural style in a formal and reusable form. In this section, we report and interpret data from experimental testing of our approach and hypothesis. More specifically, we first show that our approach supports formal specifications of architectural tactics with respect to the *architectural maps* developed for each pair of an application type and an architectural style. We then show that it also supports automatic synthesis of architectural instances which conform to the rules implied by both the application model and the architectural style as well as supporting the given architectural tactic.

In support of our approach, we have extended our tool suite, Monarch, which is available for download and inspection [1], and applied it to several case studies. This paper cannot accommodate detailed presentations of all of our experiments. Rather, we report one case in more detail, which is about the employment of a fault detection tactic in the process of formal synthesis of Lunar Lander architecture [22] in the *implicit-invocation* (II) style from its abstract application description in the *sense-compute-control* (SCC) application type. This section is followed by presenting discussion over the experiments.

A. Application Model: $Lunar\ Lander_{SCC}$

Our application case study is inspired by Taylor et al. [22]. In their new textbook on software architecture, they illustrate the structuring of an embedded control system called *Lunar Lander* in different architectural styles. The *FlightControl* analyzes the information provided by various sensors, i.e. *Altimeter*, *Gyroscope*, *Fuel level indicator* and *Engine control switch*, to maintain the state of a spacecraft. Then, it provides updated data to the various actuators: *Descent engine controller*, *Attitude control thruster* and *Display*.

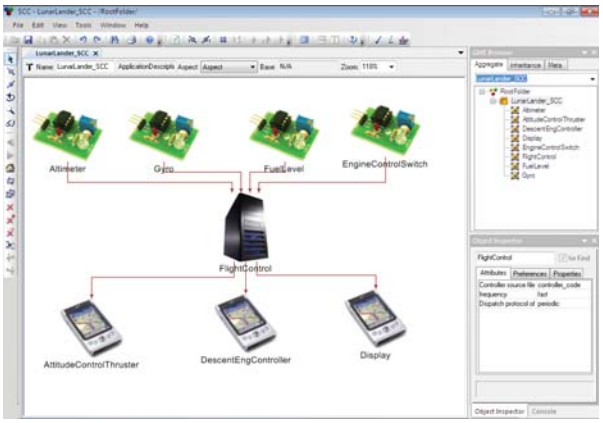

Figure 2. Lunar Lander application modeled within GME using the generated modeling environment for our SCC metamodel.

Figure 2 illustrates Lunar Lander application modeled as an instance of our SCC metamodel within Generic Modeling Environment (GME). We customize GME such that application types are realized concretely as GME metamodels, providing *architecture-independent modeling languages (AIML)*. We specify a formal model of the SCC type to model applications in which sensors and actuators are connected to controllers that cycle through the steps of fetching sensor values, computing function values, and sending outputs to actuators.

```
module LunarLander
open SCC

one sig Altimeter extends Sensor{}
one sig FuelLevel extends Sensor{}
one sig EngineControlSwitch extends Sensor{}
one sig Gyro extends Sensor{}
one sig AttitudeControlThruster extends Actuator{}
one sig DescentEngController extends Actuator{}
one sig Display extends Actuator{}
one sig FlightControl extends Controller{}{
 sensors= FuelLevel+ EngineControlSwitch+ Gyro+ Altimeter
 actuators= DescentEngController+ Display+
      AttitudeControlThruster
 controller_dispatch_state = periodic
 frequency_state = fast
 program = controller_code
}
...
```

Listing 1. Lunar Lander application description represented in Alloy

Listing 1 partially outlines the Alloy representation of the Lunar Lander application description, automatically synthesized from its concrete representation. The application model (an Alloy module) imports the *SCC* module, and defines four sensors and three actuators using signature extension to subtype the *Sensor* and *Actuator* types. The only controller of the application is then synthesized, while its properties are specified as Alloy facts.

B. Tactic: $PingEcho_{(SCC,II)}$

Ping/Echo and *Heartbeat* are two architectural tactics proposed for *Fault Detection*, which is one of the four design concerns for reliability [5]. In this case study we employ the Ping/Echo tactic, although the structures of these two tactics are very close. For detecting a fault using the aforementioned tactic, a monitor component regularly sends ping messages to receivers. The receiver is then supposed to respond with an echo message within a certain time period, otherwise it is considered to have failed.

Listing 2 partially presents the Alloy representation of the Ping/Echo tactic. It starts by importing the Alloy specification modules of the pair of an application type and an architectural style, for which an architectural map, enhanced by the architectural tactic under consideration, is developed. The parameterized predicate which gets as input a set of pinged components then, in line 6-7, dedicates an IIObject, an implicit-invocation object which extends Object [3], to the pinger. It has a port of type *Procedure* that can be called by other components. Lines 9–17 state that for each receiver, its *Procedure* port is connected to the *call* port of the pinger's IIObject via a *PrecedureCall* connector connected to it. On the other hand, the *call* ports of receivers are connected to the *Procedure* port of the pinger's IIObject.

```
1  module PingEcho_SCC_II
2  open SCC
3  open II
4
5  pred pingEcho_SCC_II(s:set needHandle){
6    one o:IIObject| o.handle = Pinger &&
7    no handled:needHandle-Pinger| handled in o.handle &&
8    one p: Procedure| p in o.ports &&
9    all n:needHandle| n in s =>{
10     one c1: procedureCall |
11     c1 in n.~handle.procedure[attachments].ran.connector&&
12     c1 in o.call[attachments].ran.connector
13
14     one c2: procedureCall |
15     c2 in n.~handle.call[attachments].ran.connector &&
16     c2 in o.procedure[attachments].ran.connector
17   }
18 ...
19 }
```

Listing 2. The Alloy predicate for $Ping/Echo$ tactic developed for the $architectural\ map$ of the pair of SCC application type and II architectural style

C. Incorporation of Tactic into Architectural Map

After modeling the application and specifying the mappings and tactics predicates, we need to define a compound module incorporating tactics' specifications into the process of synthesizing satisfying architectural models. Here, we have leveraged the architectural map for the SCC application type and the implicit-invocation architectural style specified in earlier work [4].

```
module LunarLander_SCC_II

open LunarLander as AppDesc
open SCC_II as map_SCC_II
open PingEcho_SCC_II

pred execute{
  map_SCC_II[]
  PingEcho_SCC_II[FlightControl]
}
```

Listing 3. The Alloy module for incorporation of $Ping/Echo$ tactic

Listing 3 represents the Alloy module for synthesizing Lunar Lander architectural models in implicit invocation style supporting the $Ping/Echo$ tactic. It starts by importing the modules of the Lunar Lander application description, the (SCC, II) architectural map and the $Ping/Echo$ tactic. The *execute* predicate is then specified, which calls both mapping and pingEcho predicates. The *Flightcontrol* element is then passed as an input to the parameterized tactic predicate to address the potential issue of crashing or otherwise failure of this component.

D. Satisfying Architectural Models

Given all the specifications and mapping constraints, Monarch using the Alloy Analyzer computes a set of architectural models that refine the application description in conformance with the fully formal definitions of the implicit invocation architectural style and the Ping/Echo tactic,

represented as Alloy solutions. To make those low-level, XML formatted outputs human-readable, it then using our *Alloy2ADL* transformer [4] converts them to an architecture description language (ADL).

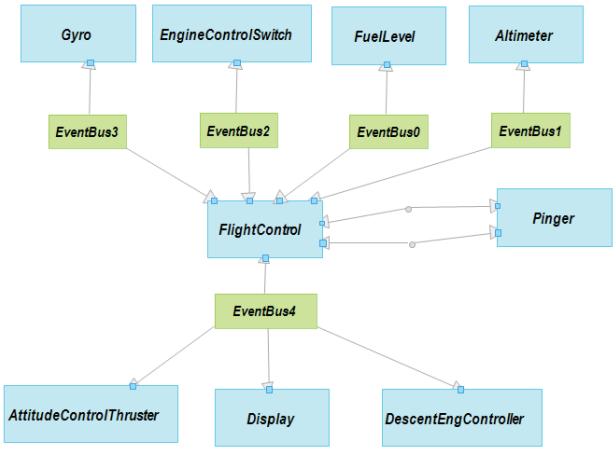

Figure 3. One of the computed architectural models represented in Acme.

A considerable number of ADLs have been proposed during the past several years to model specific application domains or as general purpose architectural modeling tools. We use Acme [11] in our tool, which is a mature general purpose ADL, with a particular support for architectural styles. It is also designed to work as an interchange between wide varieties of architecture description languages. Figure 3 shows an instance of the computed architectural models in Acme. In general, there is more than one satisfying solution, and the result is a set of formally derived architectural models for the given application with respect to the enforced architectural constraints.

E. Discussion

This work shows that architectural tactics can be formalized and implemented as executable specifications. By incorporating both the architectural styles and tactics during the synthesis, our approach formally derives narrower architectural spaces, which reduces the difficulty of design space exploration. We note that automated search could occur not only within one architectural style but across styles incorporating a set of tactics – leading to a tool able to automatically find appropriate architectural models for a given application model.

It is also worth mentioning that the incorporation of a tactic within a style might result in either the alteration of the style or even addition of a style to the architecture [14]. As a case in point, by application of the Ping/Echo tactic to an architecture developed upon the Pipe and Filter style, the derived architecture contains an added component in charge of performing monitoring process and having connections with the pinged components (filters), which consequently imposes Broker style into the architecture. The current version of Monarch avoids such mismatches by deriving an empty set of architectural instances, as there is no such architectural model that thoroughly complies with rules implied by the Pipe and Filter style and embodies an instance of the Ping/Echo tactic simultaneously. As a future work, we plan to investigate ways of handling such cases.

Another interesting avenue for future work is to provide more rigorous representation of application models especially with respect to non-functional requirements (NFRs). The more complete the specifications of application models, and the more tightly constrained the mapping specifications, the narrower the outcome architectural spaces, and the slighter the required postprocessing optimizing search. Work by Rosa et al. [19] and more recently by Jackson et al. [16], proposing that many forms of NFRs can be considered as constraints over the space of models, suggest interesting possibilities in this regard, which we intend to explore.

Finally, the upshot is that those who are doing research in software architecture, patterns, and tactics should recognize the need to specialize tactics to the particular settings induced by a choice of both application type and architectural style, and could consider the function of tactics as extending and refining architectural maps.

VI. Related Work

We can identify in the literature three categories of works that are related to our research. The first one concerns works that deal with formal modeling of architecture using Alloy. The second encompasses researches on leveraging architectural best practices to satisfy quality attributes. Finally, the last area of related work focuses on formal approaches to the evolution of architectures under the guidance of architectural styles

Focusing on the first category, numerous researchers have applied Alloy to formal specification of software architecture. Among others, Kim et al. [17] proposed an approach to translate architectural styles described formally in an architecture description language to Alloy language, and in turn, to verify properties implied by architectural styles. Georgiadis et al. [12] similarly specified structural architectural styles as a set of constraints in order to control runtime reconfiguration by means of constraints evaluation. While these works use formal modeling and verification for detecting architectural mismatch [9], we focus on preventing such mismatches with a formal synthesis approach. That is, we use Alloy not only to specify the application model or architectural constraints, but also to model the spaces of mappings consistent with both given application models as well as target architectural styles and tactics, and to automate the mapping process.

Bucchiarone and Galeotti [6] also proposed an approach based on graph grammars and *DynAlloy* [8] to verify programmed dynamic software architectures in which all

possible architectural changes are defined before run-time. Although this work, like other work we have studied, lacks an explicit notion of separating application description from other design decisions, it appears to have the potential to help us extend application models to include richer semantics.

Focusing on the second category, a number of approaches explored relating architectural styles and tactics stimulated by them regarding various quality attributes (e.g. modifiability [2], reliability [14]). Extending the same line of work, Kumar et al. [18] recently proposed a more general pattern-oriented knowledge model composed of four dimensions, including the pattern to tactic relationship. Our work is different from these works in several ways. First, our work is geared towards the systematic specification of mapping architecture-independent application models into the architectural styles and the associated tactics. Second, our approach has a formal basis which is missing in theirs.

Regarding the last area of related work, Tamzalit and Mens [21] recently proposed an approach for the evolution of an architecture description under the guidance of architectural style. To this extent, they rely on a formalism based on graph transformation. The other similar work is the recent work of Garlan et al. [10] on the evolution of programs with respect to architectural style. The premise of this work is that it is sometimes necessary to change a program written in one architectural style into a related program in another style. These works share with ours an emphasis on formal application of architectural best practices, but our work focuses on formal mappings of architecture-independent application models to a diversity of realized architectural models in practical architectural styles and tactics.

VII. Conclusion

While a wealth of research has been done on software architecture, architectural styles and architectural tactics, very little has been done on automated support for the derivation of software architecture with respect to styles and tactics. We presented an approach based on the notion of *architectural maps*, that formally supports automatic synthesis of architectural models from abstract application models in conformance with the architectural styles. In this paper, we showed that architectural maps can also incorporate architectural tactics in a formal and reusable form.

***Abstract*—Designing software architecture is an important and complex activity. To design a high quality architecture, architects need to make decisions on a number of inter-dependent design issues, each of which usually has a set of viable alternative solutions. Moreover, each viable solution often has diverse impact on different quality attributes which often conflict with each other. Existing methods for architecture design still face the challenge of bridging the gap between software requirements and high quality architecture. To alleviate the complexity of architectural design, we propose a *decision*-centric approach: ABC/DD. We attempt to provide pragmatic assistance for practitioners to narrow this gap, and also ensure the quality of target architecture. This approach transits from requirements to architectures through a five-step process including *requirement refining, solution exploiting, relation identifying, solutions and quality attributes synthesizing*, and *architecture deciding*. Finally we illustrate the applicability of this approach using a case study.**

I. Introduction

Designing software architecture is one of the most important activities for a software system. Because architecture not only provides the key framework for the earliest *design decisions*, which are taken to achieve both functional and non-functional requirements [1], but also plays a crucial role in the whole lifecycle of software system [2].

On one hand, designing software architecture is not a trivial activity. Architects need to elaborate system requirements and then transform them into a viable software architecture with respect to reusable subsystems, existing technology and quality attributes, etc. Because of the inherent gap between problem domain and solution domain, the transition from software requirements to architecture design remains a challenging problem. There is still a lack of fundamental process models and guidelines. In practice, architects usually design based on their own experience and intuition [3].

On the other hand, designing a high quality architecture is also very difficult, because architects usually need to make *design decisions* on a number of inter-dependent design issues, each of which has a set of viable alternative solutions [4]. Moreover, different alternatives usually have diverse impacts on different quality attributes. Even worse, such impacts sometimes conflict with each other. Consequently, architects have to deliberately tradeoff among these entangled problems.

* Corresponding author

In recent years, a new research trend has emerged in architecture community to facilitate a better software architecture design process. It is suggested that *design decisions* should be modeled and considered as a first class entities [5]. The seminal paper [6] advocates this perspective, in which software architecture can be seen as a composition of architectural *design decisions*. Many design methods have been proposed in such a paradigm shift [7], including Archium [8], AREL [9], ArchDesigner [4], AQUA [10], and Bayesian-Belief Network based method (BBNbASM) [11], etc. These design methods focus on describing architecture design process using *design decision* and they greatly promote the progress of research. However, most of these design methods do not aim at directly guiding architects to derive architecture from requirement. Besides, only a few of these decision-centric design methods explicitly support quality analysis. More details about these methods is analyzed in Section IV.

To address this problem, we propose a decision-centric architecture design method: **ABC/DD (Architecture Based Component composition by Design Decision)** in order to narrow the gap between requirement and architecture. We use "*Divide and Conquer*" as the principle idea of our approach. We firstly divide system requirement as a set of design issues, then solve these design issues and determine the quality attributes independently, and then synthesize solutions for each design issue to generate a set of candidate architectures, finally recommend the optimal candidate based on quality attributes. Specifically, our approach transits from requirements to architectures through a five-step process including: (1) *requirement refining*, (2) *solution exploiting*, (3) *relation identifying*, (4) *solutions and quality attributes synthesizing*, and (5) *architecture deciding*.

The remainder of this paper is structured as follows. Section II presents our approach and tool support; Section III demonstrates the applicability of our approach using a case study; then Section IV gives an overview of related work including decision-centric architecture design methods, and quality attributes related research in architecture; finally Section V concludes the paper.

II. Proposed Approach

A. Design Decision-Centric Meta-Model

Based on the Core model [12], we propose the meta-model of our approach in Fig. 1.

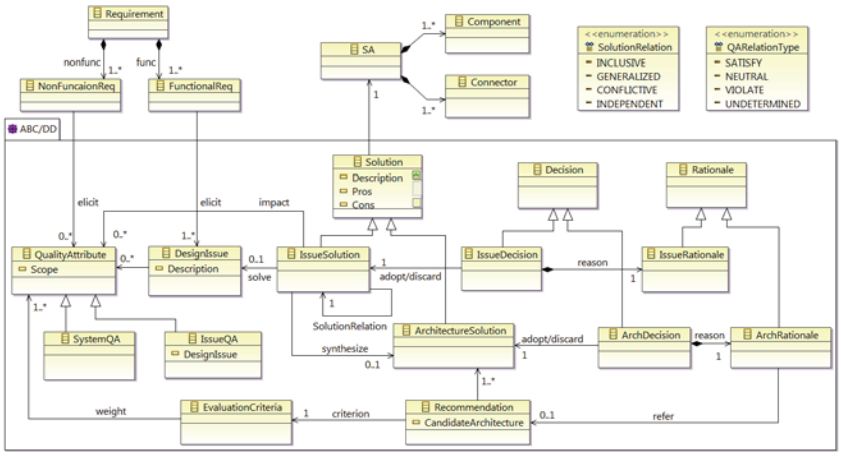

Fig. 1. The design decision-centric meta-model

In this approach, a *design issue* means an architecturally significant requirement. It acts as a linkage between the architecture design and requirements. *Design issues* can be either project-specific or reusable. For those appear in many architecture design projects, we named them "*reusable design issue*", and we can retrieve them from repository and then reuse them. And for those only appear in a specific project, they are "*project-specific design issue*", and need to be solved independently manually.

An *issue solution* provides a possible way of solving a *design issue*. And an *architecture solution* is a candidate architecture, which is synthesized from all *issue solutions* and solves every *design issue*. In our approach, each solution is instantiated by a set of components, connectors and their configuration(*C&C view*).

Quality attribute (QA), such as maintainability, portability, scalability, etc., are identified from non-functional requirement. The scope of quality attribute can be either a design issue (*IssueQA*) or the entire system *(SystemQA*). Usually, a design issue is related with multiple quality attributes. While several different design issues also can be related to the same one quality attribute.

Quality attributes do not share the same equal significance. We use an *evaluation criterion* to characterize different priorities of quality attributes in order to reflect system's quality goal. Based on an *evaluation criterion*, a *recommendation* will be presented among a set of candidate architectures. According to this *recommendation*, architects can make a *decision*, i.e., to accept or to reject one candidate architecture solution.

In addition, another important element enclosed in design process is *rationale*, which is the reason and justification behind a decision. Solution's impact on quality attributes is a kind of important rationale, and will be captured by ABC/DD automatically. Besides, architects can also denote some *pros*, *cons* and any comments to each decision. These *rationales* will be valuable when reviewing or evolving the architecture.

B. Decision-Centric Design Process: ABC/DD

Based on the above meta-model, we present an iterative process to implement our design decision-centric design method in Fig.2. We use an activity diagram to illustrate this process in five steps. Main inputs to this process include both functional and non-functional requirement. And outputs of this process include a final architecture, along with a set of unselected candidate architecture and captured rationale. We describe each step of this approach in turn.

Step (1) : Refine System Requirement

In the first step, architects need to clarify the requirements. Functional requirements describe supports that user needs, while non-functional requirements impose constraints on how the system should accomplish the systems functionality [13]. Architects deliberate and determine *design issues* from functional requirement, and identify *quality attributes* from non-functional requirement.

When architect refining the requirement, ABC/DD will search repository in order to match existing *design issues*. For example, "application integration style" is a common *design issue* when designing a distributed system, and possible alternative solutions include "Remote procedure call", "Message Bus", "Shared Database" and "File Transfer" [14]. These solutions are relatively 'stable', and less likely need to redesign in a new project. Thus, we can directly retrieve this set of alternative solutions and present them to architects. Reusing *design issue* not only reduces the burden, but also improves the quality of design.

Step (2) : Exploit Solutions

In this step, architects need to derive alternative solutions to each design issue. They can create or reuse a concrete design fragment. We adopt common used *Component & Connector View* (*C&C View*) to describe the solution.

For *reusable design issues*, architects can refer to existing issue solution and determine whether reuse one of them or not. For *project-specific design issues*, architects need to solve them on their own by designing a set of components and connectors.

Fig.3 and 4 are two examples of issue solutions.

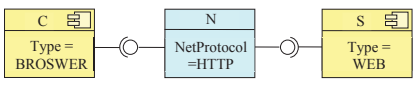

Fig. 3. Solution instance of "B/S structure"

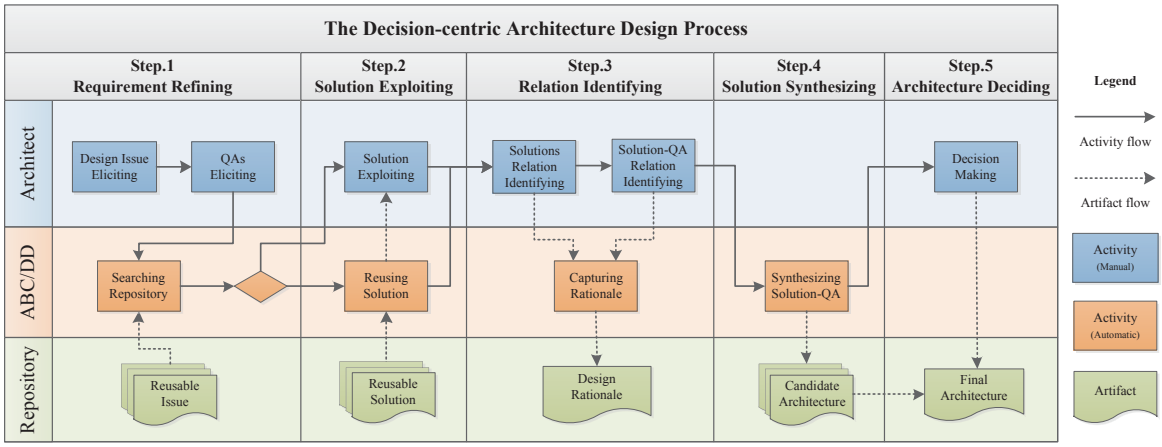

Fig. 2. The decision-centric architecture design process

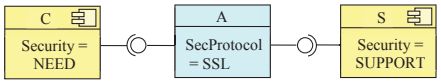

Fig. 4. Solution instance of "Security communication"

Step (3) : Identify Relations

(a) Relations between issue solutions

In this step, architects need to explore the *C&C* models for each issue solution, and identify relations between solutions of any two different issues. In [15], Kruchten et.al, present an ontology which describes a group of relations. We select four relations from them, which can be used in our approach, including:

- $INCLUSIVE$, means that one solution IS_a includes another solution IS_b, or IS_a is part of IS_b.
- $CONFLICTIVE$, indicates that two solutions are conflictive to each other and cannot be selected together to synthesize architecture solution.
- $GENERALIZED$, means that one solution is a generalization or a specialization of another solution.
- $INDEPENDENT$, means the above three relations do not exist.

Each pair of issue solutions should be identified as only one kind of these relations. Relations determined in this step are foundations for solutions synthesis in the following step. According to these identified relations, different issue solutions, which are not $CONFLICTIVE$, can be merged together. For example, issue solutions in Fig.3 and Fig.4 are $INDEPENDENT$, and they can be merged as one solution as shown in Fig.5.

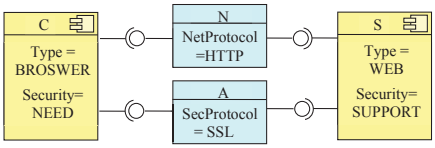

Fig. 5. The merged solution of (a) and (b) in Fig.3 & 4

(b) Relations between issue solutions and quality attributes

Each issue solution impacts on several quality attributes. And these impacts should be determined by architects after they design or reuse an issue solution. We use four kinds of relations to qualitatively describe such relations.

- $SATISFY(solution, QA)$
- $NEUTRAL(solution, QA)$
- $VIOLATE(solution, QA)$
- $UNDETERMINED(solution, QA)$ $[default]$

Step (4) : QA-Based Solutions Synthesize

According to the identified relations between the issue solutions, as well as the quality attributes for each issue solution, our recursive synthesis algorithm can build a combination tree, in which all feasible combinations of issue solutions can be explored. And it merges every feasible combination of issue solutions automatically. The outputs of this synthesis are the *C&C* models of candidate architecture solutions, and the established synthesis of quality attributes. We denote the quality of one candidate architecture as a vector:

$$CA._{QA} =< QA_1, QA_2, \ldots, QA_n > .$$

and then we assign a value to each relation as: $SATISFY = 1$, $VIOLATE = -1$, and $NEUTRAL = 0$. Then each quality attribute of candidate architecture can be calculated:

$$CA._{QA_i} = \sum_{i=1}^{n} value(IS_{x,y}, QA_i),$$

$$\forall x, y(IS_{x,y} \in CA._{QA_i} \wedge value(IS_{x,y}, QA_i) \neq null)$$

Step (5) : Architecture Deciding

(a) Evaluation Criterion

In most cases, different quality attributes have different importance. In order to express the desired quality goals, architects can give a partial order or specify concrete weights to all quality attributes.

For example:

$\{Real\text{-}time\} > \{Maintainability, Cost\}$, or

$Real\text{-}time._{weight} = 0.3$; $Maintainability._{weight} = 0.1$, etc.

These values will form a quality weight vector.

(b) Recommendation and Architecture Decision

In this final step, we already have quality value vectors for different candidates and quality weight vector. The dot product of these two vectors reflects the quality of each candidate architecture, and can be used for comparison.

To design a high quality architecture, we should satisfy QAs as more as possible. Therefore, after ranking all candidates,

the one which received the highest quality value will become the recommendation. Then architects can inspect this recommended architecture holistically and decide whether accept or reject it as the final architecture.

C. Tool Support

We have developed a visual architecture modeling tool named ABC Tool to support this design decision-centric design method. This tool implements an integrated environment that provides support for architecture design, automated architecture synthesis, quality-attribute analysis and candidate recommendation, etc. ABC Tool is developed as a suite of Eclipse Plug-ins. We mainly used two Eclipse open source frameworks: EMF (Eclipse Modeling Framework) to model our meta-model supported design method and GMF (Graphical Modeling Framework) to provide visual design ability.

III. Case Study

A. Case Description

This is a case study based on a real-world Commanding Display Systems (CDS) that has served in a Space Flight Center for years. And this system is currently in need of refactoring to deal with several emerging problems. Fig.6 shows the simplified architecture of the legacy system. In this architecture, there are a data source (DS) that reads various kinds of live data, and a set of monitors (Ms) that display the processed data. There is also a dedicated display server (Svr) that receives the data transmitted from DS, pre-processes the data in some specific ways, and pushes the data to Ms.

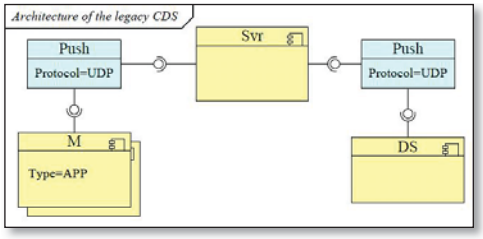

Fig. 6. Simplified Architecture of Legacy System

Several main problems of this legacy system include:

(a) Due to increasing amount of data, current design exposes the system to performance problem. When a burst of data occurs, it will cause seconds of delay. However, as a commending system, quality of real time is crucial.

(b) The history data is stored in Svr without database (DB) supporting. The management and usage of the history data are inefficient and inconvenient.

(c) Current CDS is designed as a stand-alone application. Because of a great deal of changing and upgrading requirements and implementations, the maintenance of this system is a hard work.

We applied our approach in this case study.

B. Applying the Method

Step 1: Identify System Requirement

Table I
Elicited Design Issues and Quality Attributes

Design Issue	*Description*	*Quality Attributes*	
		Issue	**System**
DI1	Live data acquiring: how to transfer the live data from DS to Ms.	Real time, Non-overload	Cost, Maintainability
DI2	History data acquiring: how to transfer the history data from DB to Ms.	Non-overload	
DI3	Persistence of the live data: how to store the lastest collected data into DB.	Recoverability	
DI4	Visually display both live and history data friendly in Ms.	N/A	

Firstly, we elicit design issues and quality attributes in Table I. In all, there are four design issues, three issue-QAs and two system-QAs.

Step 2: Exploit Solutions

Then we discover and instance a group of issue solutions for each elicited design issue. For example, there are two issue solutions for design issue 1, as shown in Fig.7 and 8:

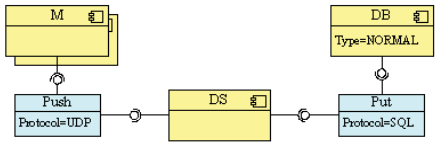

Fig. 7. Issue solution 1.1

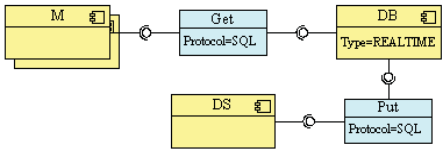

Fig. 8. Issue solution 1.2

Step.3: Identify Relations

(a) Solutions Relation

Firstly, relations between the issue solutions are identified, as shown in Table II.

Table II
Identified Relations between Issue Solution

Relation Type	*Issue Solution*
INCLUSIVE	(IS1.2, IS2.3)
GENERALIZED	(IS2.1, IS3.1), (IS2.2, IS3.2)
CONFLICTIVE	(IS1.1, IS2.3), (IS1.2, IS2.1), (IS1.2, IS2.2), (IS3.1, IS4.2)

For example, IS2.3 is part of IS1.2, so INC(IS1.2, IS2.3) is true; the DB in IS2.1 is a specialization of the DB in IS3.1, so GEN(IS2.1, IS3.1) is true; the DB in IS1.1 has different attribute value from the DB in IS2.3, so CON(IS1.1, IS2.3) is true.

(b) Solution-QA Relation

Secondly, relations between the issue solutions and quality attributes are identified. We implemented a *Solution Quality*

View, in which architects can evaluate each issue solution and determine related QA relation. Fig.9 illustrates the issue solution 1.1 and its corresponding QAs, including two issue QAs and two system QAs.

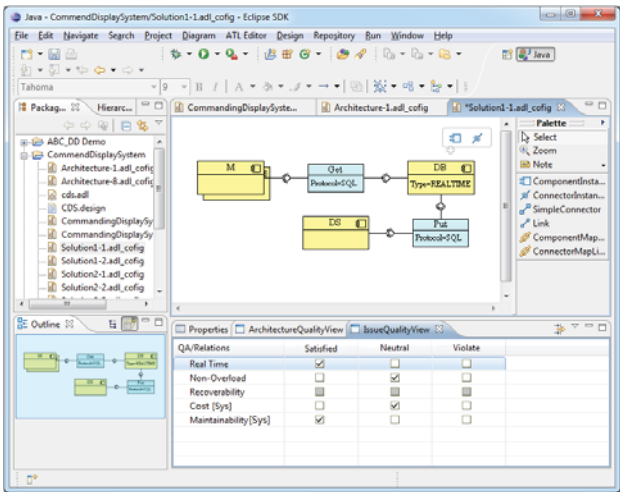

Fig. 9. Quality-View of Issue Solution 1.1

Step.4: QA-Based Solutions Synthesize

In this step, issue solutions and solution-QA relations will be synthesized to generate a set of feasible candidate combinations.

In this case study, the results are eight candidate architecture solutions, named $CA_1 \sim CA_8$. Limited by space, we only illustrate CA_7 in Fig.10.

Step.5: Recommend Candidate Architecture

(a) Specify Evaluation Criterion

We ordered these QAs and quantitatively set the weight to them.

$Real\text{-}Time = 0.3,$
$Non\text{-}overload = 0.2$
$Recoverability = 0.1$
$Maintainability = 0.2$
$Cost = 0.1$

Then, the quality weight vector can be denoted as:

$$QA = <0.3, 0.2, 0.1, 0.2, 0.1>$$

(b) Recommendation

Using this quality weight vector as a evaluation criterion, we can calculate the dot product of candidate architectures quality and weight vector as shown in Table IV.

Table IV
CANDIDATE ARCHITECTURE AND QUALITY VALUE

CA1	CA2	CA3	CA4	CA5	CA6	CA7	CA8
0.1	-0.2	0.9	0.5	0.8	0.7	**1.8**	1.3

We implemented another view to present this evaluation result. Fig.10 shows this view, in which architects can examine each feasible architecture and its various quality attributes. And the highlighted candidate architecture is the recommendation. In the case, CA_7 is highlighted.

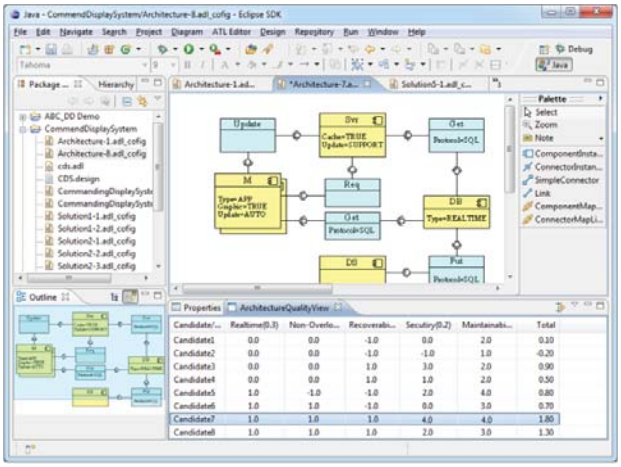

Fig. 10. Architecture Quality View of CA7

C. Discussion

This case study illustrates a simple but complete usage of our approach. From this experience, both effectiveness and limitations can be learned. We discuss about some of our finding in this section.

This approach provides the support in several activities to alleviate the difficulties. Our approach can relieve the difficulty of directly designing a complete architecture solution. When facing a number of requirements, architects need to explore every combination of the options and then present all of the resulting architectures for comparison. It will be a hard and error-prone work to accomplish. By applying the principle of "divide and conquer", we separate requirements into a set of *design issues*, and let architects concentrate on designing solutions for relatively simple problem. Then, with the help of solution synthesize algorithm, architects are able to rely on automated processes and ABC Tool that help him intelligently explore the possibility solution space, and provide a small set of humanly-intelligible recommendations for him to chose from at the end.

However, the limitation is that only the problem whose design issues are relatively independent is suitable for our approach. For the problems whose design issues are overlapping and tightly interrelated, are not quite suitable.

IV. RELATED WORK

The software architecture community has developed different methods to support reasoning about various quality attributes during architecture design and also support evaluation of final architecture's quality.

Bruin and Vliet introduce an approach named Quality-Driven Composition (QDC) [16]. It firstly derives the architecture that only addresses functional requirements and contains a number of variability points. The solution fragments addressing quality requirements are used to iteratively compose the architecture.

The ADD method [17] is proposed by CMU SEI. This method defines software architecture as a design process based on the quality attribute requirements. ADD follows a

recursive process that decomposes a system or system element by applying architectural tactics and patterns that satisfy its driving quality attribute requirements. ADD can be used with traditional and with agile software engineering methods.

Jansen et al. propose an approach named Archium [8]. They give a meta-model of software architecture decisions and they develop a tool to model design decision and architecture fragment separately. They use composition model as a glue to combine decision and design fragment.

Choi et al. introduce an integrated design-decision based architecture design approach, AQUA [10]. It has a three-step process includes finding, evaluating and changing decisions. They use a decision constraints graph as the most significant technique to support the entire process and guaranteed the quality.

Al-Naeem presents ArchDesigner [4] as a systematic approach for facilitating the architectural design. Using optimization techniques, it can determine the best combination of design alternatives that best satisfy stakeholders' quality goals and project constraints.

Bayesian-Belief Network based method (BBNbASM) [11] describes uncertain relations between quality attributes and design decisions by a formal model which can be used to predict the probability of architecture's quality.

Although the above approaches are proposed to support quality attributes to architecture design, they lack of enough support for design process. In contrast to these approaches, our approach offers a more complete support of guidance from requirement to target architecture design and support analysis of quality attributes as well.

V. Conclusions and future work

In this paper, we have proposed and implemented a decision-centric architecture design method which alleviates the complexity of architecture design . This approach provides pragmatic guidance to architects in the design process from architecturally significant requirements to candidate architecture solutions. It supports automated synthesizing candidate architecture and also recommends an optimal candidate, making the design process more efficient and effective.

This paper presents our preliminary work. So far, we have already identified a number of areas that call for further improvement.

(a) In current ABC/DD, we only use qualitative relations to describe the solution's impact on quality attributes. Three-valued score is not able to deal with the complexity of real problems. Although quantitatively measuring such impact surely will incur more burdens, there are many quality attributes which are more suitable to be quantitatively described. As a part of our ongoing work, we are trying to leverage fuzzy logic to tackle this problem and have achieved initial results.

(b) Furthermore, to enhance this approach, we are going to integrate a more sophisticated evaluation mechanism. A promising way is to leverage some existing research on quality evaluation of architecture.

(c) We do not validate the effectiveness of the recommendations. And we plan to produce some measures of the pertinence or an expert's independent opinion to compare with the results produced by our approach.

***Abstract*—Software architectures play a major role in determining system quality, since they form the backbone to any successful software-intensive system. In this context, reference architecture is a generic architecture for a class of software systems used as a foundation for the design of concrete architectures from this class. Because of their fundamental role, reference architectures need to be properly represented in order to be effectively used, and understood by all stakeholders. In this perspective, we have found initiatives proposing different approaches to represent them. However, there is a lack of detailed overview about all these approaches. In this paper, we identify possibly all approaches used or proposed to represent reference architectures. For this, we have used a technique proposed by Evidence-Based Software Engineering (EBSE): the Systematic Review. As achieved results, we can observe different approaches adopted to represent reference architectures; however, there is no consensus about which are more adequate or their effectiveness. Based on this overview, interesting and important perspectives for future research can also be found.**

Keywords: Reference Architecture, Architectural View, Architectural Description Language, Systematic Review.

I. Introduction

Reference architectures have emerged as elements that aim at facilitating and systematizing the development of software systems. However, there is no commonly accepted definition for reference architectures [1]. In this work, we considered that a reference architecture aggregates knowledge of a domain, identifying abstract solutions of a problem and promoting reuse of design expertise by achieving solid, well-recognized understanding of a specific domain.

Particularly, representing reference architectures in order to make them understandable for a wide variety of stakeholders (such as customers, product managers, project managers and engineers) consists of an essential activity for their success. Despite the relevance of reference architectures, it has been observed that their representation, in practice, is often conducted informally. Additionally, there is a lack of works that summarize all approaches that have addressed an adequate representation of these architectures.

In another perspective, during the study of a new knowledge area, researchers usually conduct a bibliographic review (almost always an informal review) to identify publications related to a specific subject. However, this kind of review does not offer any support to avoid bias during the selection of the publications that will be analyzed. In this context, Evidence-Based Software Engineering (EBSE) [2] has investigated and proposed the use of the systematic review, an technique used to summarize, assess and interpret all evidences related to a specific question, topic area, or phenomenon of interest. In this context, an individual evidence (for instance, a case study or an experimental study divulged in a publication) which contributes to a systematic review is called *primary study*.

The main objective of this paper is to identify, summarize and analyze possibly all approaches that have been proposed or used to represent reference architectures. For this, we have adopted and conducted a systematic review[1]. Results have pointed out that this is a novelty topic of research and, considering the relevance of reference architectures in the software development, more effort must be focused on this research area. Besides that, we could identify future and important research lines based on our achieved results.

This paper is organized as follows. In Section II we present the conducted systematic review. In Section III we discuss achieved results. In Section IV we summarize our contributions and discuss perspectives for further work.

II. Systematic Review Application

Our systematic review was conducted in the reference architecture context, aiming at identifying all relevant primary studies related to the representation of this architecture. It was conducted from September 1st, 2010 to October 15th, 2010 and involved three people (one software engineering researcher, one systematic review specialist, and one undergraduate student). In order to conduct our systematic review, we followed the process proposed by Kitchenham [3]. In short, this process is composed by three main phases: (i) planning; (ii) conduction; and (iii) reporting. The phases

[1]Detailed information about our systematic review is available in a technical report found in http://www.icmc.usp.br/~biblio/BIBLIOTECA/rel_tec/RT_363.pdf

are explained in more details during presentation of our systematic review.

A. Planning

In this phase, the objectives and the systematic review protocol are defined. The protocol guides the conduction of the systematic review and is composed by research questions, search strategy, inclusion and exclusion criteria and data extraction and synthesis method.

1) Research Questions: Aiming to find all primary studies to understand and summarize evidences about proposed or used approaches to represent reference architectures, the following research question (RQ) was established:

- RQ1: Which are the approaches proposed or used to represent reference architectures?

Additionally, we defined three secondary research questions to specify the objectives of our search:

- RQ2: Which are the UML techniques proposed or used to represent reference architectures?
- RQ3: Which are the ADLs proposed or used to represent reference architectures?
- RQ4: What is the maturity level of the found approaches, considering their application to describe reference architectures?

2) Search Strategy: In order to establish the search strategy, considering the research questions, we initially identified the main keywords "Reference Architecture" and "Architectural Description". We also identified synonyms for these keywords. Thus, the final search string was: *("Reference Architecture" OR "Reference Model") AND ("Architectural View" OR "Architecture View" OR "Architectural Model" OR "Architecture Model" OR "Architectural Description" OR "Architecture Description")*. In particular, we add "Reference Model" in our search string, since some authors use this referring to reference architectures. Also, we only considered papers written in English, since it is the most common language in scientific papers. Finally, we established ACM Digital Library, IEEEXplore, ISI Web of Knowledge, ScienceDirect, Scopus, and SpringerLink as search sources (i.e., publication databases) to find the primary studies.

3) Inclusion and Exclusion Criteria: The selection criteria are used to evaluate each study recovered from the search sources. Thus, the inclusion criteria (IC) used to include relevant studies in our systematic review were:

- IC1: The primary study proposes or uses an approach to represent reference architectures; and
- IC2: The primary study proposes or uses an ADL to describe reference architectures.

Alternatively, the exclusion criteria (EC) used to exclude the studies that do not contribute to answer the research questions were:

- EC1: The primary study does not address reference architectures;
- EC2: The primary study does not propose or use any approach to represent reference architectures;
- EC3: The primary study does not present an abstract or its full text is not available;
- EC4: The primary study is written in a different language than English;
- EC5: The primary study is directly related to another primary study of the same author. In this case, only the most recent primary study will be considered; and
- EC6: The primary study consists of a compilation of work, for instance, from a conference or workshop.

4) Data Extraction and Synthesis Method: We plan to build data extraction tables related to each research question, when applicable.

B. Conduction

In this phase, the primary studies are identified, selected and evaluated according to the previously established protocol. To support the organization of the primary studies, we used JabRef[2], an open source reference management system. It is worth highlighting that only primary studies published until September 14, 2010 are considered in this paper.

As a result of our search in the publication databases using the search string, 110 primary studies were recovered. After the application of the inclusion and exclusion criteria, only 10 studies were considered relevant for our systematic review. Table I presents these studies. Following, a more detailed analysis was conducted on each primary study included.

C. Reporting

In this last phase, we present analytical results of our systematic review. The obtained data extraction and synthesis of knowledge considering each research question is discussed next.

[2]http://jabref.sourceforge.net

1) RQ1: Regarding RQ1 (i.e., approaches proposed or used to represent reference architectures), we have identified 10 different adopted approaches. Table II summarizes each of these approaches. Particularly, studies S4, S5, S9, and S10 represented the reference architecture using a graphic approach other than UML. Also, study S8 proposed an architectural view, the Conceptual View, which describes by means of ontologies each of the terms that are present in the reference architectures. It is worth noting that this diversity points out that there is no consensus about how to represent reference architectures.

TABLE II
SHORT DESCRIPTION OF THE APPROACH PROPOSED OR USED IN EACH PRIMARY STUDY

Study	Approach proposed or used in the primary study
S1	Architectural Description Language ADLARS
S2	Architectural Description Language π-ADL
S3	Architectural Description Language WRIGHT
S4	Model-View-Controller and Moderator Architectural Styles
S5	Layers Architectural Style
S6	Business, Information and Computational Architectural Views
S7	Component Architectural View and Information Model
S8	Module, Runtime, Deployment and Conceptual Architectural Views
S9	Logic and Physical Architectural Views
S10	Community, Process, Service and Infrastructure Architectural Views

2) RQ2: This research question addresses UML techniques proposed or used to represent reference architectures. Table III summarizes the found UML techniques. For instance, Lopez and Blobel [9] (study S6) adopted three architectural views: enterprise, information and computational. Then, the authors used, respectively, the use case diagram, the class diagram and the component diagram of UML to represent each of these views.

TABLE III
UML TECHNIQUES PROPOSED OR USED IN THE REPRESENTATION

Study	Architectural View	UML Technique
S6	Enterprise View	Use Case Diagram
S6	Computational View	Component Diagram
S6	Information View	Class Diagram
S7	Component and Connector View	Component Diagram
S7	Information Model	Class Diagram
S8	Deployment View	Deployment Diagram
S8	Module View	Class Diagram
S8	Runtime View	Component Diagram

The enterprise view offers a perspective of the system's architecture and environment, describing the system's purpose, scope and policies. The computational view shows the logical components and their interactions through interface. The information view, also referenced by study S7 as an information model, offers a perspective on the information's structure and its semantics. The runtime view proposed by Nakagawa and Maldonado [11] is also known as Component and Connector View (C&C) by the "Views and Beyond" method [14]. The C&C view shows the system as a set of cooperating units of runtime behavior and was also proposed in study S7. The deployment view describes the machines, software that is installed on those machines and network connections that are used by the software systems. Finally, the module view shows how a software system is structured as a set of implementation units.

3) RQ3: This research question addresses the ADLs proposed or used to represent reference architectures. In spite of the diversity of ADL available in the literature, there are few initiatives of using ADL to represent reference architectures. Bashroush et al. (study S1) developed the ADLARS (Architecture Description Language for Real-time Software Product Lines), an ADL to be used in the software product line context. This ADL aims at supporting the relationship between the system's feature model and the architectural structures. The feature model encompasses the variability and commonality among the different products within the scope of a family. Thus, the link between the feature model and the architectural structures allows for automatic generation of product architectures from the family reference architecture, making the task of deriving product-specific architectures much more straightforward.

Chen et al. (study S2) applied π-ADL to describe the High-Level Architecture (HLA), which is a reference architecture and a common infrastructure for large scale distributed interactive simulation systems, accepted as an IEEE standard in 2000 [15]. In π-ADL, architectures are composite elements representing systems. In this sense, a composite consists of external interfaces and internal behavior. Therefore, π-ADL supports the description of composite dynamic behaviors. Additionally, the virtual machine for the system dynamic analysis, called π-ADLVM, can be used to test the architectural models written in π-ADL.

Fritschi and Gatziu (study S3) represented the reference architecture by means of WRIGHT [16]. This language presents the basic architectural abstractions of components, connectors and configurations, providing explicit structural notations for each of these elements. Particularly, the configuration is a collection of component instances combined via connectors.

4) RQ4: This research question addresses the maturity level of the approaches, considering their application to describe reference architectures. In order to answer this question, we classified each study in one of the following categories: (i) proposal, if the primary study proposes an approach to represent reference architectures, but does not present any case study; (ii) case study, if the primary study

presents at least one case study; and (iii) application, if the approach is already been used in a project or in the development industry. Table IV shows the maturity level of each approach. It is observed that only two studies presented a case study. In this sense, it seems interesting to concentrate efforts to increase the maturity level of these approaches and to verify if they are adequate for the representation of reference architectures.

TABLE IV
MATURITY LEVEL OF THE FOUND APPROACHES

Maturity Level	Total	Percentage	Primary Studies
Proposal	4	40%	S1, S4, S5, S10
Case study	2	20%	S2, S8
Application	4	40%	S3, S6, S7, S9

III. DISCUSSION

Results of our systematic review point out that, in spite of relevance of reference architectures to the software development, there are few recent works that show concern with their adequate representation. Therefore, more studies are necessary that investigate which are and how other, if any, architectural views can be used to properly describe reference architectures. Also, investigation of well-known graphic notations, such as UML, would be relevant, aiming at standardizing the representation of such architectures. Additionally, the use of ADLs in the context of reference architectures should be further investigated concerning their application and suitability.

Considering knowledge arisen from this work, it is possible to identify interesting and important research lines that can be investigated in future work. For instance, investigation or proposition of software tools to support the representation and modeling of reference architectures; conduction of case studies in order to increase the maturity level of the found approaches; investigation of how well-known graphic notation could be applied in order to represent different detail levels of reference architectures; and, establishment of a consensus of the best approaches to the representation of reference architectures.

Regarding limitation of this work, other research sources could be selected, such as Google Scholar, and other keywords could be added to the search string. Moreover, it is worth highlighting that systematic review conduction is not a trivial task because of the amount of papers that need to be manipulated. Besides that, relevant primary studies written in languages other than English were overlooked in this instance.

IV. CONCLUSIONS

The main contribution of this work was to present a detailed panorama about proposal and use of approaches for the representation of reference architectures. Based on this panorama, another important contribution is to bring forth new research lines on this topic. As main result, we found that the representation of reference architectures has not been sufficiently explored and there are still different perspectives that could be investigated in order to deal adequately with reference architectures, aiming at promoting their dissemination and effective use.

ABSTRACT

The implementation of an appropriate software architecture is crucial in achieving the optimum performance from a system. Web-based applications are becoming increasingly popular in replacing previous Windows-based applications. This has lead to a growth in new technologies and architectures to cope with the new workload and performance demands that web-based applications can require.

This paper will look at a current software company that provides process-heavy web-based application systems providing grant management services to medical and academic research. The purpose of this paper is to analyze the performance of their existing Web Forms based management system against newly developed dynamic component-based architecture using a variant of the Model View Controller (MVC) and Model-View-ViewModel (MVVM) patterns, which we have termed MVDVM (Model-View-DynamicView Model). Accurate and meaningful results will demonstrate how applications can now benefit from this approach.

Keywords – Component based architecture, Dynamic forms, Interoperability, Model View Controller.

I. INTRODUCTION

Web-based software applications are becoming more popular and crucial to the running of businesses in their day-to-day processes. Due to the growth of the world wide web and of Internet services capabilities, software companies are in a much better situation to offer services that previously would have only been possible through an offline platform.

Improvements in Internet connectivity and hardware performance within the last ten years has meant that software developers no longer have to worry as much about bandwidth, processor or memory requirements when implementing process-heavy applications. Although this has been beneficial to the software industry it has lead to many systems being implemented in ways that do not utilize best performance techniques available. This can deliver sub-optimal user experience and utilizes greater server capacity than is necessary at a time when datacenter costs are rising.

This paper will look at a software company that implements process-heavy web applications. The company's current working practice and techniques being used will be analyzed. The techniques will then be compared against a new dynamic component-based solution to identify the change in performance achieved for one of its key software products.

Statistics such as page load time, page size, number of database queries will be measured under varying loads and analysed to assess how these will benefit by applying latest thinking and best practice when developing high-performance software systems

In the next section, a brief overview of the product is provided followed by a discussion of related research. The subsequent sections will discuss the technology platform, the test platform and then present the performance data of the old product and the re-architected product.

II. CASE STUDY OVERVIEW

This paper analyzes a component-based dynamic solution used to manage application forms within CC Grant Tracker, a Grants Management software product. The solution builds and publishes forms, which are then used for the completion, submission and ongoing management of applications. CC Grant Tracker is a solution from CC Technology, a leading global supplier of advanced grant management software solutions, based in Glasgow, Scotland. CC Grant Tracker supports organizations such as charities, academic institutions, public funding bodies and corporate foundations who often employ a regular cycle of grant applications, where professional reviewers decide which applications are worthy of funding. For a large organization, there may be hundreds or even thousands of applications, as well as dozens of reviewers, not to mention stringent auditing requirements. In such cases, simply administering the application process is a major undertaking. CC Grant Tracker manages the full life cycle of grant administration, from initial application through evaluation, approval and ongoing management.

When CC Technology originally created the software product the emphasis of the initial analysis and design phase was based on functionality rather than the performance of the system. The application is heavily web forms-based and the initial version was delivered using the standard web development tools from Microsoft – ASP.NET Web Forms. This delivered a tightly-coupled solution with associated maintenance issues. As the number of clients and the breadth of their requirements have increased the requirement to develop the flexibility and performance of the application forms has become a priority.

CC Technology have been using a re-architected solution with a number of new large clients and the new system has been extremely well received.

III. RELATED RESEARCH

A. Web Forms vs MVC

Microsoft currently endorses two web architectures, Web Forms, which was released in 2002, and the Model-View-Controller (MVC), which was released in 2009. MVC is a standard design pattern that Microsoft has adopted. The MVC pattern helps deliver solutions that separate the different aspects of the application (input logic, business logic and UI logic), while providing a loose-coupling between these elements [1]. Both architectures provide benefits to the developer and end-user depending on the circumstances. For this study we examined both approaches to obtain a better understanding as to which provides the better performance benefits.

1) ***Web Forms*** – The major advantage of a Web Forms implementation is that it allows an application to be developed in a relatively short period of time as there is lower initial design requirements for the solution architecture. However, research and experience shows that there are a number of performance disadvantages inherent to this approach.

Web Forms allow only one form tag to be added per page. This means that in order for the page to get information to or from the server, the entire page must be posted back. A common approach to address this uses Microsoft's Ajax Control Toolkit and update panels. This reduces performance problems related to sending unnecessary data back to the server however the Ajax update methods can be just as performance heavy in bandwidth and processing on the server due to the View State that is required on all updates from a Web Form regardless of a full postback or asynchronously.

The View State holds session information for each page [2]. This adds considerably to the data size of the page and as this is exchanged in all updates this impacts the bandwidth for the solution. Many of the built-in ASP.NET components make heavy use of View State, so it is not unusual for a page to have 10's of Kbytes of View State [3]. This is measured in terms of performance for end-users and bandwidth costs at the data centre. There is therefore no performance gain in using Ajax update panels throughout the application as the net effect can be the same or greater than doing a full postback.

A further serious issue for modern web pages is the abstraction from HTML, as this hinders accessibility, browser compatibility, and integration with JavaScript frameworks like JQuery and PrototypeJS [4]. Of lesser importance to this case study, the postback model makes it harder for search engines to rank ASP.NET pages high.

2) ***MVC*** – The Model-View-Controller (MVC) architectural pattern was first proposed by Trygve Reenskaug in the late 1970s (the earliest source available is [5] but MVC was not publicly documented until 1988 [6]). It was first used in Smalltalk [7] and is an effective approach for supporting multiple presentations of data. Users can interact with each presentation in a style that is suitable to the presentation. The data to be displayed is encapsulated in a model object and each model object may have a number of separate view objects associated with it, where each view is a different display representation of the model. Each view has an associated controller object that handles user input and device interaction. MVC was devised to target desktop applications, but because of its relatively loose formulation it was easily adapted for the Web. MVC (or Model 2 using the Sun Microsystems terminology [8]) is now used widely in web frameworks (e.g., ASP.NET, Django, Ruby on Rails, Code Igniter, Apache Struts, JavaServer Faces). In Web MVC (which differs somewhat from traditional MVC), a model encapsulates application data in a way that is independent of how that data is rendered by the application. The view accepts some number of models as input and transforms them into appropriate output that will be sent to the browser. The controller connects the models and views, typically by gathering model data and sending it to the view for rendering. The view accepts data as input and produces a string as output, which may include information about its type (e.g., HTML, XML or JSON). After being manipulated by some post-processing filters, the string is sent directly to the browser. Because the view's output is treated as an opaque string, it is difficult for the framework to reason about the structure of the content. These views are complicated by the need to provide both Ajax and non-Ajax versions of a site [9]. In ASP.NET, MVC is implemented as shown in Figure 1(a).

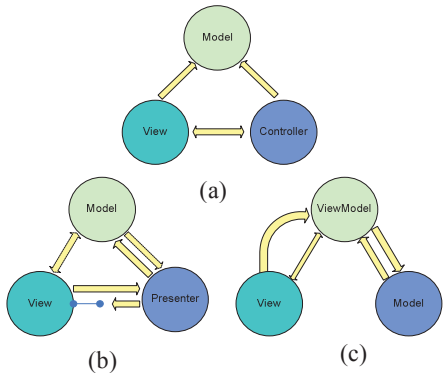

Figure 1: MVC Architectures: (a) Model-View-Controller; (b) Model-View-Presenter; (c) Model-View-ViewModel

In addition to managing complexity, the MVC pattern makes it easier to test applications than it is to test Web Forms. For example, with Web Forms a single class is used both to display output and to respond to user input, which when testing has to be instantiated along with all its child controls and additional dependent classes. Moreover, tests in Web Forms require a Web server. In contrast, the MVC framework decouples the components and makes heavy use of interfaces, which makes it possible to test individual components in isolation from the rest of the framework. The loose coupling between the three main components of an MVC application also promotes parallel development. For instance, one developer can work on the view, a second developer can work on the controller logic, and a third developer can focus on the business logic in the model.

A variant of MVC is the Model-View-Presenter (MVP) pattern [10], as shown in Figure 1(b). In MVP, the Presenter has the same responsibilities as MVC's Controller, acting as a mediator between the view and the model. It receives user input requests from the view and evokes changes on the model in response. The Presenter is able to query the view for data but to enforce separation of concern (SoC), the presenter is decoupled from the view by holding a reference to the view's interface rather than its implementation [11] [12]. Fowler describes a different approach for achieving SoC called the Presentation Model [13]. This pattern is similar to MVP in that it separates a view from its behavior and state and introduces a Presentation Model that is an abstraction of a view.

A further variant of MVC is the Model-View-ViewModel (MVVM) design pattern for Microsoft's Windows Presentation Format (WPF) [14], as shown in Figure 1(c). The MVVM pattern is a more specific version of the Presentation Model pattern [21]. MVVM also separates the view from the logic. However, unlike Controllers in MVC (Figure 1a) and Presenters in MVP (Figure 1b), an MVVM ViewModel has no awareness that a view even exists [15]. The ViewModel is an abstraction of the view but does not need a reference to the view like MVP does. The view uses the ViewModel as a data context and binds properties to fields in the ViewModel, providing a very loosely coupled design. This separation allows a graphics design team to focus on the view while a software development team can focus on implementing a stable and good ViewModel. As the ViewModel does not have to have a reference to the view, the logic can be tested without the view and it is also easy to make different views for GUI evaluations and compare them without changing the ViewModel. Note, Esposito and Saltarello [16] regard MVVM as the same pattern as Fowler's Presentation Model.

Zeller and Felton [9] introduce a stateless, framework-agnostic web application development style, which they call SVC (Selector-based View Composition) (SVC). With SVC, a developer defines a web page as a series of transformations on an initial state where each transformation consists of a *selector* (used to select parts of the page) and an *action* (used to modify content matched by the selector). SVC applies these transformations on either the client or the server to generate the complete web page. The authors contend this approach has two advantages: (i) SVC can automatically add Ajax support to sites, allowing developers to write interactive web applications without writing any JavaScript; (ii) developers can reason about the structure of the page and produce code to exploit that structure, increasing the power and reducing the complexity of code that manipulates the page's content.

There are many other approaches to SoC. Presentation-Abstraction-Control (PAC) [17] in which the UI is formed by a tree of agents for each of the three components (Presentation, Abstraction and Control). In Naked Objects [18], a UI is automatically generated from the model by analyzing the model interface using Java's reflection features. As a result, the model must contain all of the application domain logic. On the other hand, in Visual Proxy [19] the model/view separation is abandoned. While the model and view objects are still separate objects, they are implemented within the scope of a single class. The model and view layers are tightly coupled, rather than decoupled. Holub argues that the purpose of a model is to provide services to the view and if they are separated, the model cannot provide all the services for the view.

IV. TECHNOLOGY PLATFORM

CC Technology has a proven history in the use of Microsoft development tools and therefore it was logical to deliver the original system using ASP.NET Web Forms which was the prevalent Microsoft technology in 2004 when the solution was implemented. The Microsoft Ajax Control Toolkit was implemented to limit the amount of postbacks needed to the server. For database connections a custom ADO.NET entity generator connects to a SQL Server database. This platform has worked well, the technologies interact successfully and developers can develop and maintain a web-based solution without having detailed low-level web knowledge.

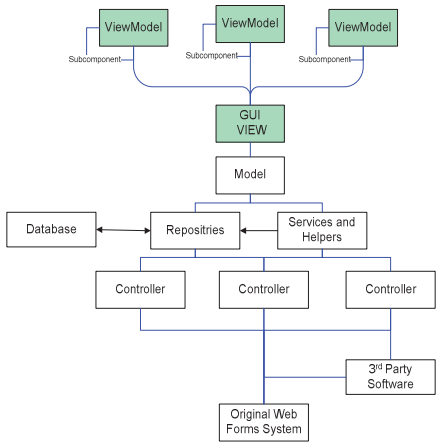

Figure 2: New MVDVM Architecture

The new component-based approach uses what we have named an MVDVM (Model-View-DynamicViewModel) architecture. The MVDVM architecture is an MVC-based architecture that is heavily influenced by the MVVM (Model View View-

Model) architecture, as Figure 2 shows. It contains a set of view-models and handles each one in a similar way. The major difference between the MVVM and MVDVM architectures is that the latter model dynamically builds and persists the view-models at runtime rather than having statically designed view-models, as in MVVM. The architecture is extremely powerful because of the ability to have encapsulated components (view-models) that persist themselves, thereby requiring no code to save and load components, producing an architecture that is extremely extensible. Each component that is added has no dependency or relationship to other components, allowing a separation of concerns and removing the risk of breaking other components when introducing new ones. By having this ability the only development that has to occur is writing new view-models. The view-models' logic and behaviour are captured in the view, which means that they can be updated or created without the need to compile. This in turn allows role-based logic to be performed on smaller subcomponents than would usually be possible. The view-models can be any user control such as text boxes, drop down lists or more complex composite user controls with contained business logic. A component can also seamlessly interact with other non-MVDVM systems and other databases meaning that saving and loading is not limited to a component's own data. The architecture allows the user to specify at runtime HTML to render each individual component to multiple document types to allow hard copies of forms. The difference between what the MVDVM architecture offers from other form designer tools and architectures is that it has no bounds or limitations as to what the components can do, other than what the .NET framework offers. The entire framework is self contained, which allows seamless integration with other architectures and systems. The scalability of controls and ease of extensibility make this architecture a good alternative to the web forms implementation.

The architecture is also advanced through use of client-side logic in JQuery components. As JQuery is now part of Microsoft's release with MVC, the integration in the development environment is seamless and therefore easy to use. Having JQuery allows quicker and more efficient behaviour and postbacks than was previously possible.

The final major change to the technologies used was the move away from the company's own entity generation tool for Database access. A repository pattern was implemented into the software so that at any time we could change the database connection technique without consequence. Initially Microsoft's Entity framework was evaluated. However, due to the early version of the software it was decided that the more established and Nhibernate model should be used.

V. Test Platform

To ensure accurate measurement of the performance of the original Web Forms and the new MVDVM architecture a common set of tests were developed. The tests were performed under the same situations and with the same metrics. A number of standard web pages in each system were tested with single users and also with increasing number of users (load testing). Both tests resulted in page load speed, number of pages per second and database information being obtained.

An accurate and consistent set of results was achieved by running a dedicated environment comprising a LAN, a test client containing load testing software, a web server running an instance of the forms software and a database server. To ensure that hardware performance was not compromising the results, the memory and CPU usage were monitored on each computer to ensure they stayed within 60% utilization. MS Visual Studio 2010 Ultimate Edition Load testing suite was used to generate relevant graphs and performance data.

VI. Server Performance

Individual tests were carried out on both architectures. The test cases used pages on each system with the same function and content, albeit with different implementations.

Area	Page Load Time (Average(seconds))	Time to receive first byte (seconds)
Opening a form	0.413	0.145
Financial page	1.361	1.113
Standard page	0.372	0.030
Saving form (including redirect)	0.635	0.588

Figure 3: MVDVM Page Times (in seconds)

Area	Page Load Time (Average)	Time to receive first byte
Opening a form	1.526	0.940
Financial page	1.556	0.599
Standard page	1.744	0.668
Saving form (including redirect)	0.656	0.114

Figure 4: Web Forms Page Times (in seconds)

The performance results in Figures 3 and 4 clearly show that the MVDVM architecture is faster on an individual load. It must be noted that there is a change in logic between the two solutions. The MVDVM application forms bind the models dynamically on every page load. Thus for every load and page exit data is read and written to the database. The Web Forms

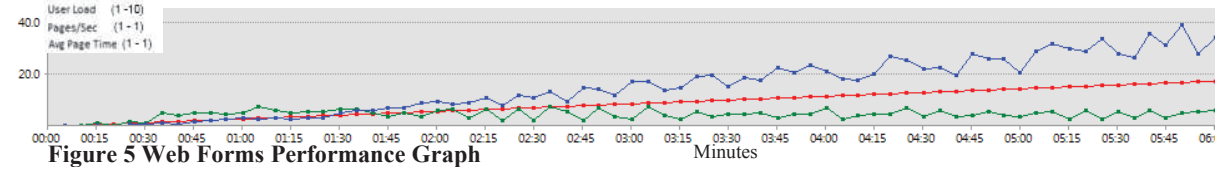

Figure 5 Web Forms Performance Graph

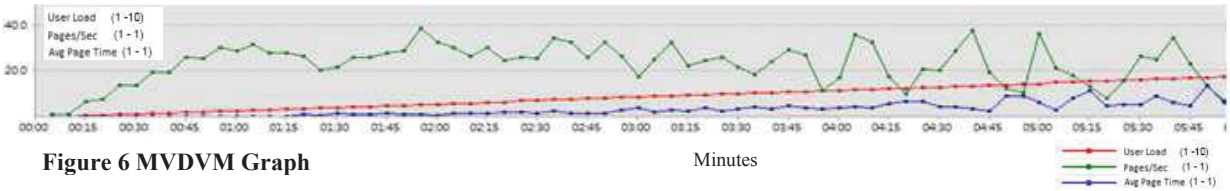

Figure 6 MVDVM Graph

solution does not write to the database until a user hits submit, which may be after n*page visits. This is reflected in the load times for the financial page. This is a complex page where hundreds of requests are being sent to the database. Although the MVDVM is still faster for this page the number of connections is the reason the difference is not as substantial.

The single tests are a good indication of the efficiency of each architecture. However, live systems are characterized by uneven and high loads. For a production system the number of concurrent users could be in the hundreds. Load testing was carried out on the same pages as noted in Figures 3 and 4. The resulting graphs are shown in Figures 5 and 6 (Vertical axis represents number of users, number of pages per second and average page load per second and all using corresponding ranges outlined in figures 7 and 8) . The graphs show that the MVDVM out performs the Web Forms by a large margin. Each test began with one simulated user running a web test. This proceeded through each page in a defined order. Every ten seconds five more users were added to the current list of users. The results are shown in Figures 7 and 8 for each run of the test.

	Range on graph	Min	Max	Avg
User load (num users)	1000	1	176	88
Pages/sec (seconds)	10	0	7.8	4.53
Ave page load (seconds)	100	0.25	39.7	16.2

Figure 7: Web Form Graph Averages

	Range on graph	Min	Max	Avg
User load (num users)	1000	1	176	88
Pages/sec (seconds)	10	1	39	23
Ave page load (seconds)	100	0.0.35	13.9	3.04

Figure 8: MVDVM Graph Averages

Figure 5 shows that the average page load speed increases in relation to the number of users. As the number of users increases the number of pages loaded per second severely decreases.

The MVDVM results are quite different. The pages per second start very high and remain so throughout the test. At the points of lowest performance where the graph dips the response times are still acceptable for an end-user. These dips occur where a large number of users (more than 100 users) tried to call an action concurrently. This is a quirk of using a test suite and the phenomena are unlikely to occur in production at this usage level. Usually in this case it would be the hardware performance that would fail or cause performance issues. The page load speed also remains very constant and, apart from the dips, remains lower than one second for each page throughout the test.

VII. Client Performance

Client performance can be characterized by the download time for the pages and of the rendering time.

Figure 9 shows the details for an average page in the performance tests. The details emphasize the earlier comments about how large or inefficient the HTML can become due to the View State and the ASP.NET automatically generating HTML. The Javascript size is also very high as the previous forms were rendering pure Javascript. The Javascript was not compressed, which is also inefficient, causing larger page sizes.

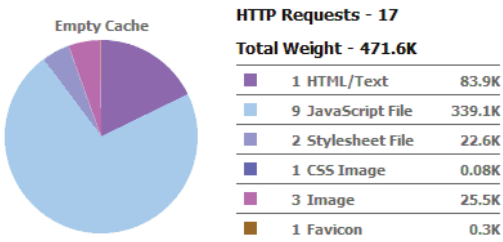

Figure 9: Web Forms Average Page Detail

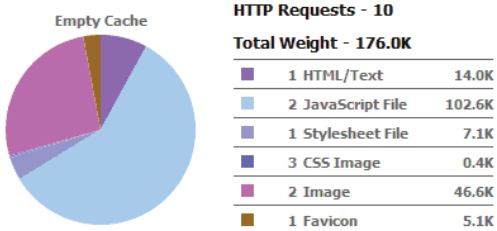

Figure 10: MVDVM Average Page Detail

The detail of an average MVDVM page in Figure 10 shows that the page size is smaller. The ability to control the HTML and use JQuery to write minimal amounts of code has resulted in a reduction of the page size from 471k to 176k.

The HTML code in the Web Forms output is controlled by ASP.NET and is not standards-compliant, whereas the MVDVM output is controlled by the developer. This control allows the developer to address client performance issues, which Google describe as 5 performance factors [20]: (i) optimizing caching, (ii) minimizing round-trip times, (iii) minimizing request overhead, (iv) minimizing payload size, (v) optimizing browser rendering. The MVDVM solution improves on each of these factors through the communications and page content.

VIII. Database Performance

A statistical analysis of the database transaction times compares the performance between the two architectures. The results are split into two parts: using all the data and using only the data that had duration times greater than zero. The results show every query that happened when the tests were run. Because of this there are many light weight queries that had durations of less than 1 ms, these show as 0ms durations.

A. Analysis using all of the data

Using the Web Forms architecture, reads were performed an average of 48.60 times (SD = 1061.05) with a range of 0 to 32,350 whereas using the MVDVM architecture reads were

performed an average of 24.54 times (SD = 283.12) with a range of 0 to 6,440.

Using the Web Forms architecture writes were performed an average of 0.0145 times (SD = 0.30) with a range of 0 to 17 whereas using the MVDVM architecture writes were performed an average of 0.0093 times (SD = 0.20) with a range of 0 to 22.

Transactions using the Web Forms architecture had an average duration of 1.01 ms (SD = 48.06) with a range of 0 to 9,157 ms where transactions using the MVDVM architecture had an average duration of 0.1223 ms (SD = 2.04) with a range of 0 to 93 ms.

Paired samples t-tests indicated that the MVDVM architecture performed significantly less read commands ($t(65,527) = 5.607$, $p < 0.000$), significantly less write commands ($t(65,527) = 3.733$, $p < 0.000$) and took significantly less time to perform read and write commands ($t(65,527) = 4.729$, $p < 0.000$) than the Web Forms architecture.

B. Analysis using only the data that had duration tims greater than zero

Using the Web Forms architecture reads were performed an average of 2,047.19 times (SD = 6,955.46) with a range of 0 to 32,350 whereas using the MVDVM architecture reads were performed an average of 990.40 times (SD = 1,664.82) with a range of 0 to 6,440. Using the Web Forms architecture writes were performed an average of 0.4087 times (SD = 1.63) with a range of 0 to 17 whereas using the MVDVM architecture writes were performed an average of 0.1095 times (SD = 0.879) with a range of 0 to 22.

Transactions using the Web Forms architecture had an average duration of 47.08 ms (SD = 324.75) with a range of 0 to 9,157 ms where transactions using the MVDVM architecture had an average duration of 5.70 ms (SD = 12.74) with a range of 0 to 93 ms.

Paired samples t-tests indicated that the MVDVM architecture performed significantly less read commands ($t(1,406) = 5.339$, $p < 0.000$), significantly less write commands ($t(1,406) = 5.996$, $p < 0.000$) and took significantly less time to perform read and write commands ($t(1,406) = 4.764$, $p < 0.000$) than the Web Forms architecture.

IX. CONCLUSION

This paper has presented a comparison of two web architectures used in process-heavy web applications. The first, Web Forms, is an established standard Microsoft approach and the second, MVC, is a relatively recent approach gaining some acceptance in the development community. This paper has proposed a variant of MVC, called MVDVM and has demonstrated that this architecture delivers performance benefit over the traditional Web Forms based architecture. The performance has been shown to be improved at the database, web server and client. With each of the tests it has been shown to be faster or more efficient.

The results of the case study have proven that under these circumstances the performance benefits are large and the move to an MVC architecture are justified.

Abstract— **Many companies look for in a implementation of a Improvement Program based on software maturity models as a way of increasing their product's quality. For knowing their maturity level, they have to submit themselves for an assessment based in models. To be assessed, a company spends some time into the definition and implementation of the necessary software processes. However, after the assessment most of the companies have some difficulties to continue the execution of some activities of the processes or leave this execution. This paper proposes the analysis of the continuity of software processes into the companies assessed in MPS.BR, the Brazilian Maturity Model, identifying factors that help or make difficult to maintain the adherence of those process to the model and the easiest practices to be maintained in execution, after the company has been assessed. With this work, we hope to make easier for consultants to implement the processes, specially those that have more percentage of leaving or difficulties.**

Keywords-Software processes; Maturity Model

I. INTRODUCTION

The software's importance grows every day and as the quality of the software products is so closely related to the quality of processes that are used to develop them, invest in the processes quality became very important to the software organizations [14].

Among these, the MPS.BR, the Brazilian Maturity Model, fits perfectly into a proposal of improving the quality of software produced in Brazil. According to [10], the program MPS.BR, launched in December 2003, aimed at improving software processes of micro, small and medium size companies.

The reference model, MR.MPS, contains the requirements that the processes of organizational units must meet to comply with the model.

However, like others maturity models, after the assessment companies have trouble to keep their processes adherent to the reference model.

Therefore, it is important to know the main difficulties to maintain such compliance.

This paper presents the results of a survey carried out with professionals involved at MPS.BR, which the objective was to find out the factors that influence positively in the continuity of the processes execution and the practices of the Project Management and Requirement Management processes considered more difficult to maintain the execution on new projects after the assessment.

This paper is organized in four sections. Section 1 is the Introduction. Section 2 presents the literature review. Section 3 presents all about the survey applied on assessed organizations. The section 4 presents the quality research using Grounded Theory. Finally, section 5 concludes the paper and presents further works.

II. LITERATURE REVIEW

As a starting point, the literature review was performed using some steps of systematic review, a kind of secondary study, widespread by [3], in order to identify factors that may influence the continuity of the software processes execution. We set a protocol for implementation of a systematic review based on the protocol developed by [13]. We used tools such as spreadsheets to supporting the registration and analysis of the data collected.

Initially, the literature review was conducted in the main papers published in relevant symposium and workshops to the software quality area in Brazil.

According to [11], [2], [6] and [12], the level of formalization of organizational structure is one factor that can facilitate the implementation of a process improvement program.

For example, [11] observed that the formalization of organizational structures in areas, functions, skills and responsibilities demonstrates a level of organization that allows a simple way to visualize how the company is organized to meet their goals. The formalization should not be understood, in this case, as bureaucracy, but as a mean to facilitate the communication into the organization. The higher the level of organization and formalization of organizational structure, the lower is the risk of short-term view on the implementation of process improvement.

This factor can also affect positively the maintenance of quality, because a company with a more formal organizational structure has the ability to get sucess and maintain awareness of their roles, responsibilities and areas.

Another factor was the level of tools and techniques for reuse of knowledge utilization. [6], [2], [4] and [12] said that a company that wants to improve the maturity of their processes needs to take advantage of existing knowledge in the organization. It might be supported by a knowledge management environment. From the reuse of knowledge the organization can implement improvements to the software processes and accelerates the implementation and execution of them.

This factor is also relevant to the continuity context, because the company that has tools and techniques to support the reuse of knowledge can more easily keep alive the knowledge of the implemented processes, encouraging

their use and keeping clear the need of their activities and tasks. [2] [6] and [12] described the use of return of investment (ROI) indicators as having a strong influence in the maintaining of a Improvement Program. [12] said that during the implementation of the processes, the team clearly felt the need for a mechanism to recognize the benefits associated with improvement efforts. It serves to motivate the members to continue the improvement of the processes aiming to achieve higher levels of maturity. [6] also advise organizations to analyze, often, the ROI achieved with the improvement of software processes, making them visible, because it decreases the risk of stopping the process of continuous improvement.

Others factor were: the level of available resources for the maintenance and improvement of the processes and the commitment of the high managers with the Improvement Program.

According to [6], a company that wants to continually improve their processes needs to provide the necessary resources, because it depends largely on investment in personnel, support tools, as well as in specialist consultants. Thus, the existence of committed high managers, providing the appropriate support, aids the company to achieve continuous improvement of their processes. High managers that keep the team motivated and the processes properly supported will likely remain adherent to the model, obtaining a continuous improvement of the processes' quality [8] [4].

One of the factors cited was the level of commitment of the Improvement Program coordinator to the implementation and improvement of the processes. [11] said that the ability of the company's SEPG (Software Engineering Process Group) to conduct the Improvement Program affects directly the performance of the project.

In some companies, it was found that the attitudes of the SEPG may difficult the monitoring of the activities related to the implementation and maintenance of the processes execution. [11], [6] and [5].

The level of the formalization of communication is other factor described by [6] and [8]. [11] said that the higher the level of organization of communication in the organization, the lower the risk of failure in interpretation and understanding the requirements to implement the activities.

To maintain the continuous improvement of the processes and adherence to the maturity model, also depends of the formalization of communication in the level of projects and inside of the Improvement Program.

There are also two factors that have similarities and are cited by [6], [8] and [9], which are: the level of knowledge about software processes and software quality, and the level of use of software engineering methodologies and concepts.

To [11], a high level of knowledge and understanding of the collaborators, mainly opinion makers, on concepts related to software quality is very important to evaluate and to understand the impact that an Improvement Program can represent to the organization. The higher the level of knowledge about concepts related to software quality and to the maturity model, the lower the risk of underestimating the resources required to the Improvement Program. [5] said that the implementation of software processes involves knowledge-intensive activities. It means that those involved in software process improvement initiatives must have deep knowledge of software engineering and must be able to use this knowledge to guide the implementation of the processes.

The company that has knowledge about software quality and software engineering, distributed among its employees, has a better chance of maintaining their activities adherent to the maturity model.

Other factor which influences the maintenance of the Improvement Program is the level of resistance to cultural changes. The comfort zone that exists before the implementation of the processes and during the maintenance of the Improvement Program is a very important barrier.

The human being has a natural resistance to changes. Whenever the organization leaves the comfort zone, some employees opposed the execution of required tasks and the use of necessary methods and techniques [6]. [4] highlighted another important factor: the level of investment in training on software processes. [11], for example, said that difficulties related to cultural changes can be mitigated with training, lectures and meetings in complementary disciplines.

A continuous investment in training facilitates the continuity of the adherence to maturity models by improving the knowledge related to software quality and software engineering.

One factor that can make difficult the benefits of training initiatives is the high turnover of human resources, because it generates high cost and the knowledge cannot be used to support the Improvement Program [8].

According to [6] and [11] an important factor to the continuity of the Improvement Program is to deal with it as a project.

In fact , [11] said that as an Improvement Program has the philosophy of a project it should be planned and monitored as any software development project, including setting marks/checkpoints and constant monitoring of progress and costs involved in this initiative.

Another factor found in the literature is the importance of consultants to obtain and maintain the software processes adherence to the maturity model.

For [6], the importance of consultants becomes clear because many of them has the opportunity to participate in others organization assessments as a consultant or as an auditor and so they know exactly what is required and the reality of others companies (benchmarking). They observed that a well qualified consultancy facilitates the definition of better business goals to the company and a more adherence to the maturity model.

However, it should be highlighted that the continuity of the Improvement Program depends of how the consultants

are able to teach the collaborators to execute their activities and how the knowledge becomes a real asset of the organization, that is, they can leave and the software process culture remains on the company.

Finally, another factor was the level of utilization of support tools. The more support of tools, lower is the risk to neglect the practices required by the maturity model [11] [2].

III. SURVEY

A. Survey's Methodology

The next step in the research was the completion of a questionnaire to identify the level of influence of factors, identified in the literature review, to maintain adherence to the software process maturity model.

We defined a questionnaire divided into three parts: the first was a set of objective questions, which sought to characterize the professional respondents, the second part listed the factors that influence the maintenance of software processes, according to the literature review, and was asked to respondents how important were the factors for the maintenance and implementation of the Improvement Program. Respondents could add others factors of significance. Finally, the third part of the questionnaire reported the expected results (practices) of processes evaluated at the level G of MPS.BR, which are the Project Management and Requirements Management, seeking to ascertain the more difficult activities to be continued after the assessment has been performed. Participants were encouraged to justify their evaluation if they considered important for his response.

The questionnaire received 27 responses and the profile of respondents was: 44% of them had master degree and 22% had finished the university. 40% had 6-9 years of experience in software quality and 30% had 3 to 6 years. 48% had been a project manager for five or more projects and 28% had managed 3-5 projects. 37% worked as project management for 1-3 years and 25% from 3 to 6 years. 66% had already participated in a software engineering process group, 40% were certified implementers, 33% were consultants and 29% were certified auditors of MPS.BR. 50% of respondents participated in one or two assessments and 30% participated in five or more.

B. Analysis of Results

To help the analysis, a table was built to register the relevance's degree of each factor, the degree of difficult to continue the execution of each practice of the Project Management and Requirement Management processes, after an assessment.

The factors were analyzed using the following scale: 0 - No relevance; 1 - Low relevance, 2 - Reasonable relevance; 3 - High relevance, 4 – Indispensable.

TABLE I. THE LEVEL OF FACTORS' INFLUENCE

Factors	0	1	2	3	4
F01-Organizational structure known by the employees	3,7%	18,5%	33,3%	25,9%	18,5%
F02-Effective structure for communication	0%	0%	22,2%	29,6%	48,1%
F03-High level of knowledge about content related to improvement process and software quality	0%	0%	34,6%	38,4%	26,9%
F04-High level of maturity of the organizational culture to use software engineering methods and techniques	0%	0%	18,5%	44,4%	37,1%
F05-High level of automated tools utilization in supporting the software process	0%	11,1%	14,8%	37,1%	37,1%
F06- Low level of resistance to changes	0%	0%	18,5%	44,4%	37,1%
F07-Commitment of project managers with the Improvement Program	0%	0%	7,4%	11,1%	81,4%
F08-Utilization of indicators that demonstrate the return obtained with the processes' execution	3,7%	0%	14,8%	48,1%	33,3%
F09-Provision of the necessary resources by the High Managers	0%	0%	0%	40,7%	59,2%
F10-Utilization of knowledge management approaches and tools	0%	18,5%	59,2%	22,2%	0%
F11-Guidance of an external consultancy	0%	7,6%	26,9%	50%	15,3%
F12- Effectiveness of the consultancy, that help the company to implement the software process, in transform the SEPG in an autonomous group and with a high level of knowledge	0%	0%	7,4%	48,1%	44,4%
F13-Low level of staff turnover	0%	0%	44,4%	44,4%	11,1%
F14-Maintanance of a strong and effective policy of trainings	0%	3,7%	29,6%	37,4%	29,6%

According to Tab. 1, the factors "F07" and "F09", "F12" and "F02" were considered the most relevant for the continuous execution of software processes, after an assessment. This result corroborated with the literature review findings.

However, the factors "F01" and "F10" were considered as the less important ones for the maintenance needs.

The third part of the questionnaire aimed to evaluate the practices (expected results) of the level G in MPS.BR, corresponding to the processes: Project Management and Requirements Management.

As we said above, each practice (expected result) was evaluated in relation to the level of difficulty to continue to perform it, after a MPS.BR assessment. For this, the following scale was used: 1 - Difficult to continue; 2 - Reasonable difficult to continue; 3 – Easy to continue. In cases when a respondent selects "1 - Difficult to continue" for the practice the questionnaire suggested the participant to justify it.

The Tab. 2 presents the obtained results for the practices (expected results) of the Project Management (PRM) process.

TABLE II. RESULTS OF PRM PRACTICES

Practices (Expected results)	1	2	3
PRM1 – The work scope for the project is defined	0%	6%	94%
PRM2 - The project tasks and work products are dimensioned using appropriate methods	6%	50%	44%
PRM3 – The model and the project's life cycle phases are defined	0%	13%	88%
PRM4 – The effort and cost to perform the tasks and work products are estimated based on historical data or technical references	50%	19%	31%
PRM5 – The budget and project schedule, including the definition of milestones and checkpoints are established and maintained	25%	44%	31%
PRM6 - Project's risks are identified and their impact, likelihood and priority to treatment are determined and registered	25%	38%	38%
PRM7 - The human resources for the project are planned considering the profile and knowledge needed to perform it	19%	56%	25%
PRM8 – The resources and work environment needed to run the project are planned	6%	44%	50%
PRM9 - The relevant data of the project are identified and planned considering collection, storage and distribution aspects. A mechanism is established to access them, including, if pertinent, issues of privacy and security	38%	31%	31%
PRM10 – A general plan to run the project is established with the integration of specific plans	6%	19%	75%
PRM11 - The feasibility of achieving the goals of the project , considering the constraints and resources available, is evaluated. If necessary, adjustments are made	25%	38%	38%
PRM12 - The project plan is reviewed with all stakeholders and the commitment to it is obtained	25%	31%	44%
PRM13 - The project is managed using the project plan and other plans that affect the project and the results are registered	13%	44%	44%
PRM14 - The involvement of stakeholders in the project is managed	19%	44%	38%
PRM15 - Reviews are carried out in project's milestones according to the planning	6%	69%	25%
PRM16 - Record of identified problems and the results of the analysis of relevant issues, including critical dependencies are established and treated with stakeholders	25%	38%	38%
PRM17 - Actions to correct deviations from the planning and to prevent the recurrence of identified problems are established, implemented and followed until its conclusion	25%	38%	38%

The practices (expected results) "PRM4" and "PRM9" were considered as the most difficult to be performed after the assessment.

According to one of the participants the PRM4 is hard to be continued because the maintenance of a database with reliable historical data is a great challenge and is fundamental to this practice (expected result). The difficulty to maintain such a database can make the involved collaborators use only subjective opinions to estimate the project's effort and cost.

The results obtained for the practices (expected results) of the Requirements Management (REM) process is presented in Tab.3.

TABLE III. RESULTS OF REM PRACTICES

Practices (Expected results)	1	2	3
REM1 - The requirements are understood, evaluated and accepted by the requirement suppliers, using objective criteria	0%	38%	63%
REM2 - The commitment of technical staff with the approved requirements is obtained	19%	25%	56%
REM3 - The bidirectional traceability between requirements and work products are established and maintained	56%	38%	6%
REM4 - Reviews in plans and work products of the project are performed to identify and correct inconsistencies in relation to requirements	25%	38%	38%
REM5 – Changes to requirements are managed throughout the project	31%	38%	31%

The practice (expected result) for "REM3" was considered one of the three expected result most difficult to be continued by the respondents. For one of them, a consultant, this result is due to the lack of automated tools that can ensure the bidirectional traceability. The tools may facilitate a little more the continuity of this practice.

IV. QUALITATIVE RESEARCH USING GROUNDED THEORY

A. Grounded Theory Research Methodology

Grounded Theory is a qualitative research method that uses a set of systematic procedures for collecting and analyzing data to generate, develop and validate substantive theories about phenomena, essentially, social, or broad social processes [15]. Application of Grounded Theory in the areas like software engineering and process improvement is even more sparse, as said [16]. But some studies have been highlighted.

Their authors, Glauser and Strauss, argue that there are two basic types of theories: the formal and substantive, as they say [17]. The first type consists of conceptual and comprehensive theories, while the second type is specific for a particular group or situation and is not intended to generalize beyond their substantive area.

According to the line proposed by Strauss, GT (Grounded Theory) is based on the idea of encoding (coding), which is the process of analyzing the data. When coding, concepts are identified (or codes) and categories. A concept (or code) names a phenomenon of interest to the researcher, abstract an event, object, action, or interaction that has a meaning for the researcher [18]. Categories are

groupings of concepts together in a higher degree of abstraction.

The encoding process can be divided into three phases: open coding, axial and selective. The open coding involves breaking, analysis, comparison, conceptualization and categorization of data. According to [15], in the early stages of open coding, the researcher explores the data scrutinizing what you believe relevant due to the intensive reading of texts. In the phase of open coding, incidents or events are grouped into codes by comparing incident-incident.

Also the open coding is performed to create categories that add the codes to reduce the number of units that the researcher will work [19].

After the identification of conceptual categories for open coding, axial coding examines the relationships between categories that make up the propositions of substantive theory [15]. The relationships between the codes can be defined by the researcher. As proposed by [18], these relationships form what the authors call as paradigm: causal conditions, players, strategies and consequences of actions / interactions.

Finally, selective coding refines the process, identifying the core category theory, with which all others are related. The core category should be able to integrate all the others and express the essence of the social process that occurs between those involved. This core category can be an existing or a new one [19].

B. Results Analysis of Grounded Theory

In this qualitative study, were performed three stages of coding proposed by grounded theory, it was possible to find the set of theories to answer the question under study (what influences the continuation or the abandonment of processes compliant with the model after an evaluation?).

From interviews with members of the SEPG of assessed companies, responses were transcribed into documents which collected their quotes. We did not use seed categories - an initial set of codes to begin coding has been created in vivo codes from the text of the questionnaires. In some codes, the quotes are changed to facilitate reading and to collect more citations. These changes have led to codes found that resembled with those components of critical success factors of [16].

The step of open coding and axial is overlap and come together because of the interactivity of the process. The codes and categories identified gone through successive revisions, of which 28 were produced codes associated with three categories and two subcategories, and all under a central category.

The core category called "Factors that influence the maintenance", and this has (using the notation "is a part of " as suggested by [20]), the following categories "Social and Cultural", "Technical", "Resources and Commitment". The Figure 1 presents, graphically, this organization.

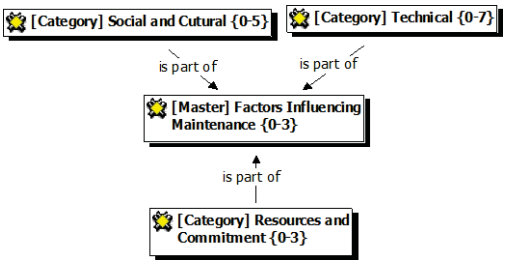

Figure 1. Axial Coding Categories.

As a memo, during the search were found many citations that reported results of a company with a presence and the with a absence of the same factor. Thus, to avoid creating two categories show that the presence and absence of them in companies realities, it was decided to add these quotes in just one factor, which would be named on the presence of the same, but would add that the quote also reported their absence. And you are using the notation "Evidence of difficulty" for when they were found only quotations that show the influence of a negative factor related to maintenance.

In several, the category with more quotes aggregated is one that combines technical factors, in other words, is the one that has a direct connection with the model MPS.BR. Two subcategories were used in those categories, to agregate the coding process areas, given as the more difficult to keep the outcomes of the G level. Figure 2 shows the connection of these codes with the category "Technical" through the use of the notation "is a" according to [20].

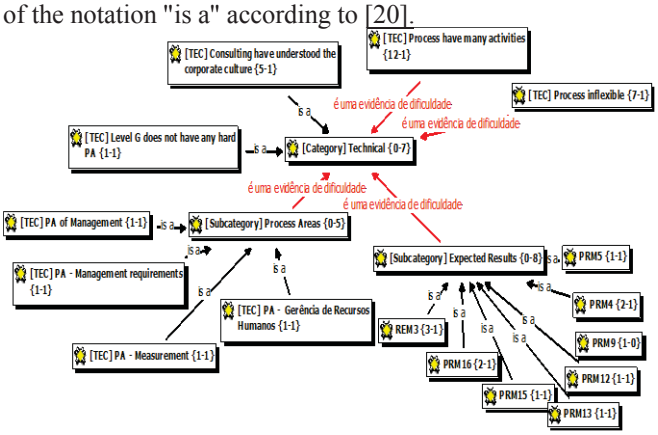

Figure 2. Category Factors "Technical".

In this category codes that stand out are "Process has many activities", “Process inflexible", that complain about the bureaucracy and about the inflexibility of the model. One of the respondents cited "If it were a process more flexible and it had not so many activities, it would be an easier process for the company to keep". Another that stands out is the code that denotes a bidirectional traceability requirement, by the model in GRE3 expected outcome, thus confirming what was said in our quantitative research.

Another category coding was found in the "Social and cultural", which collects the social and cultural factors that may influence the maintenance process of acceding to the model as follows in Figure 3.

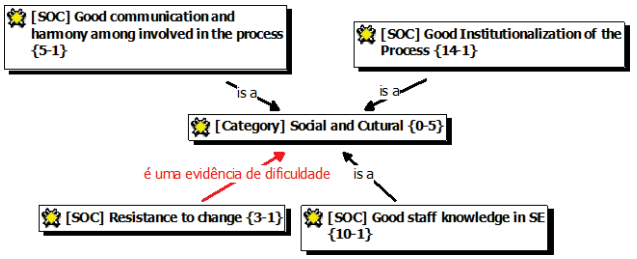

Figure 3. Category Factors "Social and Cultural".

The code that stands out in this category is the "Institutionalization of Good Process", one respondent commented that to avoid abandonment of the processes is necessary to "Add the process and project management to the company's culture."

The last category involves the factors that mention the need for resources, be they personal, cost or time, or the need for commitment of members involved in the process, managers or senior management. Figure 4 represents the connection of these codes.

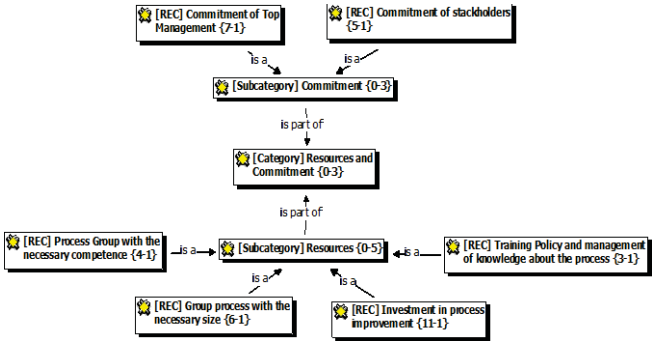

Figure 4. Category Factors "Resources and Commitment"

"Commitment of top management" was the code of this category that received more citations, confirming its importance as an influencing factor. Even the responses relating to this factor was mentioned that "top management commitment is one of the main factors that help maintain. The more committed to senior management, easier to maintain the process ".

V. Conclusion and Further Works

This work presented the result of a literature review, a survey and a qualitative research, using Grounded Theory, related to the difficulties that the software organization faces to maintain the adherence of their software processes to the maturity models, after the assessments.

The results corroborated with the literature findings, that is, the software organizations have a lot of difficulties to continue to perform some practices, considering the competitive scenario of the industry of software.

This work can be used by the software organizations to guide their actions to do not permit the abandon of some practices necessary to the adherence to the models.

As further works, we intend to increase the size of the sample and define a set of actions that may facilitate the implementation of the most difficult practices (expected results).

BDI agents to bridge cloud computing and end-users

Case study: An agent-based personal trainer to COPD patients

Kasper Hallenborg
Maersk Mc-Kinney Moller Institute
University of Southern Denmark
hallenborg@mmmi.sdu.dk

***Abstract*—Cloud computing is envisioned a dominant role in the future. Extensive amount of data are stored, applications running in the cloud, and globally accessible. However, users are not interested in observing and processing that amount of information. Thus, a mentalistic model that represents the user's goals could be integrated with the cloud to present processed extracts in a cognitively accessible way. Such an approach is presented with deliberative BDI agents both in the general and in a case study for an agent-based personal trainer for COPD patients.**

Keywords: BDI agents, cloud computing, integration, PHRs

I. INTRODUCTION

Personal/Electronic Health Records (PHR/EHR) is a perfect example for the use of cloud computing, where the multi-user / multi-role perspective, privacy, security, and accessibility issues are addressed, as both health-care professionals and you personally are involved. Clouds spawned from service-oriented architectures and semantic web services, which has approaches trying to abstract and increase flexibility of services, such as WSDL and OWL ontology. However, the composition of services must still rise from a set of basic action by the user [1]. For PHRs the heterogeneous set of users and the complexity requires medical information to be presented in a cognitively accessible way [2]. We propose a deliberative agent model based on the BDI architecture to bridge cloud-based services (SaaS) and pervasive services to the user. The model is applied in a case study for a home training of COPD patients.

II. AGENTS TO THE CLOUD

A. Limitations of a service based model

Traditionally, web services were defined as software systems designed to support interoperable machine-to-machine interaction over a network [3]. Even with semantic descriptions of the services (OWL-S), a service based model does not overcome the limitations in how users naturally will express the goals they want to achieve rather than the actions they wish to be performed [1]. Thus, several key aspects are important if user-centered cloud apps should provide intelligent services.

- *Locus of control* – design of applications must be user-centered and reflect the user's assessment of goals to be achieved.
- *Cognition* – pervasive applications should not rely on the user interaction in respect to current goals.
- *Adaptation* – information resources often reside in many systems (clouds) and needs to be combined either to be relevant or make sense for users.
- *Context* – environments are highly dynamic due to users' mobility and global accessibility.

B. Capabilities of deliberative agents

Semantic web services is built on the basis of synchronous remote procedure calls and has been preferred by industry over more abstract definitions and less strict approaches for agent technologies, which comes from asynchronous message passing architectures [1]. However, the goal-oriented agents have a lot more to offer than services founded in basic actions. From a modeling perspective the autonomous characteristic of agents and the architecture for deliberative agents, e.g. the BDI model, has a more natural mapping to a user-centered design. The BDI model has a very "mentalistic' notion for capturing user's preferences and goals [4], whereas services mostly are designed as information providers that needs further (mental) processing.

Goal-directed behaviors are the nature of deliberative agents, and goals can be abstractly described. Reasoning on percepts and other inputs is required, if user acceptance should be improved. Interoperability is central to web services, but despite profile specifications and dynamic service discoveries, web services are still relying on common standards. The agent community builds on knowledge representation and ontologies to abstractly describe content of messages, which improves the possibilities of adaptation across different systems.

III. THE AGENT MODEL

Deliberative agents extend the basic agents model given by Jennings and Woolridge [5] with knowledge representation and symbolic reasoning capabilities [6]. The locus of control is captured in terms of the autonomous characteristic of agents. A reasoning engine covers the need for cognition. Adaptation and context-awareness is well aligned with reactive and proactive behaviors of agents and their responsiveness in general. The BDI model by Rao and Georgeff [7] is the most applied architecture for deliberative agents. The scope of the demo and the presented model is to cover use of cloud computing as an information source. The operational logic of BDI agents was formalized by Rao with the AgentSpeak(L) language [8]. The BDI agent is given the tuple $\langle \mathcal{B}, \mathcal{D}, \mathcal{I}, \Pi \rangle$. Where $\mathcal{B}$ is the belief base, $\mathcal{D}$ is the desire base, $\mathcal{I}$ the intention base, and Π is the set of selection functions and plans, which are defined as practical rules in the form $\varphi \leftarrow \epsilon | \pi$. φ is the goal, π the concrete plan of action that should lead to the goal, and ϵ the event that triggers the selection function. The agent-cloud communication is covered by the social capabilities. Agents would either reactively observe changes in the cloud or proactively request or query the cloud. It corresponds to `subscribe`, `request`, and `query` FIPA protocols. The triggering events for a state change will

come from `inform` messages, that will trigger the selection function on the belief base, which formally is given by

$$\frac{S_{\mathcal{B}}(\langle \mathcal{B},\mathcal{D},\mathcal{I},\Pi\rangle)=\langle \texttt{inform},id,at\rangle}{\langle \mathcal{B},\mathcal{D},\mathcal{I}\rangle \rightarrow \langle \mathcal{B}\cup\{at\},\mathcal{D},\mathcal{I}\rangle} \quad (1)$$

Where *id* is the identifier of the agent and *at* is the predicates expressed in first order logic, as explained in [8]. In the deliberation engine of the agent it will consider the desire base if there are relevant plans that should be added to the intention base, and such a plan would be considered applicable if a unifier θ exists for the plan, so the plan is a logical consequence of the current belief base with respect to the event. Formally, we can describe it as an update to the intention base of the agent.

$$\frac{\langle \varphi,C\rangle\in\mathcal{D},\text{impact}(\beta,\varphi,start),\mathcal{B}\vDash C\theta,\mathcal{I}\nvDash\varphi\theta}{\langle \mathcal{B},\mathcal{D},\mathcal{I}\rangle \rightarrow_{\theta} \langle \mathcal{B},\mathcal{D},\mathcal{I}\cup\{\langle \varphi\theta,C,\pi\rangle\}\rangle} \quad (2)$$

where C is the commitment of the belief base, and $\text{impact}(\beta,\varphi,start)$ is evaluation of a change in belief base, β, that will lead to the desire of the plan φ being followed.

IV. A CASE STUDY

Healthcare systems are quite different around the world, especially between Europe and the US, but the need to store health related information and PHRs are universal. An overview of the system for the case study is presented in Fig. 1.

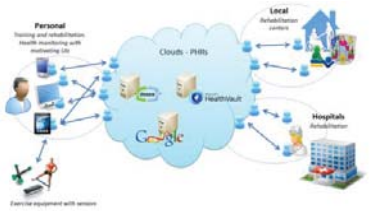

Figure 1: Overview of healthcare system with PHRs in the clouds

It is commonly known that the share of elders will double due to demographics changes and costs of healthcare services will explode. In particular expenses to chronic diseases, such as chronic obstructive pulmonary disease (COPD/COLD), diabetes, cardiovascular disorder and Alzheimer's. There were 726,000 hospitalizations for COPD in the US in 2000, and the cost of COPD is $32.1 billion [9]. Especially, for COPD patients can benefit from training. Due to breathing trouble they do not only get anxious while exercising, but also fear walking the neighbor (even if capable), which lead to social exclusion. Ideally, exercise training would be individual, customized, assisted, and supervised by physiotherapists. Unfortunately, such training sessions are only provided to a very few patient. Recent year of advancement in sensor technologies enables opportunities for monitoring training at home.

A. Our approach

COPD patients are no different than the rest of us – it is very hard to keep up the motivation for physical exercising, unless someone constantly motives you or the results/effects are very visual. Thus, we need a responsive and proactive feedback that can motivate to keep up the training. Not all COPD patients are capable of walking outside, so exercises at home are required for many patients. Exercise programs are provided by physiotherapists, and we are developing a prototype based on the Kinect camera that can verify exercises and stream data to a PHR Google Health account. Integration with Google Health is rather simple, as it is part of the Google Data Protocol. The API for the Kinect camera allows you to analyze the joint angles of the body so it can be compared to an exercise program. Fig. 4 shows the Kinect's view of joints in the body.

Figure 2: Kinect view of a body

Figure 3: Avatar

From the professional healthcare system the medical records and diagnose data of COPD is registered in the personal health records. However, as training programs are not directly supported in the Google Health the agent must reason on the extracted information and compare it to exercise plans in the desire base of the agent. The agent will update the belief base based on inputs that are received from the cloud according to (1). If the evaluation of the change in the belief base, enables a new plan to be followed it will be added to the intention base of the agent according to (2). The applicable plan will contain tasks to update the UI and feedback to the user. The prototype uses text-to-speech for an audio feedback, and we experiment with mimic software to create an avatar video. A snapshot of the avatar is shown in Fig. 5.

V. CONCLUSION

We have presented a BDI-based agent model to close the bridge between cloud computing and user-centered applications that aim to present rich and complex information from clouds in a cognitively accessibly visualization to the end-users. A prototype system is built for home training of COPD patients using extracts of information from the cloud to give motivational user feedback, so they continue training.

I. Poster Introduction: Cloud Engineering

The research in the area of Customer Relation Management (CRM) applied to two prototype studies on *learning* and *mobility* offers an opportunity to experiment new multimedia data management, data analysis, and distributed collaboration. Software engineering practices based on cloud technology techniques acquire from the Web what is needed for rapid prototyping and to satisfy the needs of customers for market validation of pricing policies and marketing strategies.

This approach allows to specify the projects' concepts by reaching stakeholders of needed Information & Communication Technologies (ICT) to implement a prototype relying on software components available elsewhere. Two sample cases are presented to clarify this cloud-engineering approach:

1) Program for Recovery Insufficient Grades in High-School (PRISC);
2) Sustainable Mobility through Social Mobility (SM^2) to reduce dependence on one's owned cars to satisfy mobility needs.

The PRISC strategy focuses on the learner and on how proficiency is assessed through grades. The action steps are:

- understanding is focused on the students' study on schoolbooks;
- assessment is delegated to exercises and tests managed on screens of mobile telephones or PCs in an interactive Web environment;
- students with excellent grades act as tutors by exploiting social networks.

The SM^2 strategy focuses on exploiting the empty seats available in most cars running in metropolitan cities with air pollution problems. Key features:

- direct negotiation via mobile devices between car drivers and ride seekers;
- short range contacts insuring prompt satisfaction;
- GPS ride surveillance.

From the standpoint of a University environment, the attention that Cloud computing receives on scientific publications [1] and on the daily press as well, indicates a major potential for business innovation besides job opportunities for young graduates once a win-win situation is established which could leverage on cloud technology techniques to acquire on the Web what is needed for rapid prototyping of business models concepts, while reducing time-to-market to satisfy the needs of customers.

Many companies provide Cloud technology: CA Technologies, IBM, Microsoft, Google, Seeweb are those we could approach. The specific focus on CRM brought to select the academic license granted by SFDC Inc. (www.Salesforce.com) for this prototype implementations because of its 11 years experience gathered in offering the "Sales Force Automation" solution in web-based modality and on-demand. The functionality covering "Service and Support Management" is of specific value for our studies allowing us to practice SaaS (Software as a Service). While the access to the programming infrastructure and the services of hosting and administration allows to develop PaaS (Platform as a Service).

The development programming environment refers to a Java language named APEX which allows to write code for any application beyond the initial CRM objective.

II. Program for Recovery Insufficient Grades in High-School (PRISC)

High School Education is a major concern for Governments since economy globalization and technological innovation in industrial processes require staff and managers able to anticipate unpredictable market changes. At the same time the economy recession and lower government budgets force to prototype new educational formats where ICT and social networking could make education more effective and profitable.

To deliver an overall better education in High-Schools requires a coordinated action on the stakeholders: teachers, students, textbook publishers, school administration board, parents, laboratories and their equipment [2]. Since PRISC strategy focuses on the learner and on how proficiency is assessed through grades, the learners involved in PRISC action are both those with bad grades and those with excellent grades who are meant to act as tutors.

At present bad grades recovery happens either with additional classroom-based teaching organized by the School and free of charge to students, or by private action where parents look for teachers (or university students) for private tutoring usually paid cash and with no receipts.
In its initial phase, PRISC focuses on a few subjects: Mathematics, Physics, Computer Science. The action succeeds when a student with bad grades in specific subjects succeeds in recovering them in order to proceed to next higher level class.

All CRM procedures are managed on the cloud. The resulting system is inherently distributed and the central management coordinates the outsourced components (users do not know where data and procedures are stored). The PRISC coordinator interacts with a set of web-services provided by the cloud interface. He doesn't know directly the actual students (both with insufficient or with excellent grades). He only interacts with standard tools reckoning the student activities and with a standard platform to access and store the teaching materials. Thus there is no need for any venture capital investment, since

the financial balance only comes from a pay-per-use fee that is tightly commeasured to the benefits of PRISC activity.

In particular:

a) the study on text-books of specific topics not well understood involves cooperation with specific text-book Publishers to edit relevant exercises related to their books:
b) modern ICT digital video-interactive communications over screens of mobile phones or PCs involves Mobile Telecommunications Carriers
c) the web-based support to a learning community (where students with good grades help other students to recover from bad-grades) involves Social Networks platforms
d) implementation involves partnership with Education stakeholders at national and local government both in public and in private sectors.

III. THE SM^2 (SUSTAINABLE MOBILITY THOUGH SOCIAL MOBILITY) PROJECT

In metropolitan areas with air pollution problems the SM^2 strategy focuses on exploiting the empty seats available in most cars. The distinguishing strategy through which SM^2 plans to hit its target is the raising up of a Social Mobility community capturing the consensus of the customers thanks to widespread ICT instruments such as Internet and GPS on the one hand and socio/economic motivations on the other [3].

The approach is distributed at a great extent, with cloud computing acting as an ideal middleware. Indeed, the community autonomously emerges from the interaction of commuters without any previous direct contact. They simply interact through an *id* that attests their mobility in the same geographic range and requires information tools in the cloud to match them on the empty seats on other commuters' cars.

The model is intrinsically distributed since the managers of the transactions are exactly the actors who access remote resources through a portal installed through APIs on their mobile terminals. This will allow to achieve the following basic goals:

a. Extemporaneity of the transaction. We assume that users wait for maximum 10 minutes between when they plan to move and the planning of an alternative ride . Otherwise they will decide to move with their own means.

b. Efficiency of the transaction. Operational and technological efficiency are needed to guarantee the above time limit.

c. Reliability of the transaction. Both the reliability and the security of the service need to be considered together with emergency procedures in case of anomalies.

d. Green mobility issues require the monitoring of energetic and ecological efficiency as keen quality parameters.

The GPS availability allows to subdivide the community in users groups by location and consequently by time-range so that we could combine *demand and offer* in an optimal way both in terms of quality of the services (QoS) and of energetic consumption. Key implementation aspects are:

1) a distributed information support for the formulation of the ride requests and offers. The peripheral hardware will be constituted by new generation mobile terminals endowed with the Android operative system. An important part of this support will be the message ciphering and anti-intrusion systems and the transaction sampling and log compacting systems.
2) a cloud database for the collection of the requests, their interface with the availabilities, and finally the dispatching of the service orders to the transport suppliers. The DB should also contain the personal data of the community members with their preferences profile and credibility, updatable on line. The DB will store the traces of the transactions, including GPS traces, for a time sufficient for any security control need, but not exceeding the limits of the privacy of the members.
3) the design and implementation of the security system guaranteeing both the passenger and the driver in a non invasive but sufficiently robust way. Main points are:

   3a) the transaction enrolment from the driver-passenger assignment to the end-of-transport message by both the actors. The transaction will be followed through the service messages (call – offer – assignment - starting point agreement - end-of-transport message) and the GPS traces of the driver and of the passenger compared with the optimal routes suggested by satellite navigators

   3b) a library of rules for the agent system constituted by passenger, driver, and central server. With this library we will face both unpredictable events caused by traffic and real events linked to any anomalous behaviour of either the passenger or the driver. We will use fuzzy rules to be calibrated both in batch mode and online with neuro-fuzzy learning mechanisms[4].

IV. CONCLUSIONS

The lesson learned is how to deliver leaner, faster and more agile services to users – students and citizens - alongside with business stakeholders – Schools and Municipal Transportation companies – which are under pressure to make their business processes cheaper and more responsive to the customer's environment.

At present these two case studies simply constitute candidate test sites for Social Clouds instances which must be engineered in order to check the effectiveness of the benefits promised by their ecological paradigm [5].

The main benefit lies in the possibility of enabling a fast prototype implementation, in time to report results of these studies to the visitors of this poster.

***Abstract*— Since its inception, the undergraduate program in Computer Engineering from the Universidad Autonoma de San Luis Potosi in Mexico has been characterized for their hard work throughout the student's education. This work has placed this academic program at the first position in the national ranking, according to the national evaluation center (**CENEVAL**) of Mexico. To achieve this, an important factor has been the pattern of development of reseedgeh and technological development in most of their courses. The software projects are prerequisites for entitlement to qualifying. This paper analyzes a sample of projects developed over fifteen years (1995-2009) to assess quality and identify their strengths and weaknesses. We analyze the evolution of software quality in terms of stage developer training throughout their academic progress and the changes in general characteristics of the software developed over the period analyzed. The first analysis allows us to draw conclusions about the development of student potential, and the second one to evaluate the development of academic programs and apprenticeship schemes. Metric proposals were considered by the Software Engineering Institute (SEI) to characterize the projects.**

Keywords- Software Metrics; Software Quality; Maintainabilty;

I. Introduction

Software (sw) products of quality are performed by sw engineers along with strict methodologies that ensure the maximum reduction in the probability of defects. These guidelines should be followed at all stages of development To be characterized as good quality, it is not enough that a sw program be functional in accordance with the purpose for which it was made, but involves a series of metrics to be taken into account. Maintainability of sw products is a quality that can be accomplished. This applies to all products generated during the process [2]. This reseedgeh analyzes the evolution of quality in sw programs in terms of academic progress of their developers. We analyzed a sample of over 450 sw projects developed by students majoring in Computer Engineering at the Universidad Autonoma de San Luis Potosí (UASLP) for fifteen years (1995 to 2009). The students after five years graduate with an academic level that puts them in first national place according with the national evaluation center of Mexico.

II. Metrics and Methodology

Currently, there are a number of metrics that allow some form of sw measurement, however, as in [3], the author says that clear attributes should be defined that establish a proper system of measures for a final sw product. Moreover, in [4], the author argues that metrics are a good way to understand, monitor, control, predict and test the sw development and maintenance projects. Pfleeger [5] says that practitioners and reseedgehers can use metrics to make better decisions. In general, little attention is given to software metrics in the undergraduate curricula [6]. In the UASLP, these issues are analyzed in a single course at the end of the program. There are some efforts to learn about metrics using systems developed in the professional field [7]. Specialized literature does not show works, which analyze the systems developed by the students to evaluate their quality based on the progress in the study of their academic program.

Initially a sample of 405 projects was selected from the complete set provided by the school. The selection was carried out as follows: The projects were classified according to their subjects. Subsequently these subjects were classified into three levels which divided the curricular map of the academic program. On one level (level I) we included the following subjects: Programming Languages, Data Structures and Algorithms and Object-Oriented Technology, areas in which they are taught the programming fundamentals and the different programming paradigms The second level (level II) was made up of the subjects: Information Management, Information Systems, Operating Systems I and II, being areas in which the student is given freedom to follow the paradigm that is most appropriate to consider. Finally, the third level (level III) was composed of following areas: Software Engineering II (where you are taught the principles of sw quality to develop functional and high quality code), Expert Systems, Teleprocessing and System Programming I and II. These courses are taken in the last year. The latter total was 315 selected projects. Developer information, courses and dates were stored with the corresponding source code.

The following metrics were selected because they demonstrated good accordance with quality factors in the

empirical analysis of the programs developed during the course of software engineering at UASLP: LOC (lines of code), COM-RAT (commentaries ratio); V (Halstead Program Volume); E (EFFORT) which can be interpreted as a measure of the work required to understand sw already developed; V (G) (cyclomatic complexity) and SEIMI (index of maintainability of a project)[7].

TABLE I. METRICS OBTAINED BY ACADEMIC LEVEL

LEVEL	LOC	COM_RAT	V(G)	V	E	SEIMI
1	1676.46	0.05	7.73	809.05	1038783.90	-64.52
2	1314.18	0.05	4.45	664.41	334869.69	-87.09
3	2954.03	0.12	4.11	450.91	703116.77	-46.77

Table 1 shows the average number of lines of code used in projects as the student progresses in their academic program. It starts with an average of 1676 LOCs in the first third and ends with an average of 2954 of LOCs in each of their projects at the end. The volume of a program is defined as V = Nlog2n, where N = N1 + N2, N1 being the number of occurrences of operators and N2 the number of occurrences of operands. n = n1 + n2, n1 being the number of different operators and n2 the number of different operands. Figure 1 shows that the program volume decreases from Level I to Level III.

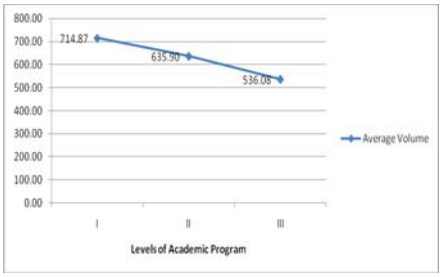

Figure 1. Program volume per level

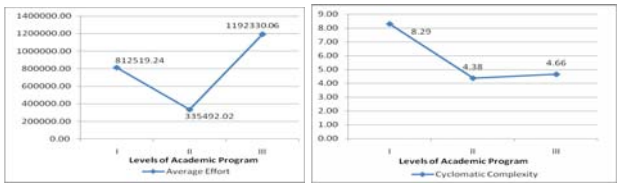
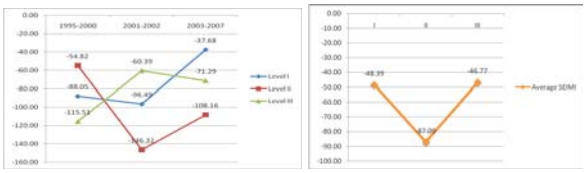
The effort to carry out a program is calculated by E = V * D. Figure 2(a) illustrates that the effort to develop programs at the end of the academic program nearly doubles the amount of the first third. The cyclomatic complexity by method or function represents the degree of ease or difficulty to understand. It is recommended [8] keeping this value below 6. Figure 2(b) shows that programs in the last two thirds of the major academic program present better maintainability.



a) b)

Figure 2. a) Effort to develop programs per level b) Cyclomatic Complexity of programs per level

We also analyzed changes in the quality of programs for students who have completed the academic program during the analyzed period of fifteen years. We used the software maintainability index (SEIMI) proposed by the SEI.[7] As shown in Figure 3(a) in recent years it is shown a very important development for level I in the last period in which there is no knowledge of concepts that contribute to the maintainability of software, this improvement is not present in levels II and III. Using the same index, we analyzed the entire project set. Figure 3(b) shows that the maintainability of the products at the beginning of the academic program decreases in the middle third and increases significantly at the end.



a) b)

Figure 3. a) Average SEIMI values per level and years b) Average SEIMI values per levels

CONCLUSIONS

Based on the information we can conclude that the programs developed by students of UASLP have the following strengths: It is noted that from the second third of the academic program, the average complexity of the program methods is reduced from 8.29 (at baseline) to 4.35 and 4.56 (in the last two levels). This improves code readability. We Identify the following weaknesses: A recommended SEIMI for professional software products exceed the value of 65 [7]. We propose a value of -65 as the minimum maintainability index of software products built by students during their academic formation. Based on this, we can conclude that the best programming practices are not applied in the courses of the middle third of the program and maintainability is reduced by increasing their complexity. It is emphasized that although the complexity of the programs developed at the end of the program is even greater, the maintainability index and hence the product quality level recovers.

Abstract

The basis path testing is one of the most used techniques for generating white box test cases. This approach depends on the unknown state of the program variables at the time of execution, i.e., each path can be seen as the result of a random experiment, associated with an execution probability. We can define the coverage probability of a test set as the sum of the execution probability of its members. Although running the program a large number of times provide us an approximation for this set, its computational cost would be equal to that of testing the program in itself. This paper presents a method that uses a small set of execution samples to select a minimal set of execution paths, which has the property of its coverage probability being above a required confidence level, and then generate a natural language specification of the test case set. Experimental results show that it is not only simple to be applied but also generates a reliable test case set.

1. Introduction

White-box testing of software modules is the test activity where the test cases are derived from the analysis of the module source code [2, 4, 5]. The basis path testing is one of the most used techniques for generating white box test cases, using a set of execution paths. However it can produce a set with elements that have a small chance to be executed in practice. This poster presents a method that uses a small set of execution samples to select a minimal set of execution paths, which has the property of its coverage probability being above a required confidence level, and then generate a natural language specification of the test case set. The structure of this paper is as follows: Section 2 presents the most important concepts and Section 3 describe in details the method. Section 4 shows the computational experiments and Section 5 presents the conclusions.

2. Conceptual framework

In "basis path testing", the program is associated with a control flow graph, that has unique entry and exit nodes. A path is a sequence of connected nodes that traverse the control flow graph from the start node to the end node. Each path corresponds to a test case element.

Since the number of paths is potentially infinite, leading to an infinite number of test cases, McCabe [3] introduced the concept of independence in a strong connected graph. An independent path is any path in the program that introduces at least a new set of commands or a new condition. Each independent path must include at least one edge that has not been crossed when determining the path. The cyclomatic number $V(G)$ of the control flow graph G is equal to its maximum number of linearly independent paths.

The empirical approach defines the concept of probability by the definition of sample space, which represents the outcome of an experiment. In our case, the sample space is

the set $\mathcal{P}$ of all paths p_i resulting from the execution of the program under test.

The set $\mathcal{P}$ may be infinite or very large. $\mathcal{P}_L$ denotes a sample (set of paths) obtained by running a program N times. In $\mathcal{P}_L$, each path p_i will appear with a certain frequency f_i. We define the probability of path p_i in $\mathcal{P}_L$ as the relative frequency $f^N(p_i) = f_i/N$.

How to choose N in order to obtain a representative sample of $\mathcal{P}$? For large samples, we can use the table of critical values of the Kolmogorov-Smirnov test [1] with desired confidence level α. It is a widely used nonparametric test for the equality of probability distributions, that can be employed to compare a sample (in our case, $\mathcal{P}_L$) with a reference probability distribution (the one associated with $\mathcal{P}$). The Kolmogorov-Smirnov statistic quantifies a distance K_N between the empirical cumulative distribution function of the sample and the cumulative distribution function of the reference.

Running N times can be very expensive. The goal of our method is to obtain a good approximation to $\mathcal{P}_L$, $\mathcal{P}_A$, using a generative algorithm and a much smaller sample size, n. To evaluate the closeness between the distribution frequencies of $\mathcal{P}_A$ and $\mathcal{P}_L$, we resort to the χ^2 test, which compares the result with the corresponding critical value obtained from the table with a desired confidence level α.

3. The method

Step 1: The objective of this step is to draw the control flow graph from the source code of program module M. This means replacing if-structures by decision nodes, while-do and do-while structures by loop nodes, for-do structures and actions by activity nodes. Junction nodes are included in the end, when a node with several inputs needs to join them into a single input.

Step 2: Probabilities must be assigned to decision and loop nodes. Since we do not have a previous knowledge of the program behavior, these probabilities are estimated from the results of a number n of program runs, using as input a random sample from the program's domain. These values will enable us to calculate the probability of an execution path, by simply multiplying the probabilities associated with decision and loop nodes in the selected path.

Step 3: After assigning probabilities to decision and loop nodes, we generate execution paths of program M and calculate the probability of each path. This temporary set of paths is denoted by $\mathcal{P}_{A'}$. Each path is identified by a sequence of nodes being traversed, e.g., the paths 1-2-3-8 or 1-2-3-4-5-6-7-2-3-8. Then, after generating $\mathcal{P}_{A'}$, we obtain the execution path set $\mathcal{P}_A$, formed by the paths from $\mathcal{P}_{A'}$ whose sum of probabilities is larger than a required confidence level α.

Step 4: Each element of the execution path set will be used to generate one element of the test case set. Although a computationally amenable solution could be attempted by the use of any of the above cited approaches, we recommend a simpler ad-hoc procedure, in which the developer translates the required node transitions into natural language specifications for the input values.

4. Validation

The method was applied in a set of fourteen programs written in C/C++. For each program, the path set $\mathcal{P}_L$ along with its associated pdf f^* were generated. Each pdf f^* was then compared to f, obtained by our method. The goodness of fit between each f^* and f in the set was verified using the χ^2 test with a confidence level of 95% (in the modern approach, the result has credibility when the confidence level of the experiment is equal or greater then 95%).

The null hypothesis was formulated as $H_0 : f^* \neq f$

These results showed that H_0 is rejected thirteen times out of fourteen. The only program for which H_0 was not rejected has a particular case of simultaneous recursion, i.e., it executes several times recursive operations in parallel.

5 Conclusions

The evaluation tests confirmed that not only the method is simple to use, but also provides, in a computationally efficient way, a good approximation when comparing $\mathcal{P}_A$ (the set of paths which is the outcome of the method) and $\mathcal{P}_L$ (a large sample of the real set $\mathcal{P}$ of execution paths).

Abstract— **Information Retrieval is a process made by a user to obtain relevant information which meets his needs using an Information Retrieval System (IRS).The main objective of IR systems is to select relevant documents related to user's information need, from collection of documents. This paper intends to address some reflections coming from the result of survey of information retrieval systems in order to create systems that, by taking into account user's profiles, can better satisfy the users of IR systems.**
***Keywords*— information retrieval, user profile, personalized IR, indexing, user re-indexing, ontology**

I. Introduction

As an Academic field of study Information Retrieval (IR) might be defined thus "Information Retrieval is finding material (usually documents) of an unstructured nature (usually text) that satisfies an information need from within a large collections (usually stored on computer)" [2]. Furthermore, in the case of textual documents in which we are interest a significant part of difficulties are due to the difficulty lies in ambiguity inherent to human languages [1] and the carelessness of the user.
This paper is a proposal of some ideas in order to improve information retrieval. It aims to develop a system for personalized IR using ontology classes to represent personal information including user profile, preference, culture, and interests

II adaptative information retrieval

The goal of the adaptive information retrieval is to adapt the process of information retrieval in order to return relevant results to the user. Techniques developed in adaptive information retrieval [4] focus mainly on the assistance in the query's reformulation.

1. *Reformulation of the query*

It aims to generate a new query without explicit retroaction of the user, just by exploring the first documents presented by the system as an answer to the user's query (blind feedback)[6].Different techniques were introduced in the literature, in models of information retrieval such as Vector Space Model, and the probabilistic model. We quote the techniques of the reformulation of the queries by relevance feedback, techniques of disambiguation of the queries sense or the techniques of clustering.

2. *Disambiguation of the query's sense*

The aim of these techniques is to assist the user in order to better express his need by adding additional semantic resources[8] (dictionaries, networks, thesauruses).Most of them are based on exploring interactive interfaces of clarification based on ontology

3. Techniques of Clustering

In order to face major growth of the web, and the difficulties faced by the classic search engines, the aim of the clustering techniques is to group the results into categories such as Grouper [9],Vivissimo, Kartoo, as well as techniques of repertorisation of the web into taxonomy of concepts (Google hierarchy).All these techniques[7] were developed in order to satisfy the user and to simplify his navigation. The theoretical study that we carried out reveals that beside the earnings bring by the techniques of adaptive information retrieval, there still some limitation such as the context, explicit interaction, impact of the user's familiarity with the subject.

III Contextual and personalized information retrieval

According to [10], the contextual information retrieval is defined as *"combine search technologies and knowledge about the query and user context into a single framework in order to provide the most appropriate answer for a user's information needs"*.

In the literature [3], the context of research is bound to dimensions dependent to the user, the query and the environment of research. We are interested in personalized information retrieval which is a specific branch of contextual information retrieval. The goal of personalization [5] in information retrieval is to tailor the search engine results. The first approaches of the contextual information retrieval have focused on the context of the user represented by his profile.

This context includes his interests, his votes, his comments, and also his knowledge. In fact people's future preferences and needs must be able to personalize services, the same way recommender systems do. The personalization is a process which changes the feature, the interface, the content information or the aspect of a system in order to

increase his personal relevance related with the socio-demographic characteristics declared by the user and his observed behaviour contained in what we call user model.

IV Proposed approach

The reflections presented in this paper are situated precisely in the context of personalized access to information. We are now focusing on the construction of the proposed architecture (Fig 1).

The objective is to add semantic value to information retrieval systems towards a new indexing process or re-indexing of the contents. We are interested to imply the user, his profile, his traces, his culture, and his point of view in order to collect all these points into ontology of interest.

The system consists of two main parts: classic IR and personalized IR.The parts are closely interrelated in the sense that the outputs of module are inputs of the other. After implementing the Baseline System containing the process of indexing, the users are classified into two categories: user having a profile and user not having a profile. The user profile data comprising his personal information, preferences, domain of competence, interests, and also comments and votes (that will be used in the process of re-indexing).At the first connection to the system, the construction of the user's profile is done and an instance of profile's ontology is created too. When the user will have a profile, a categorization of users will be made into group of users. It has the advantage of having typical information with the opportunity to refine it as and when.

We implement a generic indexing tool for structured, semi-structured and non-structured documents. We used the vector space model .For non-structured documents or "Full text", we use a test corpus CACM(Communications of the ACM) composed of 3204 documents with the title and links to bibliographic citation in the field of computer science,64 queries and a file of assessments.

We followed the steps bellow to generate the inverted documents file and the queries inverted file:

-Tokenization

-Dropping common terms (Stop words)

-Stemming and lemmatization.

V Conclusion

Although a considerable number of works focused on information retrieval, some important challenges for the research community still remain. This paper provides a brief survey of the evolution of information retrieval from the classic to the contextual, the problems faced. We have proposed architecture of personalization by implying the user with representing his interests and profile into an ontology [8] of interest, then using this ontology for re-indexing of the contents. In fact, a key part of a personalization system is the user model. We have to develop an expressive model in order to encompass all aspects of the user taking into account the environment that the user interacts with and try to identify changes in user interests and needs. Finally we can say that the ultimate goal of personalization system being the satisfaction of the user. To reach this goal, the user has to be implied in the construction process in order to add the semantic value to the information retrieval.

SEKE 2012 Call For Papers

The Twenty-Fourth International Conference on Software Engineering and Knowledge Engineering

www.ksi.edu/seke/seke12.html

Hotel Sofitel, Redwood City, San Francisco Bay, USA
July 1 - July 3, 2012

Organized by

Knowledge Systems Institute Graduate School

The Twenty-Fourth International Conference on Software Engineering and Knowledge Engineering (SEKE 2012) will be held at the Hotel Sofitel, Redwood City, California, USA, July 1-3, 2012.

The conference aims at bringing together experts in software engineering and knowledge engineering to discuss on relevant results in either software engineering or knowledge engineering or both. Special emphasis will be put on the transference of methods between both domains. Submission of papers and demos are both welcome.

TOPICS

Agent architectures, ontologies, languages and protocols
Multi-agent systems
Agent-based learning and knowledge discovery
Interface agents
Agent-based auctions and marketplaces
Artificial life and societies
Secure mobile and multi-agent systems
Mobile agents
Mobile Commerce Technology and Application Systems
Mobile Systems

Autonomic computing
Adaptive Systems
Integrity, Security, and Fault Tolerance
Reliability
Enterprise Software, Middleware, and Tools
Process and Workflow Management
E-Commerce Solutions and Applications
Industry System Experience and Report

Service-centric software engineering
Service oriented requirements engineering
Service oriented architectures
Middleware for service based systems
Service discovery and composition
Quality of services
Service level agreements (drafting, negotiation, monitoring and management)
Runtime service management
Semantic web

Requirements Engineering
Agent-based software engineering
Artificial Intelligence Approaches to Software Engineering
Component-Based Software Engineering
Automated Software Specification
Automated Software Design and Synthesis
Computer-Supported Cooperative Work
Embedded and Ubiquitous Software Engineering
Measurement and Empirical Software Engineering
Reverse Engineering
Programming Languages and Software Engineering
Patterns and Frameworks
Reflection and Metadata Approaches
Program Understanding

Knowledge Acquisition
Knowledge-Based and Expert Systems
Knowledge Representation and Retrieval
Knowledge Engineering Tools and Techniques
Time and Knowledge Management Tools
Knowledge Visualization
Data visualization
Uncertainty Knowledge Management
Ontologies and Methodologies
Learning Software Organization

Tutoring, Documentation Systems
Human-Computer Interaction
Multimedia Applications, Frameworks, and Systems
Multimedia and Hypermedia Software Engineering

Smart Spaces

Web and Data Mining

CONFERENCE SITE (HOTEL INFORMATION)

The SEKE 2012 Conference will be held at the Hotel Sofitel, Redwood City, California, USA. The hotel has made available for these limited dates (6/29 - 7/5/2012) to SEKE 2012 attendees a discount rate of USD$85 for single/double, not including sales tax.

INFORMATION FOR AUTHORS

Papers must be written in English. An electronic version (Postscript, PDF, or MS Word format) of the full paper should be submitted using the following URL: http://conf.ksi.edu/seke2012/submit/SubmitPaper.php.
Please use Internet Explorer as the browser. Manuscript must include a 200-word abstract and no more than 6 pages of 2-column formatted Manuscript for Conference Proceedings (include figures and references but exclude copyright form).

INFORMATION FOR REVIEWERS

Papers submitted to SEKE 2012 will be reviewed electronically. The users (webmaster, program chair, reviewers...) can login using the following URL: http://conf.ksi.edu/seke2012/review/pass.php.
If you have any questions or run into problems, please send e-mail to:
E-mail: seke12@ksi.edu.
