FOREWORD

Welcome to the 31st International Conference on Software Engineering and Knowledge Engineering (SEKE), in Hotel Tivoli, Lisbon, Portugal. In last 30 years, SEKE has established itself as a major international forum to foster, among academia, industry, and government agencies, discussion and exchange of ideas, research results and experience in software engineering and knowledge engineering. The SEKE community has grown to become a very important and influential source of ideas and innovations on the interplays between software engineering and knowledge engineering, and its impact on the knowledge economy has been felt worldwide. On behalf of the Program Committee, it is my great pleasure to invite you to participate, not only in the technical program of SEKE 2019 and its rich assortment of activities, but also in enjoying the stunning capital of Portugal and one of the great capitals of Western Europe. Lisbon is a city with more than 800 years where historical heritage, modernism, culture and nightlife combine in a perfect harmony. The excellence of the climate and the sympathy of the Portuguese population associated with the diversity and quality of the opportunities offered leave visitors with a desire to return to Lisbon. Lisbon and Portugal have recently won several international awards as destinations of excellence, such as those from the World Travel Award.

This year, we received 225 submissions from 29 countries. Through a rigorous review process where a majority of the submitted papers received three reviews, and the rest with two reviews, we were able to select 88 full papers for the general conference (39.1 percent), 61 short papers (27.1 percent), 3 posters (1.4 percent), 1 demo (0.4 percent) and 72 rejects (32 percent). Out of that, 9 papers have been specifically submitted, and later accepted, for the 4 special sessions (Theoretical Software Engineering TSE 4 papers, Semantic Enabled Software Engineering SESE 1 paper, Knowledge Graphs KG 3 papers and Machine Learning for SE and KE MLA 1 paper), and 140 papers are scheduled for presentation in forty sessions during the conference. In addition, the technical program includes two excellent keynote speeches from Professor Robert Laurini and Professor Rui L. Aguiar.

The high quality of the SEKE 2019 technical program would not have been possible without the tireless effort and hard work of many individuals. First of all, we would like to express our sincere appreciation to all the authors whose technical contributions have made the final technical program possible. We are very grateful to all the Program Committee members whose expertise and dedication made our responsibility that much easier. Our gratitude also goes to the keynote speakers who graciously agreed to share their insight on important research issues, to the conference organizing committee members for their superb work, and to the external reviewers for their contribution.

Personally, we owe a debt of gratitude to a number of people whose help and support with the technical program and the conference organization are unfailing and indispensable. We are deeply indebted to Dr. S. K. Chang, Chair of the Steering Committee, for his constant guidance and support that are essential to pull off SEKE 2019. Our heartfelt appreciation goes to Dr. Oscar Mortagua Pereira, University of Aveiro, Portugal, the Conference Chair, for his help and experience. In addition, we also like to express our appreciation to Prof. Jing Sun, The University of Auckland, New Zealand, to Prof. Iakov Exman, The Jerusalem College of Engineering, Israel, to Dr. Yucong Duan, Hainan University, China and to Dr. Gunasekaran Manogaran, University of California, Davis, USA for their excellent job in organizing the special sessions SESE, TSE, KG and MLA, respectively.

We would like also to express our great appreciation to all of the conference organization committee members, including the Publicity Chair, Lan Lin, Ball State University, USA and Nuno Antunes, University of Coimbra, Portugal. Moreover, we would like to appreciate and recognize our Conference Liaisons in different regions for their important contributions. They are: Asia Liaison – Hironori Washizaki, Waseda University, Japan; Australasia Liaison – Jing Sun, The University of Auckland, New Zealand; Europe Liaison - Raul Garcia Castro, Universidad Politecnica de Madrid, Spain; India Liaison - Swapan Bhattacharya, National Institute of Technology Karnataka, Surathakl; and South America Liaison - Jose Carlos Maldonado, ICMC-USP, Brazil.

Last but certainly not the least, we must acknowledge the important contributions that the KSI staff members have made. Their timely and dependable support and assistance throughout the entire process have been truly remarkable. Finally, we wish you have productive discussion, great networking, effective presentation, and pleasant stay and travel in Lisbon, Portugal to participate in SEKE 2019.

Angelo Perkusich, Federal University of Campina Grande, Brazil, Program Committee Chair
Raul Garcia Castro, Universidad Politecnica de Madrid, Spain, Program Committee Co-Chair
Diogo Regateiro, Institute de Telecomunicacoes, Portugal, Program Committee Co-Chair

SEKE 2019

The 31st International Conference on Software Engineering & Knowledge Engineering

July 10 – 12, 2019

Hotel Tivoli, Lisbon, Portugal

Conference Organization

CONFERENCE CHAIR

Oscar Mortagua Pereira, University of Aveiro, Portugal

PROGRAM COMMITTEE CHAIR

Angelo Perkusich, Federal University of Campina Grande, Brazil

PROGRAM COMMITTEE CO-CHAIRS

Raul Garcia Castro, Universidad Politecnica de Madrid, Spain

Diogo Regateiro, Institute de Telecomunicacoes, Portugal

STEERING COMMITTEE CHAIR

Shi-Kuo Chang, University of Pittsburgh, USA

STEERING COMMITTEE

Vic Basili, University of Maryland, USA

Bruce Buchanan, University of Pittsburgh, USA

C. V. Ramamoorthy, University of California, Berkeley, USA

ADVISORY COMMITTEE

Jerry Gao, San Jose State University, USA

Swapna Gokhale, University of Connecticut, USA

Xudong He, Florida International University, USA

Natalia Juristo, Universidad Politecnica de Madrid, Spain

Taghi Khoshgoftaar, Florida Atlantic University, USA

Guenther Ruhe, University of Calgary, Canada

Masoud Sadjadi, Florida International University, USA

Du Zhang, California State University, USA

PROGRAM COMMITTEE

Silvia Teresita Acuna, Universidad Autonoma de Madrid, Spain
Shadi Alawneh, Oakland University, USA
Vaibhav Anu, North Dakota State University, USA
Doo-Hwan Bae, Korea Advanced Institute of Science and Technology, Korea
Fevzi Belli, University of Paderborn, Germany
Ateet Bhalla, Consultant, India
Swapan Bhattacharya, NITK, Surathakl, India
Ivo Bukovsky, Czech Technical University in Prague, Czech Republic
Guoray Cai, Penn State University, USA
Raul Garcia Castro, Universidad Politecnica de Madrid, Spain
Keith Chan, Hong Kong Polytechnic University, Hong Kong
Wen-Hui Chen, National Taipei University of Technology, Taiwan
Maria Francesca Costabile, University of Bari, Italy
Lin Deng, Towson University, USA
Derek Doran, Wright State University, USA
Weichang Du, University of New Brunswick, Canada
Christof Ebert, Vector Consulting Services, Germany
Magdalini Eirinaki, San Jose State University, USA
Abdelrahman Osman Elfaki, University of Tabuk, Saudi Arabia
Ruby ElKharboutly, Quinnipiac University, Canada
Honghao Gao, ShangHai University, China
Kehan Gao, Eastern Connecticut State University, USA
Felix Garcia, University of Castilla-La Mancha, Spain
Olivier Le Goaer, University of Pau, France
Swapna Gokhale, Univ. of Connecticut, USA
Wolfgang Golubski, Zwickau University of Applied Sciences, Germany
Hassan Haghighi, Shahid Beheshti University, Iran
Hao Han, National Institute of Informatics, Japan
Xudong He, Florida International University, USA
Shihong Huang, Florida Atlantic University, USA
Hamdy Ibrahim, University of Calgary, Canada
Bassey Isong, North-West University, South Africa
Clinton Jeffery, University of Idaho, USA
Jason Jung, Chung-Ang University, South Korea
Pankaj Kamthan, Concordia University, Canada
Ananya Kanjilal, B.P. Poddar Institute of Technology and Management, India
Taghi Khoshgoftaar, Florida Atlantic University, USA
Jun Kong, North Dakota State University, USA
Aneesh Krishna, Curtin University of Technology, Australia
Vinay Kulkarni, Tata Consultancy Services, India
Bixin Li, Southeast University, China
Yuan-Fang Li, Monash University, Australia
Jianhua Lin, Eastern Connecticut State University, USA
Lan Lin, Ball State University, USA
Xiaodong Liu, Edinburgh Napier University, United Kingdom
Luanna Lopes Lobato, Federal University of Goias, Brazil
Baojun Ma, Beijing University of Posts and Telecommunications, China
Beatriz Marin, Universidad Diego Portales, Chile
Riccardo Martoglia, University of Modena and Reggio Emilia, Italy
Santiago Matalonga, University of the West of Scotland, UK
Andre Menolli, Universidade Estadual do Norte do Parana (UENP), Brazil
Hiroyuki Nakagawa, Osaka University, Japan
Alex Norta, Tallinn University of Technology, Estonia
Edson A. Oliveira Jr., State University of Maringa, Brazil
Oscar Mortagua Pereira, University of Aveiro, Portugal

Antonio Piccinno, University of Bari, Italy
 Alfonso Pierantonio, University of L'Aquila, Italy
 Rick Rabiser, Johannes Kepler University, Austria
 Claudia Raibulet, University of Milan, Italy
 Damith C. Rajapakse, National University of Singapore, Singapore
 Rajeev Raje, IUPUI, USA
 Henrique Rebelo, Universidade Federal de Pernambuco, Brazil
 Marek Reformat, University of Alberta, Canada
 Diogo Regateiro, Institute de Telecomunicacoes, Portugal
 Stephan Reiff-Marganiec, Leicester University, United Kingdom
 Daniel Rodriguez, Universidad de Alcala, Spain
 Masoud Sadjadi, Florida International University, USA
 Claudio Sant'Anna, Universidade Federal da Bahia, Brazil
 Klaus-Dieter Schewe, SCCH, Austria
 Abdelhak-Djamel Seriai, University of Montpellier 2 for Sciences and Technology, France
 Michael Shin, Texas Tech University, USA

 Bingyang Wei, Midwestern State University, USA
 Guido Wirtz, Bamberg University, Germany
 Franz Wotawa, TU Graz, Austria
 Peng Wu, Institute of Software, Chinese Academy of Sciences, China
 Qing Wu, Hangzhou Dianzi University, China
 Dianxiang Xu, Boise State University, USA
 Frank Weifeng Xu, University of Baltimore, USA
 Haiping Xu, University of Massachusetts Dartmouth, USA
 Lai Xu, Bournemouth University, UK
 Guowei Yang, Texas State University, USA
 Yuyu Yin, Hangzhou Dianzi University, China
 Huiqun Yu, East China University of Science and Technology, China
 Du Zhang, Macau University of Science and Technology, China
 Pengcheng Zhang, Hohai University, China
 Yong Zhang, Tsinghua University, China
 Zhenyu Zhang, Institute of Software, Chinese Academy of Sciences, China
 Zhigao Zheng, Central China Normal University, USA
 Nianjun Zhou, IBM, USA
 Huibiao Zhu, East China Normal University, China
 Eugenio Zimeo, University of Sannio, Italy

PUBLICITY CHAIR

Lan Lin, Ball State University, USA
Nuno Antunes, University of Coimbra, Portugal

ASIA LIAISON

Hironori Washizaki, Waseda University, Japan

AUSTRALASIA LIAISON

Jing Sun, The University of Auckland, New Zealand

EUROPE LIAISON

Raul Garcia Castro, Universidad Politecnica de Madrid, Spain

INDIA LIAISON

Swapn Bhattacharya, National Institute of Technology Karnataka, Surathakl, India

SOUTH AMERICA LIAISON

Jose Carlos Maldonado, ICMC-USP, Brazil

Keynote I

Introduction to Mobile Applications for Smart Cities

Professor Robert Laurini
Professor Emeritus
University of Lyon
Lyon, France

Abstract

Smart Cities can be defined with a digital layer covering several aspects of urban governance, based on four pillars such as knowledge engineering, deep learning, realtime massive data and geovisualization. After explaining the issues relative to those pillars, we will explain how they can be combined to support and develop Location-Based Services and Mobile Applications. In this talk, three categories of applications will be outlined, those based on mobility, those for which the answer varies from the location of the mover (space), and continuous applications for which also time is important.

About the Speaker

Professor Robert Laurini holds two doctorates (1973 and 1980) from the University of Lyon, France in which he was professor in information technologies at INSA-Lyon. He is a specialist in geographic information systems and more recently on knowledge engineering for smart cities. In 76-77, he was researcher at the Martin Centre, University of Cambridge, UK; in 86-87, visiting professor at the University of Maryland, College Park; during the period 1990-2000, he was part-time professor at the IUAV University of Venice, Italy. He has supervised or co-supervised 45 PhD's. He was involved in PhD committees in 17 countries. He has authored or co-authored more than 250 papers and 8 books, the last of them is "Geographic Knowledge Infrastructure, Applications to Territorial Intelligence and Smart Cities". He was one of the founders of the ACM Spatial Group, European editor of "Computers, Environment and Urban Systems" and associated editor of the "Journal for Visual Languages and Computing". He is now fellow of the Knowledge Systems Institute, USA. He fluently speaks English, French, Italian and Spanish. He is also the founder of "Academics Without Borders", which is an NGO devoted to modernizing universities in developing countries. For more details please see: <http://www.laurini.net/robert/>

Keynote II

5G - After the initial launch, is all about software

Professor Rui L. Aguiar
Institute of Telecommunications/DETI
University of Aveiro
Aveiro, Portugal

Abstract

The talk will briefly highlight the changes to be brought by the upcoming 5G networks, and present a view of the challenges and conceptual changes that the new wireless networks will bring in general, and to software engineering and knowledge engineering in particular. The discussion will touch on the control aspects of the networks, the requirements on novel control abstractions, and on new service development concepts and interfaces, focusing on the new virtualized and softwarized networks that will arise with 5G.

About the Speaker

Rui L. Aguiar received his Ph.D. degree in 2001 from the University of Aveiro. He is currently a Full Professor at the University of Aveiro, responsible for the networking area, and has been previously an adjunct professor at the INI, Carnegie Mellon University. He is coordinating a research line nationwide in Instituto de Telecomunicações, on the area of Networks and Multimedia. His current research interests are centred on the implementation of advanced networks and systems, with special emphasis on 5G networks and the Future Internet. He has about five hundred published papers in those areas. He has served as technical and general chair of several conferences, from IEEE, ACM and IFIP. He sits on the TPC of all major IEEE ComSoc conferences. He has extensive participation in national and international projects, and in industry technology transfer actions. He is the current Chair of the steering board of the Networld2020 ETP. He is senior member of IEEE, Portugal ComSoc Chapter Chair, and a member of ACM. He is associated editor of several journals and sits on the Advisory Board of several EU-projects and research units from several countries.

Table of Contents

Session Knowledge Graphs	
A DIK-based Question-Answering Architecture with Multi-sources Data for Medical Self-Service (S).....	1
<i>Menglong Li, Mengxing Huang, Yu Zhang and Wenlong Feng</i>	
Constructing a Knowledge Base of Coding Conventions from Online Resources	5
<i>Junming Cao, Tianjiao Du, Beijun Shen, Wei Li, Qingyue Wu and Yuting Chen</i>	
Combining time, keywords and authors information to construct papers correlation graph (S)	11
<i>Hanwen Liu, Huaizhen Kou, Xiaoxiao Chi and Lianyong Qi</i>	
Modeling and Simulation of CPS based on SysML and Modelica (S)	15
<i>Fei Deng, Yunqiang Yan, Feng Gao and Linbo Wu</i>	
Session Agile Software I	
AgileCritPath: Identifying Critical Tasks in Agile Environments.....	20
<i>Rachel Vital, Glaucia Melo dos Santos, Toacy Oliveira, Paulo Alencar and Don Cowan</i>	
Evaluating Software Developers' Acceptance of a Tool for Supporting Agile Non-Functional Requirement Elicitation.....	26
<i>Felipe Ramos, Antonio Pedro, Marcos Cesar, Alexandre Costa, Mirko Perkusich, Hyggo Almeida and Angelo Perkusich</i>	
Automatic Generation of Virtual Assistants from Databases using Active Ontologies.....	32
<i>Martin Blersch, Sebastian Weigelt, Walter Tichy and Kevin Angele</i>	
GADIS: A Genetic Algorithm for Database Index Selection (S)	39
<i>Priscilla Neuhaus, Julia Couto, Jonatas Wehrmann, Duncan Ruiz and Felipe Meneguzzi</i>	
Session Software Testing I	
Research on Page Object Generation Approach for Web Application Testing.....	43
<i>Yimei Chen, Zheng Li, Ruilian Zhao and Junxia Guo</i>	
A Class-level Test Selection Approach Toward Full Coverage For Continuous Integration..	49
<i>Yingling Li, Junjie Wang, Qing Wang and Jun Hu</i>	
Amplifying Tests for Cross-Platform Apps through Test Patterns.....	55
<i>Thiago Botti de Assis, André Augusto Menegassi and André Takeshi Endo</i>	
Session Theoretical Software Engineering	
Algebraic Convergence to Software-Knowledge: Deep Software Learning (P)	61
<i>Iaakov Erman and Assaf Spanier</i>	
Formal ontologies and data shapes within the Software Engineering development lifecycle.	64
<i>Jose María Alvarez Rodríguez, Valentín Moreno and Juan Llorens</i>	

Towards an Ontology to Support Decision-making in Hospital Bed Allocation (S).....	71
<i>Debora Engelmann, Julia Couto, Vagner Gabriel, Renata Vieira and Rafael Bordini</i>	
A Software System is Greater than its Modules' Sum: Providers & Consumers' Modularity Matrix.....	75
<i>Iaakov Exman and Harel Wallach</i>	

Session Agile Software

An Effort Estimation Support Tool for Agile Software Development: An Empirical Evaluation.....	82
<i>Emanuel Dantas, Alexandre Costa, Marcus Vinicius, Mirko Perkusich, Hyggo Almeida and Angelo Perkusich</i>	
Towards an artifact to support agile teams in software analytics activities.....	88
<i>Joelma Choma, Eduardo Guerra, Tiago Silva Da Silva, Luciana Zaina and Filipe Figueiredo Correia</i>	
Sprint Performance Forecasts in Agile Software Development - The Effect of Futurespectives on Team-Driven Dynamics.....	94
<i>Fabian Kortum, Jil Klünder, Wasja Brunotte and Kurt Schneider</i>	

Session Software Testing II

Research on Multi-constraint Combinatorial Test Technology for High Confidence Embedded Software (S).....	102
<i>Feng Gao, Fei Deng and Yunqiang Yan</i>	
Specification-based Testing with Simulation Relations (S).....	107
<i>Canh Minh Do and Kazuhiro Ogata</i>	
A Survey Study on the Inference Problem in Distributed Environment (S).....	113
<i>Adel Jebali, Abderrazak Jemai and Salma Sassi</i>	
Towards human-centric software testing.....	117
<i>Samantha Catania, Chris Porter and Mark Micallef</i>	

Session Software Testing III

Semantic Analysis for Deep Q-Network in Android GUI Testing.....	123
<i>Thi Anh Tuyet Vuong and Shingo Takada</i>	
Impacts of Data Uniformity in the Reuse of Acceptance Test Glue Code.....	129
<i>Douglas Hiura Longo, Patrícia Vilain and Lucas Pereira da Silva</i>	
Test Case Generation by EFSM Extracted from UML Sequence Diagrams.....	135
<i>Mauricio Rocha, Adenilson Simão, Thiago Sousa and Marcelo Batista</i>	
The Smell of Blood: Evaluating Anemia and Bloodshot Symptoms in Web Applications..	141
<i>Zijie Huang, Junhua Chen and Jianhua Gao</i>	

Session Formal Methods I

Formalization and Verification of RTPS StatefulWriter Module Using CSP	147
<i>Jiaqi Yin, Huibiao Zhu, Yuan Fei, Qiwen Xu and Ruobiao Wu</i>	
A Sound and Complete Axiomatisation for Spatio-Temporal Specification Language	153
<i>Tengfei Li, Jing Liu, Dongdong An and Haiying Sun</i>	
Formal Specification and Model Checking of the Lim-Jeong-Park-Lee Autonomous Vehicle Intersection Control Protocol (S)	159
<i>Moe Nandi Aung, Yati Phyo and Kazuhiro Ogata</i>	
<hr/> Session Bayesian Methods <hr/>	
Improving the Applicability of the Ranked Nodes Method to build Expert-Driven Bayesian Networks (S)	165
<i>João Nunes, Luiz Silva, Mirko Perkusich, Kyller Gorgonio, Hyggo Almeida and Angelo Perkusich</i>	
A systematic process to define expert-driven software metrics thresholds (S)	171
<i>Renata Saraiva, Mirko Perkusich, Hyggo Almeida and Angelo Perkusich</i>	
Multi-source fault detection and diagnosis based on multi-level Knowledge Graph and Bayesian theory reasoning (S)	177
<i>Tao Sun and Qi Wang</i>	
<hr/> Session Formal Methods II <hr/>	
Formal Specification and Model Checking of A* Algorithm	181
<i>Kazuhiro Ogata</i>	
PAT approach to Architecture Behavioural Verification	187
<i>Nacha Chondamrongkul, Jing Sun and Ian Warren</i>	
Leveraging Rigorous Software Specification Towards Systematic Detection of SDN Control Conflicts (S)	193
<i>Xin Sun and Lan Lin</i>	
<hr/> Session Software Bugs <hr/>	
The Influence of God Class and Long Method in the Occurrence of Bugs in Two Open Source Software Projects: An Exploratory Study (S)	199
<i>Aloisio Cairo, Glauco Carneiro, Antonio Resende and Fernando Brito E Abreu</i>	
Feature Evaluation for Automatic Bug Report Summarization (S)	205
<i>Akalanka Galappaththi and John Anvik</i>	
Generating Integration Tests Automatically Using Frequent Patterns of Method Execution Sequences	209
<i>Mark Grechanik and Gurudev Devanla</i>	
CrashAwareDev: Supporting Software Development based on Crash Report Mining and Analysis (S)	215
<i>Leandro Beserra and Roberta Coelho</i>	
<hr/> Session Internet of Things <hr/>	

Dynamic and Interoperable Control of IoT Devices and Applications based on Calvin Framework	221
<i>Fernanda Famá, Cleuves de Carvalho, Danilo Santos, Angelo Perkusich and Kyller Gorgônio</i>	
Reverse Engineering Behavioural Models of IoT Devices	227
<i>Sébastien Salva and Elliott Blot</i>	
A Resource Management Architecture For Exposing Devices as a Service in the Internet of Things	233
<i>Carlos Pantoja, Heder Dorneles Soares, Tielle Alexandre, Jose Viterbo and Amal El-Fallah Seghrouchni</i>	
<hr/> Session Security <hr/>	
SPRO: Security Process Framework	239
<i>Henrique Persch, Lisandra Fontoura and Adriano Fontoura</i>	
Detecting Security Vulnerabilities using Clone Detection and Community Knowledge	245
<i>Fabien Patrick Viertel, Wasja Brunotte, Daniel Strüder and Kurt Schneider</i>	
Case-Based Cybersecurity Incident Resolution	253
<i>Marcelo Colomé, Raul Ceretta Nunes and Luis Alvaro de Lima Silva</i>	
<hr/> Session Formal Methods III <hr/>	
Verifying Static Aspects of UML models using Prolog (S)	259
<i>Feng Sheng, Huibiao Zhu, Zongyuan Yang, Jiaqi Yin and Gang Lu</i>	
Modeling and Verifying TESAC Using CSP	265
<i>Dongzhen Sun, Huibiao Zhu, Yuan Fei, Lili Xiao, Gang Lu and Jiaqi Yin</i>	
PRISM Code Generation for Verification of Mediator Models (S)	271
<i>Weidi Sun and Meng Sun</i>	
<hr/> Session Adaptive Software <hr/>	
An evolutionary model for dynamic and adaptative service composition in distributed environment	275
<i>Jiawei Lu, Huan Zhou, Jun Xu, Haibo Pan and Gang Xiao</i>	
Learning - based Adaptation Framework for Elastic Software Systems	281
<i>Yingcheng Sun, Xiaoshu Cai and Kenneth Loparo</i>	
Self-Adaptive software changes analysis method based on "Detection-Recognition" Mechanism (S)	287
<i>He Zhang, Qingshan Li, Lu Wang and Wen Cheng</i>	
<hr/> Session Semantic Enabled SE <hr/>	
morph-GraphQL: GraphQL Servers Generation from R2RML Mappings (S)	291
<i>Freddy Priyatna, David Chaves-Fraga, Ahmad Alobaid and Oscar Corcho</i>	

Semantic Rule Based Program Monitoring (S).....	297
<i>Luke Tudor, Jing Sun, Hai H. Wang and Bingyang Wei</i>	
Context-aware Reactive Systems based on Runtime Semantic Models (S).....	301
<i>Ester Giallonardo, Francesco Poggi, Davide Rossi and Eugenio Zimeo</i>	
Enhancing Semantic Search of Crowdsourcing IT Services using Knowledge Graph.....	307
<i>Duankang Fu, Shufan Zhou, Beijun Shen and Yuting Chen</i>	
<hr/> Session Empirical Studies <hr/>	
An Empirical Study on Research and Developmental Opportunities in Refactoring Practices.....	313
<i>Shivani Jain and Anju Saha</i>	
An Empirical Studies on Optimal Solutions Selection Strategies for Effort-Aware Just-in-Time Software Defect Prediction.....	319
<i>Xingguang Yang, Huiqun Yu, Guisheng Fan and Kang Yang</i>	
Empirical Studies Concerning the Maintenance of BPMN Diagrams: A Systematic Mapping Study.....	325
<i>Ursula Campos, Adriana Lopes, Simone Barbosa and Tayana Conte</i>	
<hr/> Session Neural Networks <hr/>	
Multistep Flow Prediction on Car-Sharing Systems: A Multi-Graph Convolutional Neural Network with Attention Mechanism.....	331
<i>Yi Luo, Qin Liu, Hongming Zhu, Hongfei Fan, Tianyou Song, Chang Wu Yu and Bowen Du</i>	
Chinese Text Relation Extraction with Multi-instance Multi-label BLSTM Neural Networks.....	337
<i>Liubo Ouyang, Hui Tang and Guangyi Xiao</i>	
A Convolutional Neural Network Pruning Method Based On Attention Mechanism.....	343
<i>Xiao Jie Wang, Wenbin Yao and Huiyuan Fu</i>	
An Integrated Software Vulnerability Discovery Model based on Artificial Neural Network	349
<i>Gul Jabeen, Luo Ping, Junaid Akram and Akber Aman Shah</i>	
<hr/> Session Machine Learning Algorithms for SE <hr/>	
Machine Learning for Learnability of MDD tools.....	355
<i>Saad Bin Abid, Vishal Mahajan and Levi Lucio</i>	
Assessing the Influence of Size Category of the Project in God Class Detection, an Experimental Approach based on Machine Learning.....	361
<i>Khalid Alkharabsheh, Yania Crespo, Manuel Fernandez-Delgado, José M. Cotos and Jose Angel Taboada</i>	
A Services Development Approach for Smart Home Based on Natural Language Instructions.....	367
<i>Yiyang Chen, Zhanghui Liu, Zhiming Huang, Chuangshumin Hu and Xing Chen</i>	

Modeling User Contextual Behavior Semantics with Geographical Influence for Point-Of-Interest Recommendation.....	373
<i>Dongjin Yu, Kaihui Xu and Dongjing Wang</i>	

Session Deep Learning/AI

A Deep Learning Model Based on Sparse Matrix for Point-of-Interest Recommendation...	379
<i>Jun Zeng, Haoran Tang, Yinghua Li and Xin He</i>	
Improving Code Generation From Descriptive Text By Combining Deep Learning and Syntax Rules.....	385
<i>Xiangru Tang, Zhihao Wang, Jiyang Qi and Zengyang Li</i>	
Safe-by-Design Development Method for Artificial Intelligent Based Systems.....	391
<i>Gabriel Pedroza and Adedjouma Morayo</i>	

Session Software Development II

Augmenting App Review with App Changelogs: An Approach for App Review Classification.....	398
<i>Chong Wang, Tao Wang, Peng Liang, Maya Daneva and Marten Sinderen</i>	
Prudent Practices for Designing Virtual Desktop Experiments.....	404
<i>Peiyu Liu, Wenzhi Chen, Zonghui Wang and Lirong Fu</i>	
CrowDevBot: A Task-Oriented Conversational Bot for Software Crowdsourcing Platform (S).....	410
<i>Zeyu Ni, Beijun Shen, Yuting Chen, Zhangyuan Meng and Junming Cao</i>	
Retrieving Curated Stack Overflow Posts from Project Task Similarities (S).....	415
<i>Glaucia Santos, Toacy Oliveira, Paulo Alencar and Don Cowan</i>	

Session Software Defects

Software Defect Prediction Model Based on Improved Deep Forest and AutoEncoder by Forest.....	419
<i>Wenbo Zheng, Shaocong Mo, Xin Jin, Yili Qu, Zefeng Xie and Jia Shuai</i>	
Multi-project Regression based Approach for Software Defect Number Prediction.....	425
<i>Qiguo Huang, Chao Ni, Xiang Chen, Qing Gu and Kaibo Cao</i>	
Cross-Project Defect Prediction via Transferable Deep Learning-Generated and Handcrafted Features.....	431
<i>Shaojian Qiu, Lu Lu, Ziyi Cai and Siyu Jiang</i>	
An Investigation of Ensemble Approaches to Cross-Version Defect Prediction.....	437
<i>Xiaoxing Yang, Xin Li, Wushao Wen and Jianmin Su</i>	

Session Software Architectures I

A Multilevel Analysis Method for Architecture Erosion.....	443
<i>Tong Wang, Dongdong Wang and Bixin Li</i>	

The affinity Platform: Modular Architecture based on Independent Components (S)	449
<i>Alexandru Ardelean and Kuderna-Iulian Bența</i>	

A Mapping Study about Data Lakes: An Improved Definition and Possible Architectures .	453
<i>Julia Couto, Olimar Borges, Duncan D. Ruiz, Sabrina Marczak and Rafael Prikladnicki</i>	

Session Software Architectures II

Architecture for Discovery and Customization of Multi-tenant Learning Process as a service and resources allocation in cloud computing.	459
<i>Sameh Azouzi, Zaki Brahmi and Sonia Ayachi Ghannouchi</i>	

An Empirical Study about Software Architecture Configuration Practices with the Java Spring Framework (S)	465
<i>Quentin Perez, Alexandre Le Borgne, Christelle Urtado and Sylvain Vauttier</i>	

Recover and Optimize Software Architecture Based on Source Code and Directory Hierarchies (S)	469
<i>Tong Wang, Yelian Zhang, Xufang Gong and Bixin Li</i>	

Session User Centered Design

Automated user-oriented description of emerging composite ambient applications	473
<i>Maroun Koussaifi, Sylvie Trouilhet, Jean-Paul Arcangeli and Jean-Michel Bruel</i>	

Usability of Chatbots: A Systematic Mapping Study	479
<i>Ranci Ren, John W. Castro, Silvia T. Acuna and Juan de Lara</i>	

Extending Behavior-Driven Development for Assessing User Interface Design Artifacts (S)	485
<i>Thiago Silva, Marco Winckler and Hallvard Trætteberg</i>	

Session Software Development III

A Method to Recommend Artifacts to New Tasks in Software Projects (S)	489
<i>Edson Lucas, Toacy Oliveira and Paulo Alencar</i>	

SOTagger - Towards Classifying Stack Overflow Posts through Contextual Tagging (S) . . .	493
<i>Akhila Sri Manasa Venigalla, Chaitanya S. Lakkundi and Sridhar Chimalakonda</i>	

An annotated repository for MATLAB code (S)	497
<i>Antonio Relvas, Nuno C. Marques, Miguel Monteiro and Glauro Carneiro</i>	

Session Fuzzy and Stochastic Approaches

BDFIS: Binary Decision Access Control Model Based On Fuzzy Inference Systems.	503

Abstract—Medical data is amplified in terms of speed and capacity in a very fast way, which creates obstacles for users to quickly access valid information. We present a DIK-based Question-Answering Architecture for Medical Self-Service. In addition, we propose a model based on the attention mechanism to extract high-quality medical entity concepts from the Chinese Electronic Medical Records (EMR). Then we modeled the medical data based on the DIK architecture (Data graph, Information graph, and Knowledge graph), construct a Question-Answering model (DIK-QA) for medical self-service that meets the needs of users to quickly and accurately find the medical information they need in massive medical data. Finally, we have realized this approach and applied it to real-world systems. The experimental results on our medical dataset show that the DIK-QA can effectively handle 4W (who/what/why/how) questions, which can help users find the information they need accurately.

Keywords—Data graph, Information graph, and Knowledge graph (DIK); Question-Answering (QA); Electronic Medical Records (EMRs); attention mechanism

I. INTRODUCTION

Recently, knowledge graph have increasingly attracted attention in various fields. Medical Knowledge Graph (MKG) is also very popular in the medical field due to the unique expression of knowledge graph. Researchers explore with various approaches to construct the MKG. Reference [1] used deep learning method to extract 4 entities and 9 entity relationships from Chinese electronic medical records (EMR), then adopted the triple form to import data into the Neo4j and visualized the data into a knowledge graph. Reference [2] built a medical field table by using Bootstrapping and Conditional Random Fields (CRF) and solved the actual problem based on the obtained knowledge graph.

At present, research on knowledge graph is endless. Cowie et al. divided the knowledge graph into Data Graph (DG), Information Graph (IG) and Knowledge Graph (KG) according to the concept of Data, Information, Knowledge, and Wisdom (DIKW) [3].

However, there is a gap to fill for combining the MKG with the QA model. There are basically two major challenges. The first challenge is no effective framework for the union between QA and MKG for medical services. The second challenge the reliability of medical knowledge base. By addressing two major challenges, we solve and successfully construct a DIK-based QA for medical self-services. The complete structure of the DIK-QA is shown in Fig. 1. The contributions of our work are: 1) According to [4], we constructed the medical self-service DIK-QA based on the DIK. It can model massive amounts of data and quickly and accurately find the information users need and provide services to users in a friendlier manner, 2) We guarantee the data reliability of the medical knowledge base from two perspectives: clinical knowledge and health information. For clinical knowledge, we use the model BiLSTM-Attended-CRF model to obtain a higher quality medical entity concept. For health information we adopt the distributed crawlers to collect richer information, such as dietary advice and rehabilitation exercises.

II. FRAMEWORK

We divide the work into three parts: a) designing a DIK-QA framework (including three layers of knowledge graph), b) data acquisition, c) DIK-QA implementation. As shown in Fig. 1.

A. DIK-QA Architecture

According to the DIKW [3] idea, the medical knowledge graph can be divided into three categories: 1) Data graph, 2) Information graph, 3) Knowledge graph.

Data Graph Data graph can record the frequency of the data, including spatial frequency and structure frequency. We refer to the definition of data frequency in [4] to define the medical data frequency as a two-tuple.

$$DFreq = \langle f_{spatial}, f_{structure} \rangle \quad (1)$$

Where the spatial frequency, structure frequency of data are represented by $f_{spatial}$, and $f_{structure}$, respectively. The frequency of structure and spatial are the medical department of the disease and the treatment, respectively. As shown in Fig. 2.

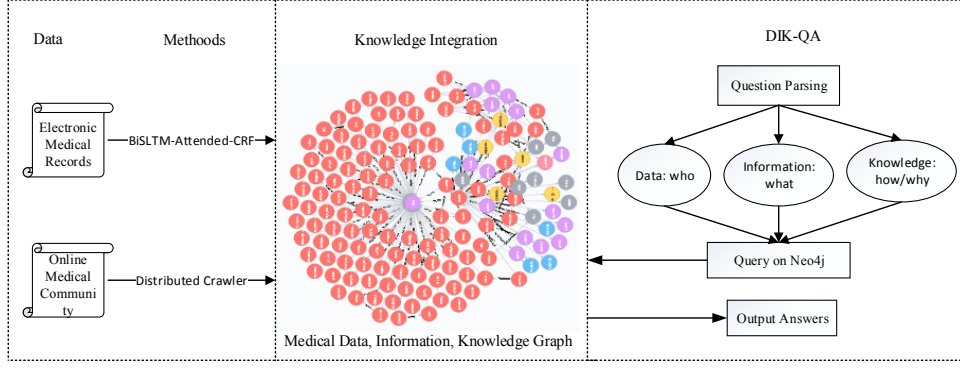

Figure 1. Overview of the DIK-QA Architecture for Medical Self-Service

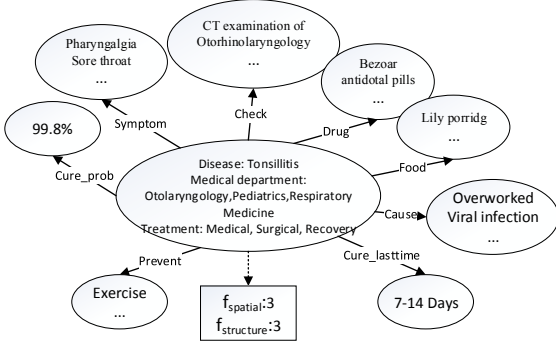

Figure 2. Statistics on $f_{spatial}$ and $f_{structure}$ of medical data.

Information Graph Information is extracted from the data for analysis and interpretation. We store the collected data as the medical knowledge base in dictionary format, as shown in Fig. 3. We define the medical knowledge base as the directed graph $G(V, E)$. The nodes and edges are denoted by V , E , respectively.[4]

$$Com_degree = \sqrt{deg^+ \times deg^-} \quad (2)$$

$$Impor = \alpha DFreq \times \beta Com_degree \quad (3)$$

The in-degree and out-degree of the node are represented by deg^+ , deg^- , respectively. In order to prevent the loss of the information, we adopt (3) to further measure the importance of the nodes. The weights of the $DFreq$ and the Com_degree is denoted by α , β .

Knowledge Graph Knowledge is the overall understanding and awareness gained from the accumulated information.

$$Cr(E_1, R, E_2) = \frac{\sum_{\pi \in Q} P(E_1 \rightarrow E_2) \theta(\pi)}{|Q|} \quad (4)$$

We use (4) to calculate the correctness of the relationship between E_1 and E_2 . Before we construct a medical knowledge graph, we need to design the knowledge graph: entity type nodes and entity relationship nodes, as shown in TABLE 1, 2.

Where all path between E_1 and E_2 are represented by Q , the weights of single path and path are represented by $\theta(\pi)$, π .

We comprehensively evaluate the importance of the nodes on the knowledge graph according to (5). N is the number of the relationship types. The weight of Rel_i is represented by λ_i .

$$Final_Impor = Impor \times \gamma \frac{\sum_{i=1}^n \lambda_i \times Rel_i}{n} \quad (5)$$

After completing the design of the DIK-based medical knowledge graph, we use the py2neo module in Python to import the dictionary type data into the Neo4j. As shown in Fig.1.

TABLE 1. The definition of the entity nodes

Entity nodes	Meaning
Department	Disease department
Disease	Disease name
Drug	Drugs for treating the disease
Cause	Cause of the disease

TABLE 2. The definition of the relationship nodes

Relation node	Meaning
do_eat	Recommended food for the disease
recommend_drug	Recommended drug for the disease
has_symptom	Disease corresponding symptoms
cure_way	Treatment for disease

B. Data Acquisition

In [1], we have extracted five entity types and nine entity relationship types by the BiLSTM-CRF model. However, we propose a novel model based on the Chinese EMR to improve the accuracy of the entity recognition, combining BiLSTM-CRF model with attention mechanism, as shown in Fig.4. Please refer to [1] for the BiLSTM-CRF model.

TABLE 3. The labeling rules of the Chinese EMR

Label Prefix	Label Suffix	Meaning
B	DISEASE,TREATMENT, CHECK, ,BODY, SIGNS	Head of the entity
I	DISEASE,TREATMENT, CHECK, ,BODY, SIGNS	Middle and tail of the entity
O	None	Other words

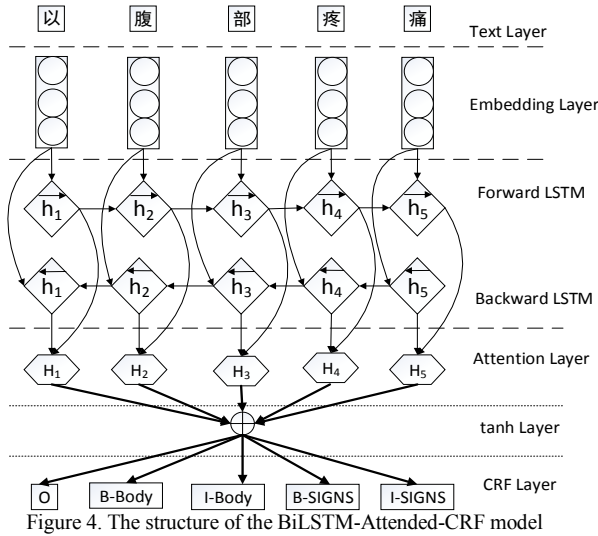

Figure 4. The structure of the BiLSTM-Attended-CRF model

BiLSTM-Attended-CRF Attention mechanism is a mechanism to simulate the attention of the human brain. The core idea is to draw on the attention of the human brain to things at a certain moment, it will focus on a certain key point, and ignore other key points [5]. We introduce the attention mechanism between the BiLSTM layer and the CRF layer to solve the challenge of extracting more precise semantic features for named entity recognition of Chinese EMR. Specifically, the attention mechanism is applied to the hidden layer of BiLSTM and then produces the newly hidden layer vectors. The implementation of the attention mechanism is as shown in (6)-(8).

$$e_{ij} = V \tanh(U_1 \vec{h}_i + U_2 \vec{h}_j + b_\alpha) \quad (6)$$

$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{j=1}^T \exp(e_{ij})} \quad (7)$$

$$\vec{H}_i = \sum_{j=1}^T \alpha_{ij} \vec{h}_j \quad (8)$$

Where e_{ij} represents energy value of the j th word to the i th word, that is to say, the relationship between the two words. We use α_{ij} represents the attention weight of the j th word to the i th word, reflecting the influence of each vocabulary in the input text X . V , U_1 , U_2 , b_α is the parameter trained with the model. The new feature representation after the attention mechanism in Forward-LSTM Layer and Backward-LSTM is represented by \vec{H}_i , respectively. We combine two new feature representations to form the final feature representation $H_i = [\vec{H}_f, \vec{H}_b]$. After the attention layer, it will pass the activation function tanh layer, then pass the mapping results of tanh layer to the CRF Layer. Finally, the model can output the predicted label sequence for input text, as shown in Fig. 4.

Disease-Oriented We constructed a medical entity dictionary for recognition of the BiLSTM-Attended-CRF model. We take the knowledge fusion based on the medical concept in the dictionary to eliminate some ambiguous entities. The Disease-Oriented Knowledge base has the advantages: the disease can integrate various information

such as symptoms, checks, causes, foods and drugs et al. into one line, as shown in Fig. 2.

C. DIK-QA Implementation

The DIK-QA model is consist of three parts: Analysis question, Question division, Query knowledge. As show in Fig.1.

Analysis question The DIK-QA can analysis the question in plain language way by the BiLSTM-Attended-CRF model. In this part, we can get the medical entity in the question, then we submit the identified results to the next part-Question division.

Question division After the analysis question, we can get the category of question. By classifying the user's questions, we can accurately get the intent of user. According to the frequency statistics on the types of questions and vocabulary that appear in the Q&A module on the medical website, we summarize two main types of questions: 1) Entity relationship template. It can solve the question of entity relationship query, including disease and symptoms, disease and drug, food, treatment and so on. For example, "what are the symptoms of hypertension?", "Recently dizzy, what disease might I get?", etc. 2) Entity attribute template. It can solve the question of entity attribute query, including disease prevention, cause and so on. For example, "why do I get the hypertension?", "Precautionary measures for the hypertension?".

Query knowledge We can take the query on the Neo4j based above part. We take the Aho-Corasick (AC) algorithm [6] as the core method to realize the Query knowledge. AC automaton is the most classic multi-pattern matching algorithm. It uses a plurality of pattern strings to construct a finite state pattern matching automaton. The DIK-QA performs knowledge reasoning on the corresponding knowledge graph (DIK) according to different question types, so that the answer can be quickly found. We can convert the question to cypher query statement and search the corresponding answer, and then return it. Cypher is a graph query language designed for operating Neo4j that efficiently queries and updates knowledge graphs. It has more powerful than SQL in relational capabilities. For example, Question: what are the symptoms of tonsillitis? Cypher statement: Match (m: tonsillitis) -[r: has_symptom] → (n: Symptom) where m.name = '{0}' return m.name, r.name, n.name. Where r, m, n are the variables of the disease name, relation: has_symptom, and symptom node, respectively. Node definition refer to TABLE 1, 2.

III. EXPERIMENTS AND RESULTS

A. Experiments on BiLSTM-Attended-CRF

To evaluate the performance of the BiLSTM-Attended-CRF model, we compared several basic model. The EMR data

from the local hospital. Other medical data comes from two medical websites¹. The evaluation indicator adopts accuracy, recall rate, and F value. The comparison algorithm uses common models such as CRF, BiLSTM, and BiLSTM-CRF. We tested 100, 128, 200, 256 and 300 on word vector dimension. The BiLSTM-Attended-CRF model has a good performance when word vector dimension is 128. Learning rate is 0.001, the LSTM layer is 4. Dropout is 0.4. The experimental results are shown in Table 4.

TABLE 4. Experimental results of each model for entity recognition

Model	P (%)	R (%)	F (%)
CRF	60.45	58.72	60.13
BiLSTM	61.42	58.23	57.68
BiLSTM-CRF	83.53	78.38	80.35
BiLSTM-Attended-CRF	89.76	85.51	88.90

The experimental results show that the BiLSTM-Attended-CRF model has better performance than state-of-the-art baselines in entity recognition. F-value and accuracy increased by 6%. In our model, all three evaluation marks have been improved.

B. Experiments on the DIK-QA

To evaluate the effectiveness of the DIK-QA, we selected five common diseases as small sample data, including cold, pediatric cold, hypertension, diabetes, cervical spondylosis. Observed from Fig.5, we can know that the DIK-QA can solve effectively some common question.

<p>DIK-QA work situation</p> <p>...</p> <p>User: 如何治疗感冒? (How to cure a cold?)</p> <p>Doctor: 感冒可尝试如下治疗: 中医治疗, 支持性治疗, 对症治疗。(You can try the treatments for cold: Chinese medicine treatment, supportive treatment, symptomatic treatment.)</p> <p>User: 感冒的症状都有什么? (What are the symptoms of a cold?)</p> <p>Doctor: 感冒的症状有: 鼻塞, 咽痛, 发热, 头痛等。(The symptoms of a cold are nasal congestion, sore throat, heat, and headache etc.)</p> <p>User: 感冒忌吃什么食物? (What food can't you eat when you have a cold?)</p> <p>Doctor: 感冒忌吃: 猪油, 咸鱼, 白扁豆, 油条等。(Avoid eating: lard, salted fish, and fritters, etc)</p> <p>User: 感冒应该吃什么食物? (What food should I eat for a cold?)</p> <p>Doctor: 感冒应该吃: 鸡蛋, 芝麻, 南瓜子仁, 鹌鹑蛋。(Recommend eating: egg, pumpkin seed kernel, sesame, quail eggs)</p> <p>User: 为什么会感冒? (Why do people catch a cold?)</p> <p>Doctor: 感冒的可能成因: 病毒感染 (70%-80%), 有受凉、淋雨、过度疲劳等诱发因素, 导致抵抗力下降。(The possible causes of a cold: viral infection(70%-80%), or factors such as cold, rain, excessive fatigue, etc., which can reduce the resistance...)</p> <p>...</p>
--

Figure 5. The DIK-QA's work situation

IV. RELATED WORK

In 2006, Rowley [7] revisits the data-information-knowledge-wisdom (DIKW) hierarchy and analyses the statement about the nature of data, information, knowledge, and wisdom. Through this process we get a consensus on definitions and transformation about DIKW. It makes the theoretical development of the further development of the DIKW. Duan et al. [8] proposes to clarify the expression of knowledge graph as a whole for lacking a unified definition and standard expression form of knowledge graph. They clarify the architecture of knowledge graph from data, information, knowledge and wisdom aspects respectively. They also propose to specify DIKW-based knowledge graph. Moreover, Song et al. [9] proposed a processing optimization mechanism of typed resources in a wireless-network-based

three-tier architecture consisting of DIK mechanism. Simulation results show that the proposed approach improve the ratio of performance over user investment.

V. CONCLUSIONS

The main task of this paper is: 1) we propose a highly accurate medical entity recognition model--BiLSTM-Attended-CRF to extract the high-quality medical concepts, 2) we construct the DIK-QA for medical self-service. The DIK-QA is mainly focused on some common diseases and questions such as colds, headaches, fever, ligament strains and some special diseases: pneumonia, etc.

However, there are still some shortcomings in this paper. We can combine DIK-QA with the deep learning method to automatically analyze the problem. Then, we can construct a smarter medical self-service. We can also try to construct a wider application of the DIKW architecture.

{junmingcao, tjsoulshe, bjshen, li_wei, wuqinyue, chenyt}@sjtu.edu.cn

Abstract—Coding conventions are a set of coding guidelines used by software developers to improve the readability of source code, increase software maintainability, and promote the reuse of coding patterns. In this paper, we introduce *CCBase*, a knowledge base of coding conventions, that was constructed from online resources. Specifically, *CCBase* was constructed as follows. We designed the ontology of the coding convention domain, crawled data related to coding conventions from a variety of online resources, and then extracted entities and relations using an NLP-enabled rule matching method. To uncover the latent relations, we further proposed a similarity metric to reveal the similar-to and relate-to relations, and developed a RCE algorithm to establish a unified type hierarchy of coding conventions. The resulting knowledge base contains 3139 coding conventions for Java and C++, with 3761 entities and 767 relations. Furthermore, we have extended the usability of *CCBase* by developing a question answering system on the base. We have conducted experiments to evaluate *CCBase*. The experimental results show that *CCBase* has a wide coverage on entities and relations in coding conventions domain, and the QA system achieves an F1 score of 84.5% on 214 questions raised in StackOverflow.

Keywords - *Knowledge Base; Coding Convention; Type Hierarchy; Question Answering*

I. INTRODUCTION

Coding conventions are a set of guidelines for a particular programming language that recommend programming styles, practices, and methods for each aspect of a program written in that language. During increasingly large and complex software development, programmers are strongly encouraged to follow these guidelines to help improve the readability, reliability, and maintainability of their source code [1]. These coding conventions can also assist code related software engineering activities, like auto-detection of code bad smells [2] and code analysis [3].

However, programmers now encounter the following problems when applying coding conventions. One is that coding conventions specified in single document are incomplete because it could hardly cover a • ll coding details, and also the relations between coding conventions could not be expressed explicitly. The second problem is that coding conventions are inconvenient to access. Programmers need to know relevant keywords to search using a search engine like Google or search

in documents, which is especially difficult for some novice programmers who lack professional knowledge.

In order to solve the above problems, we construct a coding conventions knowledge base, *CCBase*. *CCBase* is a domain-specific knowledge base, which is constructed from online resources using a top-down approach. Specifically, we first design the ontology of coding conventions domain. Then we collect data related to coding conventions from various online resources and extract entities and relations with an NLP-enabled rule matching method. The main challenge is to discover latent relations between coding conventions, including similar-to, relate-to, and especially subsumption relations, from these heterogeneous textual documents. So we designed a similarity metric to discover similar-to and relate-to relations, and propose the RCE (Relation based Cluster Expansion) algorithm to establish a unified type hierarchy of coding conventions and assign types of each coding convention. Finally, we develop a question answering system over *CCBase* to answer natural language questions automatically. *CCBase*, its SPARQL interface, and QA system can be accessed in our online platform¹.

Our main contributions are summarized as follows:

1) To our best knowledge, *CCBase* is the first knowledge base of coding conventions. It contains 3139 coding conventions of Java and C++, 3761 entities and 767 relations.

2) We propose the RCE algorithm to establish a unified type hierarchy of coding conventions. Structures of online resources entail original type hierarchies for coding conventions. However, some coding convention resources lack a hierarchy. The hierarchy extracted from one document is usually unilateral, and also different from another extracted hierarchy. Besides, every coding convention only has one type value with the original type hierarchy, which is also not comprehensive. Therefore, a novel unsupervised algorithm (RCE) is designed to build a unified type hierarchy according to the similar-to relations and assign new type values to coding conventions.

3) We develop a coding convention question answering system over *CCBase*, *CCQA*. The main algorithm of *CCQA* is subgraph matching, and we make two significant improvements to this algorithm. First, the entity linking method is changed to identify the entities regarding coding conventions in the question. Second, we collect common question templates and recognize

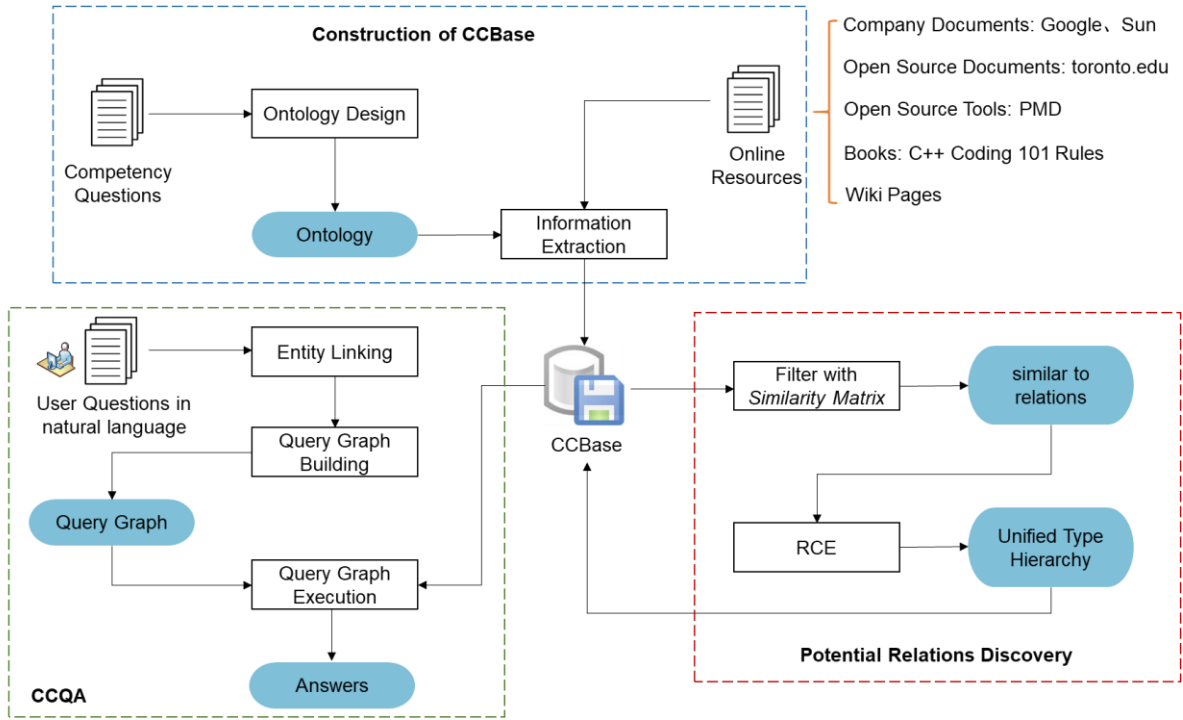

Figure 1. Overview of Our Approach

these templates from user questions, which improves the accuracy of subgraph building

4) A set of comprehensive experiments has been carried out to evaluate CCBASE. The results show, CCBASE is larger and more hierarchical than existing knowledge bases regarding code conventions; and our QA system achieves an F1 score of 84.5% on 214 questions raised in StackOverflow.

II. RELATED WORK

A. Construction of Knowledge Base

There are two ways to construct a knowledge base: top-down and bottom-up. Top-down means pre-defining the ontology of a knowledge base, and then importing entities and relations according to the ontology into the knowledge base. Knowledge bases of specific domains mostly adopt this way [5]. Bottom-up means directly obtaining entities and relations by syntactic analysis without ontology, which is common for general knowledge bases [6]. These two ways include similar steps such as information extraction and knowledge fusion.

In the software engineering domain, a few researchers have tried to build a domain knowledge base, like SEBase [5] and APIBase [7]. However, to our best knowledge, there is no published work on coding convention knowledge base.

B. Type Hierarchy Building

Types are common in knowledge bases to organize entities, and type hierarchy is their key knowledge or meta-knowledge. [8] proposed an entity-driven approach to construct type hierarchy of knowledge base systems without hierarchy structures. The type hierarchy construction problem is similar to the community detection problem. Semi-supervised algorithms, like LPA [9], are widely used in community detection, and [10]

proposed SLPA to deal with overlapping communities. However, these methods aren't suitable for our work, because our relations in CCBASE are too sparse to propagate labels from a few seed entities, and structures of documents are very helpful to build the type hierarchy. Thus in this paper, we propose a novel unsupervised algorithm (RCE) by fully utilizing structures of documents.

C. Question Answering over Knowledge Base

Some research effort has been conducted to KBQA (Question Answering over Knowledge Base) systems [12][13], which led to major advances. So far there exist two mainstreams of KBQA methods. One mainstream is semantic parsing. The main idea of this kind of solution is to translate the questions into logical forms such as query graph, then generate executable queries [12]. Information retrieval is another mainstream, which selects candidate answers directly and then ranks these answers by various approaches, such as deep learning [13].

Our work belongs to the first one. Since natural language is complex and ambiguous, semantic parsing usually requires multiple steps, like part-of-speech tagging and entity linking.

III. CONSTRUCTION OF CCBASE

We construct CCBASE in a top-down way for the following reasons: 1) Bottom-up is difficult to meet the quality requirements of domain-specific knowledge base. 2) The complexity of entities and relations in the coding conventions domain is tractable enough to be designed in advance. 3) Entities and relations could not be automatically obtained by syntactic analysis, so ontology is necessary to guide the extraction of entities and relations.

The overall approach is shown in Fig. 1. We first design the ontology of CCBBase, then extract the information from the semi-structured and unstructured data, and finally discover the latent relations between coding conventions.

A. Ontology Design

We collect massive coding conventions from various online resources, including coding conventions published online by companies, standards organizations, research groups and experts, coding conventions in open source tools, books, wiki pages, etc. The ontology is initialized from the investigation of these data. We use Protégé², an open source software developed by Stanford, to design the ontology.

Then we use the competency question-driven method to perform ontology improvement [14]. We select 30 competency questions from 214 coding convention related questions from StackOverflow, and improve the ontology until these questions could be answered with the ontology. The final ontology has 11 key concepts and 14 kinds of relationships, as shown in Fig. 2.

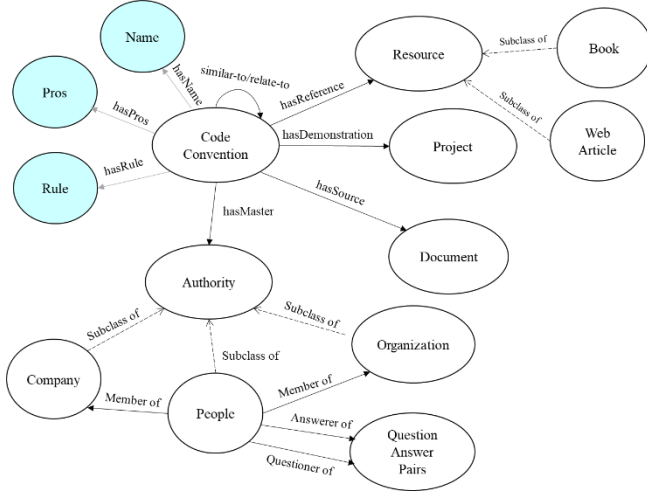

Figure 2. Ontology of CCBBase

B. Information Extraction

Guided by the ontology, we extract instance data from collected textual materials and store them in CCBBase.

The syntactic analysis approach [15] is widely used to extract <subject, predicate, object> triples from sentences, but it isn't applicable for constructing CCBBase. It is because entities and property values of coding conventions could not be directly collected from sentences, and also predicates in triples parsed by syntactic analysis approach could not be used as relations in CCBBase. Therefore, we propose a semi-automated method to import entities and relations into CCBBase, which consists of four steps:

- 1) Parse file structures of documents.
- 2) Define a set of rules based on keywords like "example", "benefits" and "author" to match candidates of entities, relations, and properties of entities.
- 3) Extract candidate entities and relations by rule matching.

² <https://protege.stanford.edu/>

- 4) After quality checking by experts, the final results are imported into CCBBase.

The semi-automated method is more accurate than the syntactic analysis method, while it does not cost as much as fully human collection method. Fig. 3 shows some entities and relations gained from information extraction, except for similar-to and relate-to relations, which would be discovered further in section C.

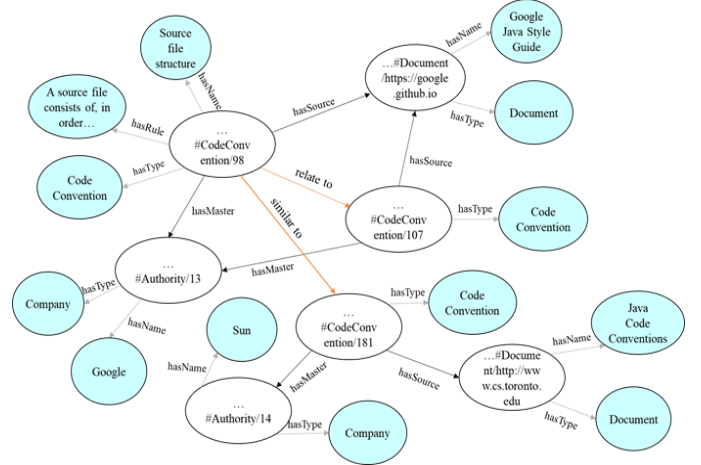

Figure 3. One Fragment of Instances in CCBBase

C. Relation Discovery

It is necessary to further discover the latent relations between entities. According to the ontology structure of CCBBase, the relations between entities include the relations between different coding conventions, and relations between coding conventions and other types of entities. The latter, like hasSource and hasMaster in Fig. 2, could be obtained through information extraction. Thus we focus on discovering latent relations between coding conventions.

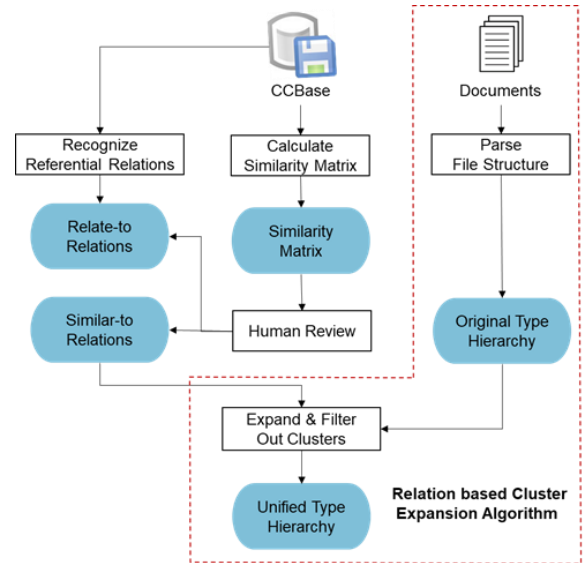

Figure 4. Relation Discovery

We propose a semantic similarity measuring approach to discover these following relations, as shown in Fig. 4.

1) **similar-to**. [16] lists a set of widely accepted metrics to measure the similarity between entities. Considering most properties of entities in CCBase are long texts, we adopt WHIRL as the similarity metric, which is based on TF-IDF. Then we set up a threshold by experiments to obtain the *Similarity Matrix*, which contains entity pairs with high WHIRL metric values. Finally, experts decide on whether entity pairs in *Similarity Matrix* have similar-to relations.

2) **relate-to**. There are two types of relate-to relations in CCBase. One is referential relations between coding conventions from the same document. The description of a coding convention may refer to other coding conventions in the same document. For example, the coding conventions named "Package Statement" in the Google Java Style Guide is described as "The package statement is not line-wrapped. The column limit (Section 4.4, Column limit: 100) does not apply to package statements." It refers to the coding convention named "Column limit: 100". For this type of relations, we could find them through information extraction. Another kind of relate-to relations come from entity pairs in the *Similarity Matrix* that do not have similar-to relations.

3) **subsumption**. There is an original type hierarchy of code conventions in each document. For example, coding convention named "Naming Convention" includes "Function Naming Convention", "Variable Naming Convention", etc. However, original type hierarchies have three shortcomings as described in the introduction section. Thus, we propose the RCE algorithm to establish a unified type hierarchy for coding conventions from all documents.

Algorithm: RCE

Input: Given entity set E , document set D , original type hierarchy set S . S_{ij} is the j_{th} primary type of type hierarchy S_i from D_i and S_{ijk} is the k_{th} secondary type belonging to S_{ij} .

Procedure:

1: Expand candidate entity clusters with the same type C according to relations.

```

for  $i, j$  in range(0, length( $D$ )), range(0, length( $S_i$ )):
     $C_{ij}.entity \leftarrow \emptyset$ 
     $C_{ij}.layer \leftarrow primary$ 
    for  $k$  in range(0, length( $S_{ij}$ )):
         $C_{ijk} = \text{Entities of } S_{ijk}$ 
        for  $e$  in Entities of  $S_{ijk}$ :
             $C_{ijk}.entity \leftarrow C_{ijk}.entity \cup similarEntities(e)$ 
             $C_{ijk}.layer \leftarrow secondary$ 
             $C_{ij}.entity \leftarrow C_{ij}.entity \cup C_{ijk}.entity$ 

```

2: Filter out replicated clusters and clusters with too few entities. Name every cluster to get type hierarchy R .

```

for  $c_1, c_2$  in  $C$ :
    if similarity( $c_1, c_2$ ) >  $\theta$ :
         $C.remove(c_2)$ 
        similarity( $c_1, c_2$ ) =  $|c_1.entity \cap c_2.entity| / |c_1.entity \cup c_2.entity|$ 
for  $c$  in  $C$ :
    if  $|c| < \delta$ :
         $C.remove(c)$ 
    else:
         $t.entity \leftarrow c.entity$ 

```

```

 $t.layer \leftarrow c.layer$ 
 $t.name \leftarrow \text{select one name from original types of } t.entity$ 
or make a new name
 $T.push(t)$ 

```

3: Generate type lists for entities.

```

for  $t$  in  $T$ :
    for  $e$  in  $t$ :
        if  $t.layer$  is primary:
             $e.primary\_type\_list.push(t.name)$ 
        else:
             $e.secondary\_type\_list.push(t.name)$ 

```

Output: Unified Type hierarchy T , entities set E' with primary and secondary type lists.

The unified type hierarchy T holds two layers: the primary layer, and the secondary layer. As we expand clusters with similar-to relations in Step 1, some entities would belong to multiple clusters and finally multiple types, like entities in Freebase. Thus, we use lists to store primary types and secondary types in Step 3. Although there are no direct relations between entities that share the same types, we could group these entities easily by type. This is the reason that we take it as a kind of relation. As a result, a unified type hierarchy for coding conventions is built with 16 primary types and 53 secondary types, as shown in Fig. 5.

Figure 5. Part of the Unified Type Hierarchy

When applied in CCBase, RCE has the following advantages over LPA and LPA-based algorithms, like SLPA:

- As LPA-based algorithms are semi-supervised, they need many labeled seeds or dense relations between entities to propagate labels, but relations in CCBase are too sparse. Since RCE is unsupervised, it does not suffer from this problem.
- RCE fully utilizes original type hierarchies of documents, while only one layer of original type hierarchies could be used as labels in LPA-based algorithms.

IV. QUESTION ANSWERING OVER CCBASE

To demonstrate the value of CCBASE, we develop a question answering system over it, called CCQA. It can assist programmers to retrieval information about coding conventions in a more natural manner.

Inspired by Hu et al.’s work [4], we propose the LE (long entity) Node-First framework to answer coding convention questions by subgraph matching. As Fig. 1 shows, we first extract semantic relations based on the dependency tree of question sentences to build a semantic query graph Qu . A semantic relation is a triple $\langle rel; arg1; arg2 \rangle$, where rel is a relation phrase, and $arg1$ and $arg2$ are its associated node phrases. After that, a SPARQL query statement is generated from Qu and then executed to get final answers.

LE (long entity) Node-First framework improves Hu et al.’s work from the following two points.

First, since entities about coding conventions are usually complete sentences instead of words or phrases, we use Jena Full Text Search and combine rule-based method for entity linking. We merge words within specific property of entities into one node to obtain clearer sentence structures, and thus the further generated dependency tree can achieve higher accuracy.

Second, when building a query graph Qu , the algorithm of [4] also extracts wh-words (what, how, why etc.) as nodes. However, if a question only contains one entity and does not contain any wh-word or relation, the query graph Qu will only be formed as one node and the query will be failed. Thus it could not answer Yes/No questions and declarative sentence. To improve the ability of CCQA, we collect some common question templates, such as questions begin with “*Is there any*”. These templates will also be recognized as nodes from questions.

So far CCQA has been developed as a plugin in IntelliJ IDEA, which can be downloaded from our Github project³.

V. EVALUATION

Several experiments have been conducted to evaluate CCBASE and CCQA.

A. Performance of Information Extraction

We construct CCBASE in a top-down way, extracting entities and relations from unstructured documents guided by ontology. To evaluate the effectiveness of this method, we compare it with two bottom-up extraction methods: the popular open information extraction tool – *open IE* [20] and a domain-specific extraction method – HDSKG [15]. Three popular metrics are selected: precision, recall and F1 score.

We collect 8 documents about coding conventions as the dataset of this experiment, and then we ask three experts to label the data manually. Fig. 6 shows the results of the comparison. Open IE and HDSKG both extracts the dependencies from sentences to generate relation triples. However, the entities and relations in coding convention domain are too complex to be directly extracted from one single sentence. The top-down extraction method outperforms HDSKG by 44.2% in F1 score.

Furthermore, we also conduct an experiment to compare the algorithms of relation discovery. We use LPA, SLPA, and RCE to build different versions of knowledge bases. The results are shown in Fig. 7. We can find that SLPA and RCE perform much better than LPA, because types generated by LPA do not overlap, which is unreasonable for coding conventions. Benefiting from the original type hierarchies of documents, RCE outperforms SLPA by 4.3% in F1 score.

Figure 6. Evaluation of Information Extraction Methods

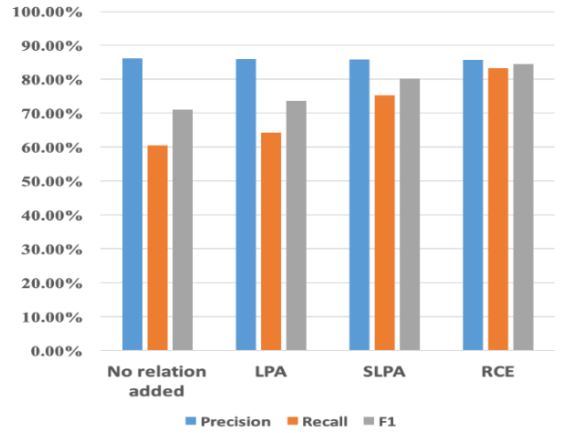

Figure 7. Evaluation of Relation Discover Methods

B. Comparison with other Knowledge Bases

As there are no public knowledge bases in the field of coding convention, we compare CCBASE with related subsets of a software engineering knowledge bases such as SEBase [5] and software.zhishi.schema [19]. We also compare it with YAGO [18], a general knowledge base.

TABLE I: Comparison with Other Knowledge Bases

	CCBASE	SEBase	zhishi	YAGO
Concept	3761	128	38	31
Subsumption	181	57	50	0
Relate-to	524	12	0	0
Similar-to	62	0	0	0

³ <https://github.com/14dtj/code-convention-robot>

Table I shows the number of entities and relations of each dataset. We could discover that our knowledge base is larger than other existing datasets as for the entity number related to coding conventions. Besides, the relations between entities are richer, especially as for subsumption and related-to relations.

C. Performance of Question Answering

We crawled 214 code convention questions from StackOverflow as experimental datasets. The performance of a QA system is measured by the ratio of questions that are answered correctly.

Figure 8. Evaluation of Question Answering Methods

We compare our approach (LE Node-First Framework) with Node-First Framework by Hu et al. [4]. Fig. 8 reveals the results on 214 questions. Node-First Framework adopts CrossWikis dictionary [17] to map entities in user questions, which is not suitable for long entity linking. Besides, it could not handle Yes/No questions and declarative sentences. It is shown that our LE Node-First Framework achieves 84.5% in F1 score, while the F1 score of original Node-First Framework is only 77.5%.

VI. CONCLUSION

In this paper, we designed and constructed CCBASE, the first coding convention knowledge base, from online resources. And for programmer's convenient access, a question answering system over CCBASE was further developed. Experiments show that CCBASE contains much more entities and relations about coding conventions than previous knowledge bases, and our QA system achieves an F1 score of 84.5% on 214 questions raised in StackOverflow.

As for future work, we will try to extract more entities and relations about coding conventions from Github and other Web sites to enrich CCBASE. Moreover, it would be interesting to explore more potential applications based on this CCBASE such as code bad smell detection.

Combining Time, Keywords and Authors Information to Construct Paper Correlation Graph

Hanwen Liu, Huaizhen Kou, Xiaoxiao Chi, Lianyong Qi*

School of Information Science and Engineering

E-mail: lianyongqi@qfnu.edu.cn

Abstract—Nowadays, recommender systems have become one of the main tools and methods for users to search for their interested papers from massive candidates. Typically, through analyzing the typed keywords by a user, a recommender system can easily retrieve the papers that cover the keywords, in an efficient and economic manner. However, one paper often only contains partial keywords that the user is interested in; therefore, the recommender system needs to analyze a pre-built paper citation graph and then return a set of papers that collectively satisfy the user's requested keywords. While the existing paper citation graph does not consider the possible self-citations and potential correlations among the papers that are not connected in the paper citation graph but with close publication time. Considering the above drawbacks, in this paper, we propose a link prediction approach that combines time, keywords and authors information for constructing a new relation graph. Finally, a case study is employed to explain our approach step by step and demonstrate the feasibility of our proposal.

Keywords—link prediction; paper citation graph; paper correlation graph; time; keywords; author information

I. INTRODUCTION

Currently, when searching for interested papers via existing paper search websites, e.g., Google Scholar and Baidu Academic, users can type their preferred keywords and then the websites will recommend appropriate papers that cover the typed keywords to the users [1]. Generally, a paper often contains only partial keywords that a user is interested in; therefore, to meet the user's paper search requirement, a paper recommender system often needs to return the user a set of papers that collectively cover all the requested keywords. However, the keywords of a paper can only represent the paper topics or themes; therefore, considering keywords only in paper search process may generate a set of papers that belong to different research domains and are actually not correlated, which fails to satisfy the original user requirements on deep and continuous research on a certain domain or topic.

Fortunately, paper citation graphs that depict the citation relationships among different papers have provided a promising way to model the paper correlations from both width and depth perspectives. However, current paper citation graphs still face a big challenge, i.e., they do not consider the possible self-citations from authors and potential correlations among the papers not connected in the paper citation graphs but with close publication time.

Considering this challenge, we propose a novel link prediction approach to improve the traditional paper citation graphs, as link prediction has already been proven the best solution for various link optimization problems in graphs [2][3]. More specifically, link prediction attempts to estimate the likelihood of the existence of a link between two nodes based on the existing properties information of nodes and network structures.

Overall, our contributions in this paper are three-fold:

- We propose a novel link prediction approach to construct new relation graphs among papers (i.e., paper correlation graphs). Our proposal considers a wide range of factors that influence the correlations among different papers, such as paper publication time, paper keywords and paper authors. In addition, our link prediction approach takes the network structure of paper citation graphs into considerations, which makes the predicted results more reasonable and convincing.
- We improve the existing paper citation graphs by reducing the negative influence of intentional self-citations from partial authors.
- At last, we evaluate the feasibility of our proposal through a case study.

The rest of paper is organized as follows. Related work is presented in Section II. In Section III, we introduce the research motivation. In Section IV, the details of our proposed link prediction approach is described. A case study is investigated in Section V to demonstrate the effectiveness of our link prediction approach. Finally, in Section VI, we summarize this paper.

II. RELATED WORK

Currently, link prediction has made massive strides in many research areas and played an important role in more and more fields. According to [4], link prediction approaches can be classified into three categories: similarity-based methods, maximum likelihood approaches and probabilistic methods. However, the similarity-based methods can be used to the large-scale networks, which is because it can calculate the similarity score between two nodes [5]; although maximum likelihood approaches can obtain specific parameters and probabilistic methods can predict missing links by using the trained model, maximum likelihood approaches and probabilistic methods often fail to deal with the large-scale networks [6]. Therefore, in our research we mainly consider the similarity-based approach. In addition, the work in [7] investigated the use of link strength

for the link prediction problem, and they proposed the weighting criterion was based absolutely on topological data: the frequency of existing interactions (i.e. the number of edges) between nodes in the social networks. But they don't take full advantage of node information in the weighting criterion.

In view of existing link prediction approaches, a novel the link prediction approach to construct the paper correlation graph, that is, the similarity-based weighting method.

III. RESEARCH MOTIVATION

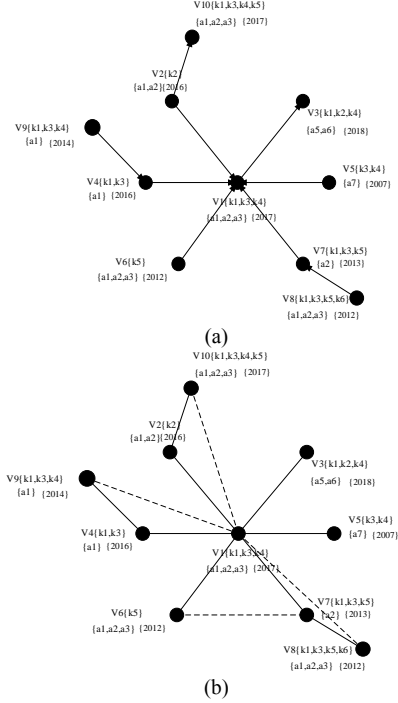

Figure 1. (a) Paper citation graph and (b) Paper correlation graph.

An intuitive example is presented in Fig.1 to motivate our paper. Assume that there is a paper citation graph G_C and a paper correlation graph G_P , Fig.1(a) and Fig.1(b) are a part of G_C and G_P , respectively. Fig.1 contains 10 nodes, i.e., v_1, \dots, v_{10} , each of which represents a paper and contains some node attributes (i.e., paper publication time, paper keywords and paper authors). In Fig.1(a), the self-citation relationship between node v_1 and node v_2 in the paper citation graph is generated merely due to the common authors of v_1 and v_2 , which is not reasonable and fair for accurate paper recommendation. Therefore, in this paper, we need to reduce the effect of the intentional self-citation phenomenon through a weighted approach. Besides, in Fig. 1(a), node v_1 and node v_{10} are published in same period and they also have common keywords and common authors, but there is no link (edge) between them. Thus, in Fig.1 (b), we need to establish the new link between node v_1 and node v_{10} by using the link prediction approach. In view of the aforementioned analyses, a link prediction approach is necessary to improve current paper citation graphs, which will be introduced in detail in Section IV.

IV. LINK PREDICTION APPROACH

According to the analysis of the research motivation, we propose a link prediction approach by using the attributes information and network structure of nodes. To the best of our knowledge, the fundamental process of the unsupervised link prediction model follows the task sequence, which was first proposed by Kleinberg [8]. Concretely, our process of link prediction approach can be seen from Fig. 2. This process mainly consists of the following five activities:

Activity 1: Pre-processing of the graph. In our research, the paper citation graph (G_C) is regarded as an undirected paper citation graph (G), which is because it is easier to construct the paper correlation graph.

Activity 2: Graph partition. In this activity, the G is divided in to two parts. One is training sub-graph (G_{train}) and another one is test sub-graph (G_{test}). In the G_{train} , we need to get the Maximum Score from existing pairs of nodes. And in the G_{test} , we need to get the weighted values of the two unconnected nodes.

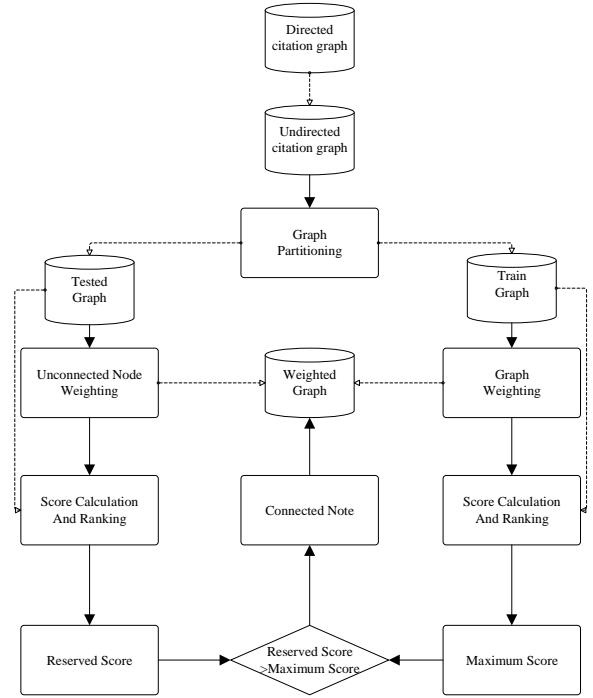

Figure 2. Process for weighting-based link prediction.

Activity 3: Graph to be weighted. The weights of the two connected nodes are calculated by using the weighting criteria in the G_{train} and the weights of two unconnected nodes are calculated in the G_{test} .

Activity 4: Score calculation and ranking. (1) Firstly, we use a similarity function formula WCN to calculate a weight value of two unconnected nodes in the G_{train} . Then we produce a ranking list in descending order of score. At last, the Maximum Score is saved in $w_{max}(v_{itrain}, v_{jtrain})$.

The Weighted Common Neighbor - $WCN(v_{itrain}, v_{jtrain})$ and the Maximum Score - $w_{max}(v_{itrain}, v_{jtrain})$:

$$\sum_{v_{jtrain} \in \Gamma(v_{itrain}) \cap \Gamma(v_{jtrain})} \frac{w(v_{itrain}, v_{jtrain}) + w(v_{jtrain}, v_{itrain})}{2} \quad (1)$$

$$w_{train}^{WCN}(v_{itrain}, v_{jtrain}) = \frac{WCN(v_{itrain}, v_{jtrain})}{|\Gamma(v_{itrain}) \cap \Gamma(v_{jtrain})|} \quad (2)$$

$$w_{max}(v_{itrain}, v_{jtrain}) = \arg \max_{i,j=1,N} w_{train}(v_{itrain}, v_{jtrain}) \quad (3)$$

Where $|\Gamma(v_{itrain}) \cap \Gamma(v_{jtrain})|$ represents the number of common neighboring nodes of node v_{itrain} and node v_{jtrain} .

(2) In the G_{test} , we will perform score calculation of two unconnected nodes and produce a descending ranking list.

Activity 5: Connecting nodes. LP (link prediction) is defined as in equation (4):

$$LP = \{w_{test}(v_{itest}, v_{jtest}) > w_{max}(v_{itrain}, v_{jtrain})\} \quad (4)$$

A. Proposed Weighting Criteria

Consider that each paper of the G contain paper attributes information (time, keywords and authors). In addition, the link prediction approach offers the similarity functions WCN that can be used for the weight calculation. Therefore, here we consider three sets of those functions: Time, Keyword and Author, and we propose the general weighting model as described in Eq. (5), where $time \in Time$, $keyword \in Keyword$, $author \in Author$ and $x_{time}, x_{keyword}, x_{author} \in \{0, 1\}$.

$$w^*(v_i, v_j) = time^{x_{time}} \times keyword^{x_{keyword}} \times author^{x_{author}} \quad (5)$$

The proposed general weighting model allows the generation of the different weighting criteria by Eq. (5). In addition, it is significant to emphasize that the product between the weighting criteria in link prediction approach formulation ensures that the selected node attributes must be considered simultaneously. Thus, we propose two different weighting criteria as below:

Keywords and Authors Weighting. In our research, if the number of common keywords and co-authors of two papers increases, the weighted values between the two nodes will be greater. But when there is no common keyword in two papers, the weighted values between the two nodes will decrease as the number of co-authors increases. Such strategies have been adopted to reduce the effect of the self-referencing. Thus, the weighting criteria for a pair of nodes v_i and v_j are defined as in equations (6)-(9):

$$\gamma = \begin{cases} 1 & \text{Contains common keywords} \\ 0 & \text{Otherwise} \end{cases} \quad (6)$$

$$cosine(K_{v_i}^a, K_{v_j}^a) = \frac{|K_{v_i}^a \cap K_{v_j}^a|}{\sqrt{|K_{v_i}^a|} \times \sqrt{|K_{v_j}^a|}} \quad (7)$$

$$cosine(A_{v_i}^a, A_{v_j}^a) = \frac{|A_{v_i}^a \cap A_{v_j}^a|}{\sqrt{|A_{v_i}^a|} \times \sqrt{|A_{v_j}^a|}} \quad (8)$$

$$w^{KA}(v_i, v_j) = C \times (r \times \beta^{(1-cosine(K_{v_i}^a, K_{v_j}^a))} \times \alpha^{(1-cosine(A_{v_i}^a, A_{v_j}^a))} + (1-r) \times \beta \times \alpha^{cosine(A_{v_i}^a, A_{v_j}^a)}) \quad (9)$$

Where α/β ($0 < \alpha, \beta < 1$) is arbitrary damping parameters used to calibrate the importance of authors and keywords in the weighting criteria. $A_{v_i}^a / A_{v_j}^a$ ($K_{v_i}^a / K_{v_j}^a$) is a set of authors (keywords) of the node v_i/v_j . $A_{v_i}^a \cap A_{v_j}^a / K_{v_i}^a \cap K_{v_j}^a$ represents the node v_i and node v_j have same authors/keywords. A constant C is defined for convenience of calculation.

Time, Keywords and Authors Weighting. According to the Keywords and Authors Weighting, if the published time of two papers are relatively close, the weighted values between the two nodes will be greater. Thus, the weighting criteria for a pair of nodes v_i and v_j are defined as in equations (10)-(11):

$$k(t_p) = \frac{t_c - \max(t_{p_{v_i}}, t_{p_{v_j}})}{t_c - \min(t_{p_{v_i}}, t_{p_{v_j}})} \quad (10)$$

$$w^{TKA}(v_i, v_j) = C \times k(t_p) \times (r \times \beta^{(1-cosine(K_{v_i}^a, K_{v_j}^a))} \times \alpha^{(1-cosine(A_{v_i}^a, A_{v_j}^a))} + (1-r) \times \beta \times \alpha^{cosine(A_{v_i}^a, A_{v_j}^a)}) \quad (11)$$

Where $t_{p_{v_i}}/t_{p_{v_j}}$ indicates the time of publication of the paper p_{v_i}/p_{v_j} , t_c is the current time.

B. Paper Correlation Graph

Definition1. Paper correlation graph: Paper correlation graph is represented by $G_p = \{V_p, E_p\}$, where V_p and E_p denotes its sets of nodes and edges respectively. In addition, the paper correlation graph is undirected. Meanwhile, for each paper, the paper correlation graph G_p has a corresponding node v , and for each of nodes pair (v_i, v_j) , the paper correlation graph contains the edge $e(v_i, v_j)$ between v_i and v_j .

V. A CASE STUDY

In this section, a case study is discussed to demonstrate the process of link prediction approach. Due to the limitation of the length of the paper, the case study only considers the first weighting criteria (i.e., the Keywords and Authors Weighting) for the link prediction task. Thus, the process of constructing the paper correlation graph is demonstrated as follows:

Figure 3. Paper citation graph.

Step1: Pre-processing of the graph. In our case, we regard the paper citation graph of Fig.3 as an undirected citation graph.

Step2: Graph partition. In our case, the G is divided into two parts. One is training sub-graph (G_{train}) and another one is test sub-graph (G_{test}). Therefore, in the Fig. 3, the (a) is the G_{train} and the (b) is the G_{test} .

Step3: Graph to be weighted. We use the Keywords and Authors Weighting to calculate the weight of two connected nodes in the (a) and two unconnected nodes in the (b). Meanwhile, we range the values of α ($0 < \alpha < 1$) from 0.5 to 0.7 with step 0.2, and $\beta=0.5$ (see Table 1). Here, we set up the different parameters value that will obtain the different weight value.

TABLE I. PARAMETERS SET.

Similarity function	Parameters set	
	α	β
$w^{KA}(v_i, v_j)$	0.5	0.5
$w^{KA}(v_i, v_j)$	0.7	0.5

(1) we use: $\beta=0.5, \alpha=0.5$ and $C=1$:

Weighted calculation in training sub-graph:

$$\begin{aligned} (v_1, v_2): r=0; \cosine(K_{v_1}^a, K_{v_2}^a) &= 0; \cosine(A_{v_1}^a, A_{v_2}^a) \approx 0.81; w^{KA}(v_1, v_2) \approx 0.29 \\ (v_1, v_3): r=1; \cosine(K_{v_1}^a, K_{v_3}^a) &\approx 0.71; \cosine(A_{v_1}^a, A_{v_3}^a) = 0; w^{KA}(v_1, v_3) \approx 0.41 \\ (v_1, v_4): r=1; \cosine(K_{v_1}^a, K_{v_4}^a) &\approx 0.87; \cosine(A_{v_1}^a, A_{v_4}^a) \approx 0.58; w^{KA}(v_1, v_4) \approx 0.68 \end{aligned}$$

Weighted calculation in test sub-graph:

$$\begin{aligned} (v_5, v_6): r=1; \cosine(K_{v_5}^a, K_{v_6}^a) &\approx 0.82; \cosine(A_{v_5}^a, A_{v_6}^a) = 0; w^{KA}(v_5, v_6) \approx 0.44 \\ (v_6, v_8): r=1; \cosine(K_{v_6}^a, K_{v_8}^a) &\approx 0.41; \cosine(A_{v_6}^a, A_{v_8}^a) = 0; w^{KA}(v_6, v_8) \approx 0.33 \\ (v_7, v_8): r=1; \cosine(K_{v_7}^a, K_{v_8}^a) &\approx 0.41; \cosine(A_{v_7}^a, A_{v_8}^a) = 1; w^{KA}(v_7, v_8) \approx 0.66 \end{aligned}$$

(2) we use: $\beta=0.5, \alpha=0.7$ and $C=1$:

Weighted calculation in training sub-graph:

$$\begin{aligned} (v_1, v_2): r=0; \cosine(K_{v_1}^a, K_{v_2}^a) &= 0; \cosine(A_{v_1}^a, A_{v_2}^a) \approx 0.81; w^{KA}(v_1, v_2) \approx 0.37 \\ (v_1, v_3): r=1; \cosine(K_{v_1}^a, K_{v_3}^a) &\approx 0.71; \cosine(A_{v_1}^a, A_{v_3}^a) = 0; w^{KA}(v_1, v_3) \approx 0.57 \\ (v_1, v_4): r=1; \cosine(K_{v_1}^a, K_{v_4}^a) &\approx 0.87; \cosine(A_{v_1}^a, A_{v_4}^a) \approx 0.58; w^{KA}(v_1, v_4) \approx 0.79 \end{aligned}$$

Weighted calculation in test sub-graph:

$$\begin{aligned} (v_5, v_6): r=1; \cosine(K_{v_5}^a, K_{v_6}^a) &\approx 0.82; \cosine(A_{v_5}^a, A_{v_6}^a) = 0; w^{KA}(v_5, v_6) \approx 0.62 \\ (v_6, v_8): r=1; \cosine(K_{v_6}^a, K_{v_8}^a) &\approx 0.41; \cosine(A_{v_6}^a, A_{v_8}^a) = 0; w^{KA}(v_6, v_8) \approx 0.47 \\ (v_7, v_8): r=1; \cosine(K_{v_7}^a, K_{v_8}^a) &\approx 0.41; \cosine(A_{v_7}^a, A_{v_8}^a) = 1; w^{KA}(v_7, v_8) \approx 0.66 \end{aligned}$$

Step4: Score calculation and ranking.

(1) For KA weighting criteria, when $\beta = 0.5$ and $\alpha=0.5$, we can get the Maximum Score, i.e., $w_{max}(v_{itrain}, v_{jtrain}) = w_{train}(v_2, v_4) \approx 0.55$. When $\beta = 0.5$ and $\alpha=0.7$, we can get the Maximum Score, i.e., $w_{max}(v_{itrain}, v_{jtrain}) = w_{train}(v_2, v_4) \approx 0.68$.

(2) In the G_{test} , we can get such a ranking list that $w^{KA}(v_7, v_8) > w^{KA}(v_5, v_6) > w^{KA}(v_7, v_8)$.

Step5: Connecting nodes. Seen from the Step 4, When $\beta = 0.5$ and $\alpha=0.5$, we can get such a ranking result that $w^{KA}(v_7, v_8) > w_{max}(v_{itrain}, v_{jtrain}) > w^{KA}(v_5, v_6) > w^{KA}(v_7, v_8)$. Therefore, we can draw a conclusion that v_7 with v_8 constructs a new link. And we can construct the paper correlation graph by connecting a pair of nodes v_7 with v_8 .

VI. CONCLUSIONS

In this paper, we mainly put forward a novel link prediction approach to construct the paper correlation graph. In addition, we investigated whether the combination of time, keywords and authors information in the weight computation could reduce the

effect of the self-citation. Finally, the feasibility of this the link prediction approach is validated by a case study. In the future work, we will design and deploy a set of real-world experiments to further prove the feasibility of our proposal. Besides, as recommendation process often involves the data privacy issues [9-18], we will further refine our work by considering the privacy-preservation.

Abstract—Cyber-Physical Systems (CPS) is usually associated with large numbers of domains. The domain relevance allows system engineers' knowledge to spread many domains. The efficiency and accuracy of modeling are not able to be guaranteed. Therefore, in this paper, a set of CPS modeling guideline is proposed based on SysML, and the system's 4-layer abstract hierarchy and the kind of modeling products obtained on each layer are defined. Based on this, a modeling specification containing seven sub-processes is designed. In order to verify the correctness of CPS function and the consistency of the business logic at the primary phase of the design, we summarize the mapping rules of SysML-Modelica and define the algorithm of model conversion. Finally, a simple CPS case is used to verify our task. The results show that this method can be effective in CPS's modeling and Simulation.

Keywords—Cyber-Physical Systems; Modeling ;SysML; Modelica;

I. INTRODUCTION

CPS is organic and in-depth integrity of Computation, Communication, and Control technologies, and a next-generation intelligent system that closely integrates and coordinates computational resources with physical resources [1-3]. CPS integrates such systems engineering as environmental perception, embedded computing, and network communication, closely coordinates computing and physical resources, covering all aspects of social life. As computing technology, network technology and control technology are constantly developing, CPS has become a new trend of research and development of modern information technology. Modeling and simulation are quite significant to the construction of CPS. It can not only verify the CPS at the primary phase of the design but also is an important section of model-based development and testing.

Since CPS is usually associated with multiple domains and the domain relevance allows the system engineers' knowledge to associate with many domains [4]. The efficiency and accuracy of modeling are not able to be guaranteed. Therefore, a set of the modeling guide of the CPS system based on SysML is proposed in this paper, and 4-layer abstract hierarchy of the system and the kind of modeling products obtained on each layer are defined. Based on this, a modeling specification containing seven sub-processes is designed. In order to verify the correctness of CPS function and the consistency of business logic at the primary phase of design, we summarize the mapping rules of SysML to Modelica model and define the algorithm of model conversion. Finally, a simple temperature control system case is used to verify our method.

The structure of this paper is organized as follows: In the DOI reference number: 10.18293/SEKE2019-167

second section, the background and the related work are overviewed. In the third section, the overall framework is proposed, and CPS modeling method, model mapping cabinet and conversion algorithm are described in detail. In the fourth section, the case analysis is performed. In the fifth section, summary and prospects are made.

II. BACKGROUND AND RELATED WORK

A. Cyber-Physical System

The typical CPS architecture mainly includes the following three kinds of parts: sensor, actuator, and controller [6]. The sensor is used to perceive all information of the physical domain. The controller can accept information from the sensor and send orders according to the control logic. The actuator receives a control order and begins to control the physical objects. The operation mechanism among the basic components is shown in Fig. 1.

Fig. 1. C typical Cyber-physical system

In the simulation study of the CPS system, Lin Jing et al. from the Missouri University of Technology used agent-based modeling to construct a model of CPS [7]. Based on the service-oriented architecture (SOA), the University of Texas proposed Physical-entity service model for CPS modeling [8]. Frank Wawrzik et al. proposed a SysML-based CPS modeling simulation method SICYPHOS CPS [4].

SysML (System Modeling Language) is a system modeling language extended from UML (United Modeling Language) [5,9-10]. Based on the nine types of SysML graphs, system engineering personnel can easily regulate term, model, design, and analysis and verification on the system [11], which is widely used in the industry field. Although SysML is widely used now, from the perspective of system security analysis, the current SysML specification cannot effectively support the dynamic simulation of physical engineering systems. Therefore, Modelica[12-13] will be selected for dynamic simulation of CPS in this paper.

III. MODELING AND SIMULATION OF CPS

Based on the analysis of SysML and Modelica features and the current challenges for CPS simulation and verification, we designed a CPS modeling and simulation framework based on

SysML and Modelica, and realized the SysML-Modelica automatic conversion tool (Fig.3).

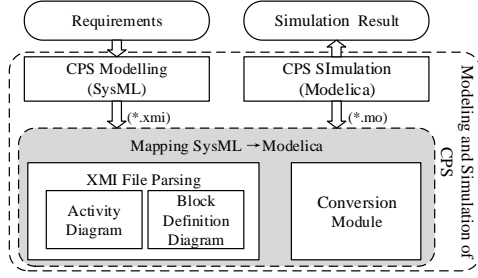

Fig. 2. Logic framework diagram of conversion

The overall logical framework is shown in Fig. 2: Firstly, construct SysML model according to the files and requirements of system design, and export of XMI [14] data model, and the automatic conversion of SysML-Modelica is realized according to the mapping rules of the construction model. Finally, input the Modelica model to verify the correctness of CPS function and the consistency of the business logic.

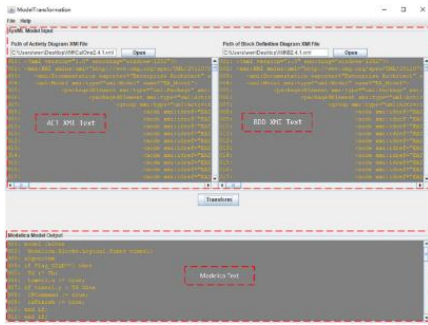

Fig. 3. Model Conversion Tool GUI

The workflow of data conversion processing and conversation in this process is shown in Fig. 4:

- 1) Use Enterprise Design (EA) to construct the CPS behavior model and structural model, and use export function owned by the EA tool to export the CPS SysML model as the XMI file;
- 2) Analyze XMI files with Java-based extension tool DOM4J;
- 3) Convert the extracted information into the grammatical format conforming to the Modelica modeling language, and output Modelica Text semantically equivalent to SysML information;
- 4) Use OpenModelica to simulate Modelica Text.

Fig. 4. Flow of data processing

There are two main technical points to achieving this work: (1) CPS modeling: Due to the increasing complexity of CPS, it makes the system modeling process more complex and difficult; (2) The conversion rules of SysML-Modelica modeling languages: Since SysML and Modelica are two different modeling languages, there are differences in

grammatical descriptions in many model elements. Therefore, we need to construct a set of semantic equivalent model conversion rules based on model semantics.

A. CPS Modeling

From the above analysis on the structure of the CPS system, it can be clearly known that all physical entities in the CPS only belong to one of these three types. When modeling the static structure, a structural model can be constructed for each entity. After structural modeling, it is required to model the dynamic behavior of each entity. When the industry world constructs the corresponding SysML model, select Block Definition Diagram (BDD) and Internal Block Diagram (IBD) that can express system architecture information, to construct a structure model and use Activity Diagram (ACT), Sequence Diagram (SD), or State Machine Diagram (STM) to express dynamic activity information. Considering the semantic features contained in our Modelica model, mainly use BDD to construct the structure model of CPS and use ACT to construct the activity model of CPS in this paper.

a) Modeling Guidelines

The complex structure and activity of CPS allow the modeling process of the system to be more complicated and difficult to grasp. One of the most effective ways to solving these problems is to construct a hierarchical model for the system. Abstraction layers that are hierarchical and clearly defined can effectively reduce system complexity which helps system modeling personnel to create and manage system models at different levels of granularity. We define the system 4-layer abstract hierarchy, which is the system layer, function layer, software and hardware layer, and deployment layer from top to bottom with an increasing amount of granularity described in each layer.

In the practical modeling, from the primary requirement of CPS, the modeling design process is divided into 7 sub-processes based on the four levels, and in each modeling process, different modeling tasks need completing.

Fig. 5. Modeling process

1) *Sub-process SP1* supports the development of primary requirements for system layer. The top-level requirements of the system are described from the angel of system realization according to the system prospect and the needs of relevant stakeholders.

2) *Sub-process SP2* supports system layer initial activity scenarios and the development of system structure. The initial behavior scenario describes a coarse- granular workflow; The development of the initial architecture mainly includes limiting system boundaries, defining system interfaces, and linkage between systems and external environment entities.

3) *Sub-process SP3*: Based on the output of SP1 and SP2, refine and expand the initial requirements, activity scenarios, and architecture, and focus point shifts to the internal system.

This process is a constant iterative course until the system engineering gets a satisfactory result.

4) *Sub-process SP4* is responsible for coordinating and integrating the cross-system layer and functional layer as well as the inconsistencies of requirements, activities, and structural products.

5) *Sub-process SP5* develops the requirements, activities, and architecture of the hardware and software layer based on the results of SP4 integration. The focus shifts from logical functional components to hardware or software components.

6) *Sub-process SP6* is similar to sub-process SP4, in charge of coordinating and integrating across functional layer and hardware layer as well as inconsistencies in requirements, activities, and structural products within the software layer.

7) *Sub-process SP7* is responsible for the designing scheme of deploying software and hardware to physical units.

B. XMI file Parsing

The information in the diagram can be read by parsing the XMI file of the active graph and the module definition graph.

The block definition diagram displays the static structure information of the system. Its main element is block. We can obtain the information contained in the entity through parsing block and its value attribute tags, and use Variable and Parameter respectively to save them. The Variable data type is used to store variables information in a block. As shown in Table 1, it includes two attributes: name and type, the name represents the variable name, and type represents the variable type. The Parameter data type stores information of parameters in a block, containing attributes' type, name, and value. The attributes' name and type have the same meaning as the Variable data type, and the value attribute represents the default value of the parameter.

TABLE I. THE MAPPING RELATIONSHIP BETWEEN XMI TAGS AND GRAPH ELEMENTS

Model	Graph element	XMI Label	Define data types	Contains properties
BDD	block	<packagedElement xmi:type="uml:Class">	Variable	type, name
	Value attribute	<ownedAttribute>	Parameter	type, name, value
	Activity zoning	<group>	ActivityPartition	name, classname, id
ACT	node	<node> <ownedParameter>	Node	id, name, classname, owner, type
	Transfer edge	<edge> <guard>	Transition	id, source, target, guard

The main elements in the activity diagram include nodes, edges, detection values of the edge, activity parameters, and active partitions. The basic element information corresponds to node, edge, guard, ownedParameter, and group of the label in the XMI file. As shown in Table 1, we store the parsed active graph elements into the following three data types: Node, Transition, and ActivityPartition. The Node data stores information of the control nodes, action nodes, object nodes, and active parameter elements in the SysML activity diagram, which contains 5 attributes in total: ID name, classname, owner, and type, respectively. Among them, type represents the node type and contains owned Parameter. The Transition data type stores information of the edge elements in the SysML activity diagram. Its specific type is shown as follow and contains 4 attributes in total like ID, source, target, and guard. id uniquely identifies one edge, source and target are the id values of the edge source node and the target node, and guard is the monitor value, that is, the transfer condition of the edge. The ActivityPartition data type stores information of active partition elements in the SysML activity diagram and contains three attributes in total like id, name, and classname. Id uniquely identifies an active partition, name is the name of the active partition, and classname is the type of active partition.

Based on the above analysis of the block definition graph and activity graph XMI file and customized data types, the element information under the tags is stored according to the corresponding data type created by traversing each label in the XMI file as required.

C. Mapping Rule of SysML2Modelica

According to the modeling rules for CPS in the previous section, we will obtain a series of block definition diagrams and activity diagrams. After establishing the mapping rule,

SysML model can be converted to Modelica model. The element in the block definition diagram is mainly converted to an element in the Modelica model declaration area, and the elements in the activity diagram are mainly converted to elements in the Algorithm area of Modelica model.

The block of the block definition diagram is the basic unit in SysML and corresponds to an instance of the Modelica model, thus establishing the mapping rules for SysML block and Modelica model. The value property of the block maps the variables of Modelica model; The port and components of the block (Instances of other modules) map to the member type in Modelica model. They are directly mapped to Modelica model equation if modular constraints are not combined with other SysML activity diagrams. At this, the structure of the module has been basically built successfully in Modelica model.

When modeling CPS, we use activity charts to represent the activity of CPS. The action in the activity diagram represents processing or transformation, so it is mapped to the equation of Modelica. Determines that the node is mapped to if-else judgment, and the merge node indicates that the above input continues to execute when arriving, and is mapped to continue executing downwards in the code of Modelica model.

The following table summarizes the rules for mapping elements in the above two SysML diagrams to Modelica elements.

TABLE II. MAPPING RULES BETWEEN SYSML AND MODELICA

	SysML	Modelica
BDD	block	model
	interfaceblock	connector
	port node	instance of
	value	connector variable

	constraint	equation
	decision node	if-else
ACT	merge node	execute sequentially
	action	equation
	State	Step
	Transition(no trigger)	Transiton

According to the above mapping rules, the model conversion algorithm is defined according to section 3.4, and the SysML diagram can be directly converted to Modelica code.

D. Model Conversion Algorithm

The conversion algorithm converts the block definition diagram and activity diagram into the Modelica model according to the conversion rules. The input of the algorithm is the XMI file for the block definition diagram and the active graph, and the output is Modelica model. The basic idea as follows: Firstly, use the resolution algorithm of the active graph XMI file to obtain all active partition collections, node collections, and edge collections. Construct a Modelica model for each active partition, and use the XMI file resolution algorithm in block definition graph to obtain the corresponding block variable collection and parameter collection, and then declare these variables and parameters in the model declaration area. If the activity diagram contains latency actions for relative time events, Declare an instance of Timer in the model declaration area. Then, go down from the starting node of the active partition and output different contents in the model algorithm region according to the node type, including selection, circulation, and concurrent structure processing. The specific model conversion algorithm is shown in Table 3 of the arithmetic.

TABLE III. SysML-MODELICA CONVERSION ALGORITHM

Algorithm: SysML2Modelica	
Input: Activity zoning set AP, node set N, edge set T, variable set V, parameter set P	
Output: Modelica model	
Procedure SysMLtransformModelica(M) Begin	
1. for each ap in AP do	
2. Create Modelica Model;

IV. CASE

In this section, a simple temperature control system [15] is used to illustrate how to model CPS, to convert into the Modelica model by mapping rules and finally conduct stimulation. The temperature control system is a temperature adjustment system involving temperature sensors, air conditioners and switch controllers. The system requires temperature control between 16 °C and 28 °C and limits the season to be summer. The temperature sensor senses room temperature and transmits the temperature to the switch controller. The controller learns the temperature and sends the coolOn or coolOff order after judging. The air conditioner implements cooling operations according to the corresponding order. If the air conditioning does not work, the temperature will gradually increase as time. Due to the space limitation, in this paper mainly take the switch controller as an example to illustrate.

A. Structure Modeling

The structure analysis on the temperature control system shows that temperature sensor corresponds to sensor entity in CPS, air conditioner corresponds to the actuator entity, and controller corresponds to the controller entity. For each such entity, block is used to define the basic information in the block definition diagram. The temperature sensor has 2 ports with one port perceiving temperature and one port transmitting temperature information to the switch controller. In this case, we require the temperature sensor to learn the temperature directly from the temperature port of the air conditioner. The controller also has two ports, one of which learns the temperature from the temperature sensor as described above, and one port sends order to the air-conditioning. Similarly, the air conditioner has a port for receiving order and a port for transmitting temperature. Besides, air conditioners accept different order and follow different temperature variable equation constraint. Temperature sensors follow only one working equation constraint. At this point, the block definition diagram for each entity and that for the port can be given. The BDD of the system is shown in Fig. 6.

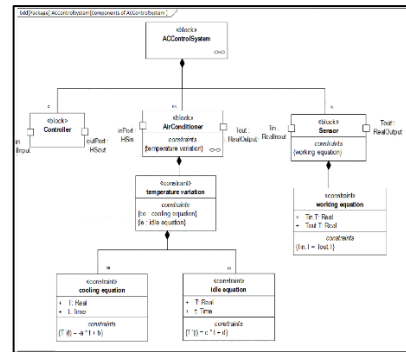

Fig. 6. System Entity Block Definition Chart

B. Behavior modeling

As mentioned above, for controllers SysML activity graph is used to represent activity information, controllers usually have complex control logic. The biggest advantage of activity graph is that they can represent the logical information well.

Fig. 7 is the activity diagram of the switch controller in the temperature control system.

Fig. 7. Activity Chart of Switching Controller

C. SysML-Modelica Model Conversion

Firstly, according to the entity block definition diagram, we know that there are three different entities in the entire system, and each entity corresponds to Modelica model. In terms of the switch controller, combined with the block definition diagram and the activity diagram, according to the SysML-Modelica model mapping rule in Section 3.3, Modelica code shown in Fig. 8 (a) can be obtained.

Fig. 8. Modelica code Code for Switch Controllers and Systems

Though temperature sensors and air conditioners belong to different types of CPS entities, alike switch controllers, they can be converted to Modelica code combined with module diagrams and model mapping rules. For all models required for StateGraphics library, automatically a line of Modelica code is required to "addinner Modelica.StateGraph.StateGraphRootstateGraphRoot;". It is pointed out particularly that the two temperature variance equations are quadratic equations of time t . After the time T is derived, two Timer types are required to add to the Modelica code to calculate the temperature variable. Finally, the important step is to connect all Modelica models according to BDD to form the entire temperature control system. From Fig. 6, we can see the system model Modelica code as shown in Fig. 8.

D. Analysis of Simulation Results

Introduce all model converted code into the OpenModel tool for simulation. We can know the variation of room temperature with the time in the temperature control system, as shown in Fig. 9. The entire room temperature fluctuates directly from 16 °C to 28 °C according to the switch controller.

Fig. 9. Temperature variable curve

V. SUMMARY AND DISCUSS

In this paper, firstly the architecture of CPS is analyzed and divide it into three types: sensors, actuators, and controllers. For the two aspects of structure and behavior, CPS is hierarchical modeling with SysML. In order to be able to simulate modeling, the mapping rules between the SysML-Modelica models are summarized. On this basis, the model conversion algorithm is designed, the SysML-Modelica model automatic conversion tool is realized, and an case analysis is conducted by the temperature control system. Although in this article the CPS modeling and simulation process based on SysML and Modelica has been realized, there are still shortcomings. We will further study the following two aspects: 1) Extend SysML-Modelica mapping rules to support automatic conversion of more SysML-Modelica models; 2) Provide more modeling language interfaces, such as SystemC. Establish a unified modeling and simulation framework for CPS that can be applied to more domains.

Abstract—Planning and monitoring the execution of software development activities in agile environments are not trivial procedures. One of the main flaws of agile planning is not considering the dependencies that exist between project tasks. Dependencies between tasks found in software development project plans may lead to the emergence of critical paths, where tasks need to be handled in a strict sequence because the completion of some tasks depends on the completion of others. Not managing such critical paths may reduce team performance and delay product delivery. We performed a study to demonstrate that not identifying dependencies may impair team performance and even increase the risk of costly project delays. The study is divided into three parts: (1) an exploratory study performed in the industry; (2) the development of a tool, AgileCritPath, as a way to support development teams in identifying critical project tasks; and (3) an *in vivo* evaluation of AgileCritPath based on the Technology Acceptance Model (TAM). The results of the exploratory study provided empirical evidence that there is a need to identify and control dependencies between the tasks in the development of software in agile environments. Using the AgileCritPath tool, allowed us to introduce the Critical Path Method concepts in an agile software development organization. Moreover, the *in vivo* evaluation demonstrated the benefits of managing tasks dependencies.

Index Terms—Software Engineering, Critical Path Method, Agile, Software Development.

I. INTRODUCTION

The software development principles behind the “Manifesto for Agile Software Development” are widely used in software development project management. Although the adoption of such agile principles brings numerous benefits, including the delivery of software products on time and budget [1], estimating and planning projects using agile methodologies is still a complex process. Part of this complexity comes from the difficulty of identifying dependencies between tasks, which is a critical factor for coping with agile project failures [2].

Dependencies between tasks often lead to decreases in team’s agility level [3] and can adversely impact the delivery time of software products. For Bick and his colleagues [4], managing task dependencies is a fundamental issue in agile software development, because it can be used as a basis to define the coordination between project tasks. Additionally,

proper identification of task dependencies is important to maximize project efficiency and reduce risks [5], [6], [7], [8], [9], [10].

The critical need to manage dependencies found in agile-based software development projects is a topic that has been already explored in the literature [5], [11], [4], [12], but, currently, empirical studies on the subject are still scarce. There is a clear need to investigate this topic further, given that the lack of knowledge about task dependencies may have consequences for project duration, coordination, risk, and efficiency.

To understand the problem of identifying the dependencies properly between agile projects and software development tasks, we conducted an exploratory study in a software development organization. Through this study, we obtained empirical evidence that this is a real problem that can negatively affect software development organizations, especially when they use agile methods. After performing the exploratory study, we used the techniques of the Critical Path Method (CPM) to inform a team in a specific software development organization that already uses agile methods about the critical tasks. We have also developed a tool, which we call AgileCritPath, to evaluate the adoption of CPM in an organization. The evaluation followed the Technology Acceptance Model (TAM) [13] approach.

This paper is structured as follows. After a brief introduction in Section I, Section II describes supporting concepts. Section III presents an Exploratory Study. Section IV presents the AgileCritPath tool and a TAM evaluation of this tool. Finally, Section VI presents conclusions and future work.

II. BACKGROUND

The increased adoption of agile practices has caused traditional project management to be redefined.

Many agile methods provide some level of management for tasks, but out of the main techniques applied [14] none guarantees that teams follow what was planned. Cohn [2], in his book “Agile Estimating and Planning”, addresses the main flaws of agile planning. Among them, the author cites that tasks are not independent and that it is an error for the agile

teams to plan the tasks as if they were separate, with no need for task coordination.

In agile methods, the technical work of the development team is defined through tasks. Each team estimates tasks and, generally, they represent a small part of the expected work [2]. Tasks can be visualized using the Kanban board presented in Figure 1. Kanban boards visually depict work at various stages of a process using cards to represent tasks and columns to represent each stage of the process. Cards are moved from left to right to show progress and to help coordinate the teams performing the work. The Kanban board is a visual approach that teams use to monitor task execution.

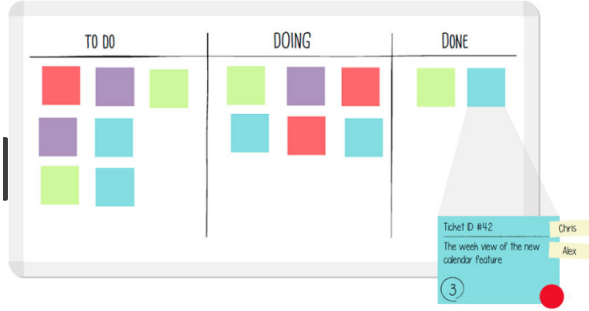

Fig. 1. Kanban board example.

Progress monitoring is an essential activity in Software management, whereby it ensures that a project plan advances according to budget, schedule, and quality expectations [15], [16]. The implementation of progress monitoring mechanisms in an agile environment is fundamental to the success of the project.

Although the Kanban framework is widely adopted in organizations, it does not show task dependencies. It is not possible to see on the Kanban board which tasks can block the execution of others and, for this reason, the flow of task execution becomes unclear to the team.

The Agile Kanban method lacks a mechanism for progress tracking. Thus, it needs to be integrated with other methods because it does not have a standard definition for software development and its specific practices have not yet been rigorously defined [12].

However, although managers can have, based on the Kanban board, support to understand progress status and progress better, they can not get information about the impact of the execution of the flow of tasks, especially when it comes to task dependencies.

III. EXPLORATORY STUDY - IDENTIFYING CRITICAL TASKS

To correctly understand the dynamics of the organization concerning project planning in an agile environment, we conducted an exploratory study in a specific software development organization. Exploratory studies have proved to be adequate in software engineering to study new ideas [17].

Through the exploratory study, we have: (1) observed the existence of dependencies between tasks in real software

development projects that use agile methods; (2) applied concepts based on the Critical Path Method to identify critical tasks in projects that use agile methods; (3) collected, analyzed and discussed the results. The exploratory study is divided into the following steps: definition of the study, data collection, data analysis, and presentation of results.

A. Definition

The study was conducted in a Brazilian software development company that has a staff of 30 employees, most of whom are software developers. The organization has been using agile methods for at least 10 years. Teams are small, usually groups of 3 to 8 people.

B. Data collection

The task execution log has been extracted from the Redmine¹ project management tool. Through the organization's task management system, we were able to identify which tasks were planned and which tasks were performed. We retrieved data from three iterations of the same project for analysis.

C. Data analysis

In this step, we identified the dependencies between tasks. The dependency identification was performed with the help of an experienced developer who was familiar with the scope of the tasks, the processes of the organization, and knew the technological architecture used in the project. Task dependencies were classified into Process and Context dependencies, following a classification suggested in a taxonomy of dependencies [5].

D. Results and discussion

From the analysis of the data, the projection of the maximum effort rate per period was obtained. Therefore, regardless of the number of people on the team, we can not plan activities with effort higher than the maximum effort rate. For the calculation of the maximum effort rate, we consider the estimated effort of the tasks performed by the team and their respective dependencies.

Figure 2 illustrates the planning performed by the team (blue line) and the maximum effort rate of the tasks (red line). The red line represents the shortest time to complete the activities and indicates the maximum rate of production (speed) at which the team can work. Regardless of the number of people, the tasks will not be completed before this deadline (red line). In this case, we can see that the team planned a delivery that can not be performed on the expected date.

Table I presents the number of dependencies identified in the study and the number of tasks defined by the team, which are extracted through the task execution log. The number of dependencies is higher than the number of tasks, within the three analyzed iterations.

¹redmine.org

Fig. 2. The burndown graph with maximum effort rate.

TABLE I
PERCEIVED DEPENDENCIES.

Release	Task	Dep	% Dep	Process Dep	Business Dep
Release 2.12	100	96	96%	52	44
Release 2.13	69	77	112%	53	24
Release 2.14	70	84	120%	67	17

Our results show that handling task dependencies may not be straightforward when there are many tasks. Another factor we noticed was that there were several tasks, and consequently, dependencies, that are were not planned but were identified during the iteration execution.

During the analysis of the Iteration execution log, we verified that some tasks were discovered during the execution of the iteration and, consequently, the execution flow of the tasks changed because the new tasks had dependencies that should have been considered. This shows that the identification of critical tasks should occur throughout an iteration, and not only at the end.

Based on the exploratory study we conclude that there is evidence that when considering task dependencies it is possible to find the critical tasks, which if delayed, can have serious consequences, including the product release delays. Because of this evidence, we decided to develop the work further and implement AgileCritPath, a tool that could help developers identify critical tasks. The tool implementation and details are presented in Section IV.

IV. THE AGILECRITPATH TOOL

The AgileCritPath tool implements the Critical Path Method to be used in agile environments and support teams to identify and prioritize critical tasks that can block the execution of other tasks and cause costly project delays.

A. Identifying Critical Tasks

During the exploratory study, we identified that some tasks compromise or block the flow of execution of other tasks. These tasks are referred to as Critical Tasks because they can decrease the agility level of the team.

The critical path is the longest duration path through the network. The tasks that lie on the critical path cannot be delayed

without delaying the release. In agile environments, Critical Tasks are identified by building a network diagram of tasks. This network diagram is built to represent task dependencies. Figure 3 presents an example of a network diagram with seven tasks. The solid lines represent dependencies between tasks, and the dashed lines represent the association of the tasks from the beginning to the end of the graph. Critical tasks are identified as the tasks that make up the longest delivery path.

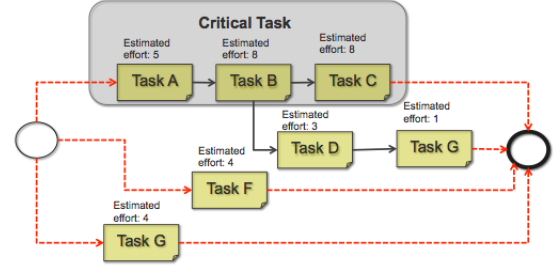

Fig. 3. Network Diagram with Critical Tasks.

B. Proposed Model

Figure 4 illustrates in detail the mechanism used to find out the Critical Task in GitHub projects.

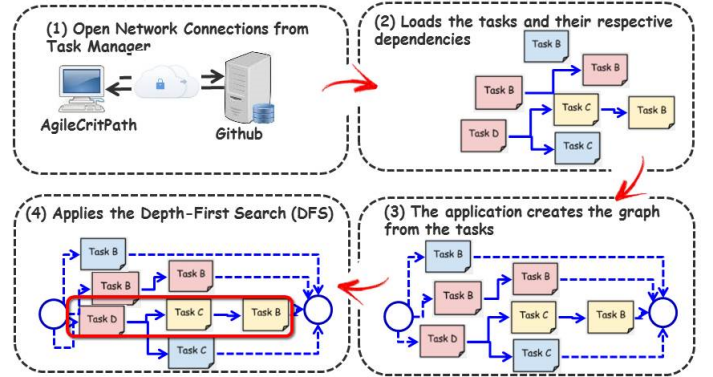

Fig. 4. Illustration of AgileCritPath.

In step (1), the application connects to the task manager to load all tasks and their dependencies. In step (2), the associations between tasks are created according to the dependencies. In step (3), the resulting graph is created. Tasks without predecessors are automatically linked to the initial node of the graph. The tasks without successors are automatically linked to the final node of the graph. In step (4), the Depth-First Search (DFS) algorithm is applied to find all paths in the graph. While reading the path, the total effort to complete the task flow is calculated.

All the found paths are displayed in descending order, from the longest path to the shortest path, according to the calculated effort for each path. Next to the path listing is the status of the task, the developer responsible for the execution of the task, and the effort of each task that makes up the path. The path size is calculated by the sum of the planned effort

reported in the individual tasks that are part of the path. If the task is finished, we consider the effort to complete the task.

Knowing all the paths in the network task is important because we can identify the “Near-Critical Paths”. Other important paths through are considered the “Near-Critical Paths” if they are at risk of becoming the Critical Path. To make this information visible to the team, we display all the paths found in the task network.

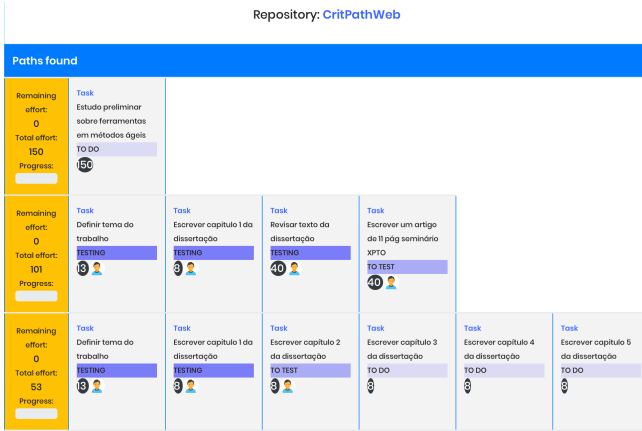

Fig. 5. Query results.

Figure 5 presents the result of querying the paths of a task network from a GitHub repository.

C. Architecture model

AgileCritPath was developed following the architecture presented in Figure 6.

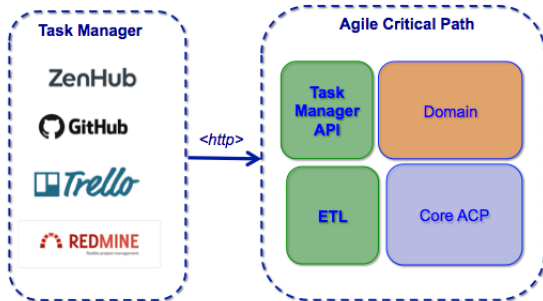

Fig. 6. The AgileCritPath architecture.

The application works autonomously and connects to the task manager through an integration API (task manager API). The Extract, Transform and Load (ETL) module performs the necessary information processing, according to the information available in the task manager. An ETL module was developed to meet the integration requirements with GitHub, ZenHub and Redmine. The ETL loads objects from the application domain, which works in isolation from the task management tools. The Core ACP module loads a task-oriented graph and implements a Depth-First Search algorithm that searches for all paths in the task network.

Planning in an agile environment is different from approaches used in traditional plan-oriented software development models [18]. Rather than employing plans in projects based on a set of predefined factors and constraints, agile models rely on the human factor to self-organize. In this work, we seek to offer systemic support, allowing the information to be accessible to all team members, and the decisions about the order of task execution to be made at any time.

V. THE AGILECRITPATH TOOL EVALUATION

The evaluation of the AgileCritPath tool was performed according to the Technology Acceptance Model (TAM). The TAM approach was proposed by Davis in 1989 [19] and suggests the acceptance of a new IT technology depending on two variables: (1) perceived ease of use and (2) perceived utility usefulness. For Davis, people tend to use or not use technology to improve their performance at work - perceived utility. However, even if a person understands that a particular technology is useful, its use may be impaired if the application is too complicated, so effort does not compensate for use - perceived ease.

A. Procedures

The general objective of using TAM was to evaluate the potential of the AgileCritPath tool in an industrial environment. The evaluation was performed in a company that has been working in the area of software engineering for 20 years and adopts development processes based on agile practices. The project used in the evaluation was selected by the organization. The selected company uses Redmine as a task management tool. For the execution of the study, we modified our tool so it could access Redmine.

B. Execution

The study was performed in-vivo. *In-vivo* studies are studies that involve people in their own working environment under realistic conditions [20]. Case studies made in an industrial environment are an important type of *in-vivo* study since they allow the analysis of a particular process in the context of a software life cycle [21].

To ensure that the study did not impact the organization's software development process, we restricted ourselves to observing the tasks performed in the team's daily routine and added to their lists the activities required to use the tool, as presented in Figure 7.

Figure 7 presents the activities performed in the organization. The activities in red are the activities we included so that CPM could be used by the team.

At the iteration planning meeting, the team began to include task dependencies. During the execution of the iteration, the team performs daily meetings (daily Scrum meeting). As suggested in Scrum [22], daily meetings should last 15 minutes, where the team discusses what has been done in the last 24 hours, the plan for the next 24 hours, and what task impediments (anything that keeps a team from being productive) occurred. The meeting is held in front of a

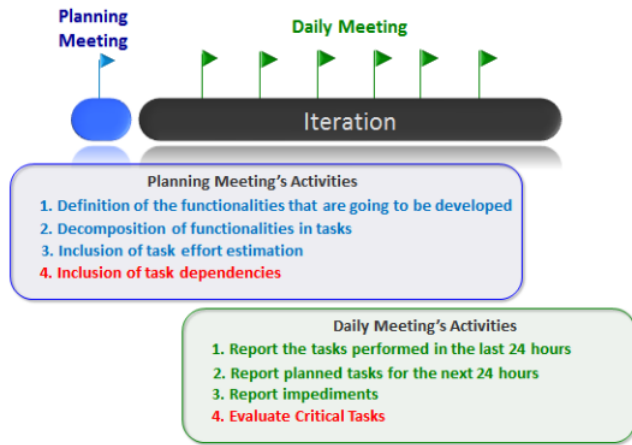

Fig. 7. The activities performed during an iteration.

Kanban board. The visualization of the paths calculated by the AgileCritPath tool was presented at the end of the daily meetings.

During the planning and execution of the iteration, the participants had access to the AgileCritPath tool, and in the daily meetings, the tasks that were part of the critical path were presented to the team. The iteration lasted two weeks, and at the end, the participants were asked to answer the questions directed towards the evaluation of the tool.

At the end of the iteration, the participants completed the Participation Consent and Clearance Form, Participants Characterization Form and the TAM Model Evaluation. The forms were completed individually and without any contact between participants.

C. Discussion

A team of six employees participated in the study. Participation was free and voluntary. The questionnaire was sent to all developers of the company. The participants, in general, have a bachelor's degree, except for one participant, who is in the process of concluding a bachelor's degree. The academic experience varies greatly among the research group since the team has 2 senior, 1 junior and 1 trainee members. All participants are familiar with the basics of project management and are knowledgeable about the Scrum methodology.

From the results of the study, based on the Perceived Utility evaluation criterion, we verified that the participants agreed that the use of the tool could improve the productivity and quality of the work of the team members. All participants recognized the tool as useful for performing their tasks. Regarding the Perceived Usability Facility variable, the team indicated that identifying dependencies between tasks and identifying the Critical Path as reasonably difficult activities. Even though the team has indicated difficulties in identifying dependencies and evaluating the critical path, 75% of respondents felt inclined to use the tool during the planning and execution of tasks. Despite having to make a more significant effort in task dependency identification, the team recognized the benefits that the use of the tool can provide.

The participants were asked to identify the benefits and limitations of the tool. The key highlighted benefits were: the visualization of dependencies between tasks, as a facilitator to determine which tasks should be prioritized, and the improved visualization of the total planned effort to complete critical path tasks. As a tool limitation, the participants recognized that it would be nice if the tool could display estimated versus realized information of the tasks in progress and could provide more metrics for monitoring work progress.

During the daily meetings using the tool, we were able to capture observations made by the team as follows:

- The team observed that using the tool allows everyone on the team to get a sense of what tasks are critical;
- The team found it interesting to leave the critical tasks to the most experienced developers on the project, especially when the deadlines for these tasks are tight;
- Visualizing the critical path is also a way of evaluating the most complex points of the project;
- The team observed that the task priority they provide at the time of task planning did not make sense and, in some cases, the team acknowledges that they might have had a greater gain prioritizing critical path tasks;
- The team evaluated the critical path analysis as a tool complementary to the Kanban framework because in the Kanban framework they could not keep track of the dependencies between the tasks.

The lack of knowledge about dependencies between planned tasks in agile environments emerges in a misaligned business plan that the team may not be able to execute. Also, the lack of awareness about the dependencies that exist between the tasks of the software development process constitutes a possible explanation for inefficient team coordination and project delays.

The AgileCritPath tool enables organizations to use dependency information across tasks to improve task prioritization in agile environments by identifying which dependencies can compromise or block the flow of task execution.

In this study, the evaluation of the usability of the AgileCritPath tool in the industry was conducted. Usability is one of the aspects related to the quality of use of systems, being one of the most important acceptance criteria for interactive applications in general, and in particular for Web applications [23]. The acceptance of technology is related to the quality and use of its systems, the quality of the provided information and user satisfaction [24]. Through the use of the acceptance model, it was possible to evaluate the use of the AgileCritPath tool in an industrial environment.

VI. CONCLUSION

Agile approaches are based on the idea that developers can self-organize and perform their work collaboratively [4]. However, some studies suggest that large and complex software development projects can benefit from the combination of the flexibility inherent in agile teamwork and models that support a plan-oriented structure [25], [26], [27].

Bick et al. [4] and Badampudi et al. [18] propose that organizations should continue to adopt agile methods, including the established practices of traditional methodologies that guarantee more predictability, reliability, stability and effective use of resources. In addition, through analysis of dependencies, the team can evaluate the shorter time for product delivery. Not considering the dependencies between tasks can generate delivery plans that are not aligned with the reality of the organization.

Considering dependencies on software projects is crucial to identifying critical tasks. Critical tasks are tasks that can delay the execution of others and thereby delay the delivery of the product. In this paper, we present an exploratory study that demonstrated that in a real software development scenario, the number of dependencies could be large and difficult to manage. Through the results of the exploratory study, we proposed the use of the Critical Path Method (CPM) concepts to identify critical tasks in agile projects. Critical Path Method has already consolidated in traditional project management models. In Agile Environments, this technique can help the team identify critical tasks, and thus direct their efforts toward tasks that can impact the development of other tasks.

The proposal presented in this article was materialized in the AgileCritPath tool, which allows development teams to have a view of dependencies between the tasks and, therefore, identify at any time which tasks are critical. The tool is compatible with any agile methodology and can support development teams to make decisions easily and quickly. The tool was developed in open source format and is available on GitHub (<https://github.com/RachelVital/CritPath>).

The evaluation of the use of the tool was based on the TAM technological acceptance model. During the evaluation, we were also able to gather insights and encourage the adoption of the tool in the industry. Through the responses obtained in the TAM application, we were able to evaluate that, despite the additional effort to identify the dependencies, the use of the CPM in agile environments proved to be relatively simple and viable in the selected organization. At the end of the evaluation of the use of technology, we could verify that the whole team was able to perceive the utility of the identification of critical tasks.

As future work, we plan to evaluate the use of AgileCritPath in continuous software development and DevOps environments. The application of the acceptance model could also be conducted in other software development companies.

Abstract—Due to the need for flexibility to requirements changes, agile software development methods have been attracting the attention of academic and industrial domains. Unlike traditional approaches, agile methods focus on the rapid delivery of business value to customers through empirical and incremental development processes. Despite being effective in delivering quality functional requirements, agile practices generally neglect non-functional requirements until the later stages of software development. However, neglecting non-functional requirements during requirements analysis can lead to project failures. In this paper, we present the NFRec tool, which aims to support software developers in the elicitation of non-functional requirements in the context of agile software development. Additionally, we report the results from a case study to evaluate the acceptance of the NFRec tool from the point of view of software developers of four projects from a Brazilian software company. To gather information about the tool acceptance, we applied a questionnaire based on the indicators from the Technology Acceptance Model. Overall, the four teams considered the NFRec tool useful and easy to use for supporting the management of non-functional requirements in agile projects.

Keywords—Non-functional requirements; agile requirement engineering; supporting tool; empirical study; technology acceptance.

I. INTRODUCTION

Since the declaration of the Agile Manifesto in 2001, academic [8] and industrial [16] communities have devoted considerable attention to agile software development (ASD) methods, such as Scrum and eXtreme Programming. One of the key aspects of the ASD is to rapidly adapt to volatile requirements [8], following a development process that places a great emphasis on frequent delivery of business value for customers [8].

Although agile practices are considered effective in the delivering of valuable functional requirements (FRs) [14], non-functional requirements (NFRs) are commonly neglected until the later stages of software development [14]. However, neglecting NFRs can lead to software failure [2], since NFRs are often more critical to determine the perceived success or failure of a software product than FRs [9].

By addressing this problem, some studies proposed techniques to support the NFR elicitation in the agile context [10], [11], [12], [13]. Maiti and Mitropoulos [12], [13] presented a methodology to collect NFRs metadata from software requirements artifacts such as documents and images available in the initial stages of projects. Farid et al. [10], [11] proposed a solution based on decision trees to predict NFRs from future iterations of agile projects based on the metadata collected with the methodology proposed in Maiti and Mitropoulos [12], [13]. However, to the best of our knowledge, none of these works proposed the use of historical data of previous projects to provide suggestions of NFRs for ongoing ones. Additionally, there is a lack of empirical evaluations of proposed solutions in real industrial environments.

In our previous work [15], we proposed a non-functional requirement recommendation system (RS) for Scrum-based projects, which is based on the analysis of information from past projects. As a result, our solution achieved a recall rate of up to 81%, showing the feasibility of automating the definition of NFRs through historical data of Scrum-based projects. To allow the applicability of the proposed recommendation system on industrial environments, we developed a tool based on an improved version of the solution presented in [15], called NFRec.

In the current paper, we focus on the empirical assessment of the NFRec tool and report the results obtained through a case study to evaluate its acceptance in a real industrial environment. For matters of validation, our work focus on Scrum, which is the most popular agile method [17]. As a result, the subjects of the case study considered the NFRec tool useful and easy to use for supporting the management of non-functional requirements in agile projects.

This paper is organized as follows. Section II presents a background and a motivation to use a supporting tool for NFRs elicitation in ASD context. Section III shows the NFRec tool. Section IV presents details about the empirical evaluation. Section V discusses the threats to validity. Finally, Section VI details our conclusions and perspectives for future works.

II. BACKGROUND AND MOTIVATION

Non-functional requirements play a key role in the successful development of software products [2]. Moreover, they are considered as a factor of differentiation among software products that present similar FRs [1].

In this sense, Bourimi et al. [3] proposed a framework that aims to conceptually impose the early consideration of NFRs, by considering the adoption of the stakeholder of NFRs in the Scrum team. In contrast, Farid [7] proposed a framework for modeling NFRs in the context of ASD.

Although the presented techniques provide a means for identifying NFRs on agile projects, there is still room for improvement. For example, solutions such as the ones proposed by Bourimi et al. [3] and Farid [7] present only a conceptual reinforcement or/and the addition of artifacts and roles in the agile process. Therefore, no solutions are proposed to support automated NFR elicitation. In contrast, solutions presented by Farid et al. [10], [11] and Maiti and Mitropoulos [12], [13] require that project documents and images are available on early stages of the software development, which is not common when dealing with ASD. The presented needs have been considered in the NFRec tool.

III. NFRREC TOOL

In this section, we present the NFRec tool, which aims to support developers in the early elicitation of NFRs during the Sprint Planning Meetings¹. NFRec comprises the following two activities: (i) Structuring of Project Information; and (ii) NFR Recommendation.

A. Structuring of Project Information

To enable the generation of the NFRs recommendations, it is necessary to structure the projects' information to guarantee the retrieval of information by the recommendation system. In the NFRec tool, user stories and project profiles are structured based on the assignment of categories and tags.

The first activity accomplished in the NFRec tool by Scrum teams is to create project profiles based on the assignment of tags referring to the five factors that directly affect the definition of NFRs [15], i.e., platform (e.g., web, mobile, embedded, desktop, etc.), project domain (e.g., health, banking, etc.), project objective (e.g., product or prototype), software architecture (e.g., client-server, MVC, multilayered, etc.), and technology tags, which represent basic technologies for the development of a software product (e.g., programming language, database, etc.). In Figure 1, we present an example of a structured project profile created in the NFRec tool. The project is from the domain *Development Tools* (1), its objective is to develop a *Product* (2), the software architecture is *Client-server* (3), the platform is *Web* (4) and the technologies used are the programming languages *Java* and *JavaScript* (5) and the frameworks *Angular* and *Spring Boot* (6). We highlight that previously stored tags must be reused by Scrum teams to avoid data inconsistencies.

Besides project profiles structuring, all user stories (USs) specified in the NFRec tool must be categorized to enable the retrieval of information by the RS. Therefore, during the Sprint

¹Sprint Planning Meeting is an event of the Scrum in which the Scrum team plans the work to be performed in the Sprint.

Fig. 1: Example of a structured project profile created in the NFRec tool

Planning Meetings, developers use the NFRec tool to create and store USs, which are classified by a category (module) and a subcategory (operation) that indicate the purpose of the FR specified by the US. In Figure 2, we present an example of a structured user story created in the NFRec tool. The US is classified with the module *Registration* (1) and the operation *Retrieve data* (2). We highlight that previously stored categories (i.e., modules and operations) must be reused by development teams to avoid data inconsistencies.

B. NFR Recommendation

For each US defined by the development team, the NFRec tool recommends a list of NFRs based on historical data

analysis. NFRs are represented in the tool by a type, an attribute, and a sentence. The classification with type and attribute follows the indications presented by Mairiza et al. [9]. Additionally, NFR sentences are written following the indications presented by Eckhardt et al. [5], [6].

In Figure 3, we present an example of NFR recommendations presented in the NFRec tool, in which three NFRs are suggested for a US of the module *Registration* (4) and the operation *Retrieve data* (5). In the example, the developers have already accepted/considered one of the three recommendations

Non-functional requirements

Module: Registration ④
Operation: Retrieve data ⑤

type	attribute	sentence
security ①	access control ②	the system must provide the capability for users see just the information they have permission to access. ③
reliability	availability	the system must notify users and customers when the function they are accessing is unavailable.
performance	response time	in 100% of all cases, the system must have a mean response time of <= 3s between event <search items> and event <display text information of listed items>. it is assumed that there are 200 concurrent users.

Back **Finish**

Fig. 3: Example of a NFR recommendation presented in the NFRec tool

(6), a NFR of type *security* (1), attribute *access control* (2), and sentence “*The system must provide the capability for users to see just the information they have permission to access.*” (3).

By using the tool, developers can visualize suggestions of NFRs for each US of current or future Sprints. Thus, NFRs can be considered early in the software development process, mitigating the risk of negligence with non-functional requirements resulted from agile practices.

IV. EMPIRICAL EVALUATION

To evaluate the practical use of the NFRec tool, we conducted a case study in four ongoing Scrum-based projects from a Brazilian software company. We intend to: (i) assess the acceptance of the NFRec tool by agile software developers; (ii) evaluate the precision of generated recommendations.

A. Case Study Design

We performed an embedded case study [18] in which each project was considered a unit of analysis and each development team the subject of study. This step of the research lasted a month and each project executed two Sprints of 15 days during this period. Meanwhile, we collect information from different recommendation scenarios, and hence, we consider a sufficient period to answer the research questions.

The overall objective of the case study is to evaluate the cost-benefit of the NFRec tool from the perspective of development teams, regarding the support of non-functional requirements management. To accomplish that, we formulate the following research questions (RQs):

- **RQ₁**: is the NFRec tool useful to assist in eliciting non-functional requirements in Scrum-based software projects?
- **RQ₂**: is the cost to use the NFRec tool in Scrum-based software projects acceptable?
- **RQ₃**: what is the precision of the recommendations of the NFRec tool?

Therefore, we consider the cost-benefit of the NFRec tool worthwhile if the questions are positively answered.

As previously stated, we consider four software projects as study analysis units, referred as Project A, Project B, Project C and Project D. All of them consisting of Web information systems with the following scopes:

- **Project A:** development of a system with a cloud service and a Web client to enable independent or shared writing of poetry. It is composed of two developers;
- **Project B:** development of a Web client for generating graphics resources such as badges and business cards. It is composed of three developers;
- **Project C:** development of a system with a cloud service and a Web client to support the management of training projects through the management of students' activities and schedules, selections of participants to projects, etc. It is composed of five developers;
- **Project D:** development of a system with a cloud service and a Web client to assist the building and executing of Bayesian Networks. It is composed of five developers.

Prior to the case study, all projects performed requirements management during the Sprint Planning Meetings using a tool without NFR recommendation. Therefore, they did not perform any direct activity to define NFRs through the tool. They described them as acceptance criteria, DoD items, functional requirements, failures identified by test cases, etc.

To gather data for evaluating the acceptance of the NFRec tool, we apply a questionnaire based on the Technology Acceptance Model [4]. TAM aims to explain why individuals choose to adopt or not adopt a specific technology when accomplishing a task and it is based on two variables: Perceived Usefulness (PU) and Perceived Ease of Use (PEU). PU is related to the degree to which an individual believes that the use of a certain technology would increase his/her performance in the work. In contrast, PEU refers to the degree to which an individual believes that the use of a certain technology would be free of mental and physical effort.

Therefore, by adapting the TAM to the context of this work, we formulate 14 questions to evaluate the PU of the NFRec tool (RQ_1) and 14 to assess its PEU (RQ_2). For each question, we use a five-level Likert scale to collect participants' responses. The scale adopted the values: (1) Strongly Disagree, (2) Disagree, (3) Neither agree nor disagree, (4) Agree, and (5) Strongly Agree. In addition, we calculate the precision of the recommendations processed during the case study (RQ_3).

Overall, we collected 4 answers for the questionnaire, i.e., one for each development team. On average, the teams of projects B and C have one year of experience in Scrum-based software projects. On the other hand, the teams of projects A and D had a mean of three years of experience in the same type of project.

B. Case Study Execution

To run the case study, we make the NFRec tool available to the teams of each project via a web link. The execution of the study comprised two stages: (i) training, and (ii) execution.

During the training phase, we presented concepts about the structuring of project information and the non-functional requirements recommendation, followed by a demonstration of the NFRec tool. The training lasted 1 hour. After this phase, the teams started using the NFRec tool at their projects' Sprint Planning Meetings, i.e., a real evaluation scenario in the industry.

First, they used the tool to create the profiles of their respective projects based on the assignment of tags referring to the five factors that affect the definition of NFRs (i.e., application domain, platform, project objective, software architecture, and technologies [15]). None of the teams had reported any troubles at this step.

Next, for each current Sprint, the teams used the NFRec tool to support the requirement management process during the Sprint Planning Meetings, in which they created structured USs. For each created US, the teams received NFRs recommendations and they could freely interact with the tool, accepting or rejecting suggestions. The duration of the meetings did not change in any of the projects, i.e., they continued within the planned interval of 1 hour. In the following, we present the activities carried out in the first moment of the case study.

In the first observed Sprint of Project A, the team selected one US, which received two NFR recommendations. The team accepted only one of them. Therefore, the RS achieved a precision rate of 50% for the corresponding Sprint from Project A.

For the first observed Sprint of Project B, the team selected two USs. For the first described US, the NFRec tool generated six NFR recommendations. The team accepted five of them. In contrast, for the second US, the tool generated two NFR recommendations, but the team accepted only one of them. Therefore, the RS achieved a precision rate of 75% for the first evaluated Sprint from Project B.

In the first observed Sprint of Project C, the team selected three USs and the NFRec tool generated three NFR recommendations for each one them. For two of the USs, the team accepted all the suggestions. On the other hand, for the remaining one, the team accepted only two of the recommendations. Therefore, the RS achieved a precision rate of 88.88% for the respective Sprint from Project C.

Finally, in the first observed Sprint of Project D, the team selected three USs. Two of them received three NFR recommendations, which were accepted by the team. In contrast, for the remaining one, the tool presented two suggestions of NFRs, of which only one was accepted by the team. Therefore, the RS achieved a precision rate of 87.5% in the first evaluated Sprint from Project D.

We highlight that the Product Owners of each project validated the recommendations accepted by the development teams. However, we did not evaluate whether the constraints specified by the recommended NFRs were considered in the development of the USs within the current Sprints since this issue is not part of the scope of this work. In the following, we present the activities carried out in the second moment of the case study.

In the second observed Sprint of Project A, the team selected two USs during the Sprint Planning Meeting. The NFRec tool presented one recommendation for one of the US

and three for the other. The team accepted all the suggestions. Therefore, the RS achieved a precision rate of 100% in the second evaluated Sprint from Project A.

In the second observed Sprint of Project B, the team selected two USs during the Sprint Planning Meeting. The NFRec tool recommended one NFR for two of them. For the other one, the tool presented two recommendations. Overall, the team accepted two of the four suggestions. Therefore, the RS achieved a precision rate of 50% in the second first Sprint evaluated from Project B.

In the second observed Sprint of Project C, the team selected two USs. The NFRec tool recommended one NFR for the first described US and two for the later. The team accepted all the suggestions. Therefore, the RS achieved a precision rate of 100% for the corresponding Sprint.

Finally, for the second observed Sprint of project D, the development team selected three USs and the NFRec tool generated two NFR recommendations for each one of them. The team accepted all the suggestions for two of the USs but rejected one of the recommendations for the remaining one. Therefore, the RS achieved a precision rate of 83.33% for the corresponding Sprint from Project D.

At the end of the case study, all subjects filled in the questionnaire regarding their acceptance of the NFRec tool.

C. Results and Discussion

After the case study execution, we calculated the precision of the recommendations generated during the observed period. In Table I, we present the results of the overall precision and the precision for each project. Overall, the NFRec tool recommended 44 NFRs, of which 36 were accepted by the developers, resulting in a precision rate of 81.8% of the recommendations for the 20 considered USs. Therefore, we considered the results promising, concluding that RQ_3 was positively answered. Among the four evaluated projects, we observed a higher precision rate in Project C (91.7 %), which is composed of professionals with previous experience in the use of the structured model of USs. On the other hand, we observed the lowest precision rate in Project B (66.7 %), which is the only one of the four projects that it is not developing a cloud service (*back-end*). Therefore, some recommendations were rejected for suggesting back-end assumptions/constraints such as validating the integrity of data sent to the server. Additionally, the team of Project B reported difficulties during the classification of the USs with modules and operations.

TABLE I: Results of precision calculated from the data obtained in the case study

Project	Num. USs	Num. accep. NFRs	Num. rec. NFRs	Precis.
Project A	3	5	6	83,3%
Project B	5	8	12	66,7%
Project C	5	11	12	91,7%
Project D	7	12	14	85,7%
Total	20	36	44	81,8%

As mentioned before, at the end of the case study, each development team answered a questionnaire to assess the acceptance of the solution regarding the perceived usefulness and perceived ease of use. To evaluate the responses, we summarized them as follows: Likert scale values represented by (1) and (2) were considered as indicative of disagreement

(*Disagreement*); (3) as indicative of neutrality (*Neutral*); and (4) and (5) as indicative of agreement (*Agreement*).

In Tables II and III, we present the data collected for PU and PFU, respectively. Positive responses to variables are highlighted in bold. The maximum number of answers per question is four since we considered four subjects in the study. Therefore, as we formulate 14 questions for each TAM variable, the maximum number of responses per variable is 56. The final result for each analyzed variable is given by the sum of the answers per positive indicative (i.e., *Agreement*) divided by the maximum number of responses to the corresponding variable (i.e., 56).

By analyzing the data of the Table II, we verify that the research participants showed good acceptance for 13 of the 14 analyzed items of PU. Only items PU9 and PU12 did not receive mostly positive evaluations. For PU9, participants gave three neutral answers and one positive. In contrast, for PU12, they gave two positive responses and two neutral ones. Overall, the PU was positively assessed in 48 of 56 possible responses. The evaluation demonstrated an acceptance of the perceived usefulness of 85.7%. Therefore, it is possible to state that the research participants considered the tool useful (RQ_1).

By analyzing the data of the Table III, we verify that the respondents showed good acceptance for 12 of the 14 analyzed items of PFU. Only the items PFU1, PFU11, PFU12, PFU13, and PFU14 did not receive mostly positive evaluations. For PFU1 and PFU13, the respondents gave two positives and two negative responses. In contrast, for PFU11, PFU12, and PFU14, they gave two positives and two neutral responses. Overall, the respondents positively assessed PFU in 41 of 56 answers, i.e., an acceptance of the perceived ease of use of 73.2%. Initially, some developers encountered difficulties in structuring USs and defining modules and operations. This fact may explain why PFU acceptance values were lower than those of PU. Even so, it is possible to state that the research participants considered the tool easy to use (RQ_2).

TABLE II: Results for perceived usefulness from TAM

ID	Item	Agreement	Neutral	Disagreement
PU1	Job Difficult Without	4	0	0
PU2	Control Over Work	4	0	0
PU3	Job Performance	4	0	0
PU4	Addresses My Needs	4	0	0
PU5	Saves Me Time	3	1	0
PU6	Work More Quickly	4	0	0
PU7	Critical to My Job	4	0	0
PU8	Accomplish More Work	3	1	0
PU9	Cut Unproductive Time	1	3	0
PU10	Effectiveness	4	0	0
PU11	Quality of Work	3	1	0
PU12	Increase Productivity	2	2	0
PU13	Makes Job Easier	4	0	0
PU14	Useful	4	0	0

V. THREATS TO VALIDITY

In this work, we consider the classification of validity threats proposed by Wohlin et al. in [18]. In what follows, we present the identified threats to validity.

Conclusion validity threats. We conducted the case study for two 15-day Sprints only, which represents a conclusion validity threats since we could get different answers with a longer period. However, to mitigate this threat, we evaluated four teams simultaneously, which returned similar results. In

TABLE III: Results for perceived ease of use from TAM

ID	Item	Agreement	Neutral	Disagreement
PFU1	Confusing	2	0	2
PFU2	Error Prone	0	1	3
PFU3	Frustrating	0	0	4
PFU4	Dependence on Manual	0	1	3
PFU5	Mental Effort	0	0	4
PFU6	Error Recovery	4	0	0
PFU7	Rigid and Inflexible	1	1	2
PFU8	Controllable	4	0	0
PFU9	Unexpected Behavior	0	0	4
PFU10	Cumbersome	0	1	3
PFU11	Understandable	2	2	0
PFU12	Ease of Remembering	2	2	0
PFU13	Provides Guidance	2	0	2
PFU14	Easy to Use	2	2	0

addition, we collected data regarding the different types of USs, i.e., we could observe different recommendation scenarios during the case study.

Internal validity threats. On average, developers from two of the four projects had just one year of experience. This fact can lead to a threat to internal validity, since they may not be mature enough to properly answer the questionnaire. To mitigate this threat, developers of each project answered the questionnaire together, and hence, they had the opportunity to discuss their responses with each other, aggregating their knowledge. Another threat to internal validity refers to the construction of the questionnaire. However, to mitigate this problem, we generated it based on the TAM, which is a validated and extensively used model in the literature to evaluate new technologies.

Construct validity threats. Factors related to the type of project (e.g, scope, complexity, familiarity with technology, team experience, etc.) might affect the acceptability of the tool, which can lead to a threat to construct validity. To mitigate this problem, we tried to select projects with different scopes and domains. However, we reinforce that further research is needed to investigate this threat to validity.

External validity threats. The case study was carried out with four projects from the same company and, consequently, it is not possible to generalize the obtained results to other companies that use Scrum. However, as future work, we intend to continue the empirical evaluation of the NFRec tool in more projects from different companies.

VI. CONCLUSION AND FUTURE WORK

In this paper, we presented the NFRec tool for supporting agile non-functional requirement elicitation. We reported the results of a case study to evaluate the acceptance of the tool from the point of view of development teams of four software projects from a Brazilian software company.

The empirical evaluation indicated that the NFRec tool seems to be able to accurately recommend NFRs, responding positively to the research question RQ_3 . Furthermore, the results of the case study obtained through the questionnaire showed that most of the subjects considered the NFRec tool useful and easy to use for supporting the elicitation of non-functional requirements, responding positively to the research questions RQ_1 and RQ_2 .

For future work, we intend to replicate this study with a greater number of subjects, analyzing different projects from distinct software companies to mitigate the validity threats.

Abstract—Virtual assistants such as Siri or Google Assistant are omnipresent. However, their development remains costly. One must either manually model the problem domain or provide thousands of labeled samples.

We propose to automatically create virtual assistants based on Active Ontologies for interacting with databases. Our approach generates Active Ontologies; we use the database structure to derive a concept hierarchy and database values together with synonyms to extract information from user queries. Our approach also learns common phrases from samples, e.g. from existing Dialogflow agents. We extract pre- and postfixes and attach them to concepts, e.g. *at* to detect a succeeding location. The generated Active Ontologies reply to previously unseen and composed requests. The approach is not limited to virtual assistants but can be applied to any system with a textual or voice-based conversational interface such as chatbots.

We evaluate our approach in three domains: tourism, hotel, and web cams. The study shows that automatically generated Active Ontologies extract relevant information from user utterances with a precision of 58%. The precision increases to 79% (recall 46%, F_1 58%) when we use sample utterances. Our approach successfully transfers between domains, e.g. we learn phrases from the tourism domain and use them to reply to hotel requests without any adjustments.

I. INTRODUCTION

Virtual assistants and other systems with conversational interfaces (CI) are used by an ever-growing number of people. Users ask Siri for their next meeting, talk to chatbots, or tell Alexa to turn on the lights. While these systems are a blessing for casual users, they remain a curse for developers. They are complicated to build and hard to maintain. Today’s virtual assistants are either trained on thousands or even millions of (manually) labeled samples, or their linguistic competence is modeled manually, i.e. they are built by domain experts. Both require serious manual effort to make the system appear human-like to the user. However, users will soon expect CIs for all kinds of applications. Thus, the efficient creation of CIs (i.e. developer assistance, transferability, automation, etc.) will become one of the major challenges in software engineering.

We propose to generate systems with CIs largely automatically. As underlying technology we use Active Ontologies [1], [2] (AO) that originally were at the core of Apple’s Siri. AOs are hierarchical domain models equipped with processing

rules. In terms of structure they are trees, where the leaves react to words in user utterances. The inner nodes join information and the root creates a services call, e.g. a restaurant reservation.

As a prerequisite for our generation process, we assume that a service provider stores information in a database, e.g. the addresses, ratings, and names of restaurants. Having this information, our AOs are supposed to answer requests such as, “Show me restaurants in Lisbon.” We automatically generate AOs from the databases in two steps. First, we use the structure of the database to infer the concept hierarchy of the AO. Second, we add leaf nodes to provide the AO with linguistic competence. We generate those from database values and add synonyms obtained from Wiktionary¹. Optionally, if a data set of sample user utterances is present, we can further improve the linguistic competence. We extract related phrases for each concept. For example, we can learn the phrase *where can I find* for the concept `location` from examples like, “Where can I find an Italian restaurant.” Our generated AOs reply to previously unseen request, e.g. finding a hotel in a city (which was learned from *finding* web cams and listing tourist attractions *in a city*). Moreover, they correctly respond to complex requests composed of two or more simple requests, e.g. asking for both, the location and opening hours of a restaurant, at the same time. The developer reviews the result of the generation process and adapts the AO. Usually, this involves altering the type of inner nodes and adding common phrases to leaf nodes.

The remainder is structured as follows. First we introduce the basic elements of Active Ontologies in section II. Then, we discuss related work in section III. In section IV we present our approach and the generative process in detail together with a discussion about its inherent limitations. Afterwards, we evaluate our approach in section V. We conclude our work and discuss further improvements in section VI.

II. ACTIVE ONTOLOGIES

Active Ontologies were first proposed by Guzzoni et al. [1], [2]. Originally, they were used to build virtual assistants. However, they can be used as a generic CI. We present

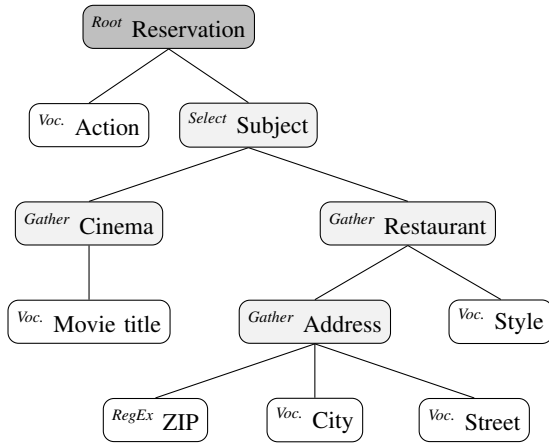

Fig. 1. An AO for the problem domain “reservations”. The AO is can create service calls to cinema and restaurant reservation systems. The root node is colored in gray, the inner nodes in light gray, and leaf nodes are white.

the fundamental elements and basic processing of AOs. All upcoming examples refer to the AO depicted in Figure 1. Detailed descriptions may be found in the above reference.

AOs combine concept hierarchies with processing rules. On the one hand, they model the domain as an ontology. On the other hand, AOs process natural language requests and turn them into service calls. The concepts and relations form trees, i.e. an AO is a concept hierarchy of a problem domain. Information is processed bottom-up. The leaf nodes react to words in the user utterances. The concept nodes (i.e. the inner nodes) join information and gradually create an abstract representation of the utterance. Finally, the root node gathers all information and initiates a service call. Basically, all nodes react to input as follows. When they receive a message (i.e. a piece of information), they decide whether they send information upwards or not. For the creation of new messages, nodes often use parts of the received information. Additionally, they attach a confidence to the fired message. This may support the decision-making processes of nodes at higher levels. The decision whether, what, and with which confidence they fire depends on the particular usage. All of that is implemented by rule sets. In the following we describe common node types.

Basic leaf nodes (called *vocabulary nodes*) simply match a predefined set of keywords, e.g. city names. Often, *pre-* and *postfix nodes* are used. They define a pre-/succeeding word or phrase, e.g. the prefix “from” to match the departure airport for flight booking systems. Another common type of leaf node is the *regex node* that matches input with a regular expression, e.g. to detect ZIP codes. Usually, there are two types of inner nodes: *gather nodes* and *selection nodes*. Gather nodes simply collect information sent by their child nodes; e.g. an *address* gather node might collect *ZIP*, *city*, and *street* facts. Selection nodes decide which information will be passed on; e.g. a *subject* selection node might decide whether the user talks about restaurants or cinemas. Most commonly, selection nodes decide on the basis of the confidences of the respective inputs.

However, other strategies are possible. The most common type of root node is the *call node*. It creates a service call and passes it to the *service broker*. The service broker is a sub-system that selects the most suitable service provider(s) for the call. A language generation module post-processes the response to the service call. The result is presented to the user.

III. RELATED WORK

In this section, we first review proprietary virtual assistants (see subsection III-A). Then, we present platforms for developers to create systems with CIs, e.g. chatbots and the like (see subsection III-B). Finally, we discuss work from the research area natural language interfaces to databases (see subsection III-C).

A. Proprietary Virtual Assistants

Virtual assistants both for home environments (e.g., Amazon Echo, Google Home) and mobile use (e.g., Apple Siri, Google Assistant, Microsoft Cortana) are omnipresent. However, little is known about the technology behind these assistants. US patent no. 8,677,377 [3] suggests that Apple’s Siri makes use of Active Ontologies. Amazon’s Alexa interacts with third-party services through so-called “skills”. Google uses a knowledge graph to answer user queries² and Amazon states that they use “deep learning technologies”³ to develop Alexa.

B. Platforms for Conversational Interfaces

Besides proprietary assistant systems, all major companies provide platforms for developers to create CIs, e.g. IBM Watson⁴, Microsoft LUIS⁵, Facebook’s WIT⁶, Amazon Lex⁷, and Google’s Dialogflow⁸.

Dialogflow provides an API for developers to add natural language processing capabilities to applications. One can build CIs to create chatbots and the like. Developers build so-called *agents*. Agents determine the user’s intent from an utterance. Each agent deals with one or more *intents*, e.g. requests for weather forecasts or web cams. When an agent grasps an intent, it extracts relevant information and passes it to a connected service. Since users may express intents in different ways, it is necessary to provide Dialogflow agents with a variety of different phrases for each intent. The developer does not only have to provide the phrases but also annotate actions and parameters in all phrases. One must also specify the parameter mapping, i.e. which word must be translated to which parameter in the service call.

Almond [4], developed by the Stanford University, is an open and crowd-sourced platform to build virtual assistants. Almond is composed of three modules: a virtual assistant, the knowledge base *Thingpedia*, and the runtime environment

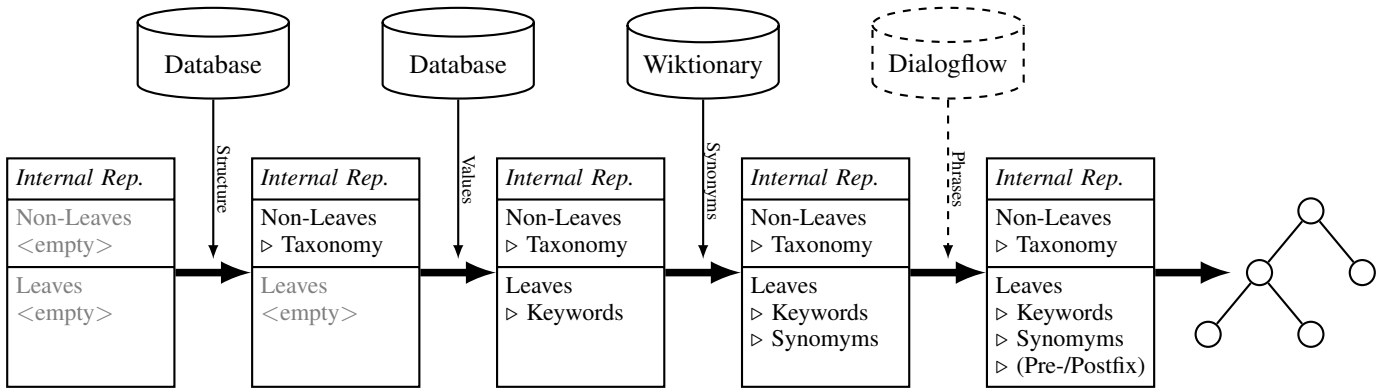

Fig. 2. The process to automatically create AOs. We use an (initially empty) internal representation that is successively populated from different sources: database structures and values, synonyms from Wiktionary, and – optionally – sample utterances from Dialogflow or similar sources.

ThingSystem. The virtual assistant translates natural language queries to the specialized programming language *ThingTalk*. The code is executed on *ThingSystem*, which creates service calls to the respective providers. Developers contribute to Thingpedia, a crowd-sourced public knowledge base of open APIs and their natural language interfaces. They specify trigger-actions such as If-This-Than-That (IFTTT) structures. The virtual assistant uses trigger-actions during code generation. The evaluation of the prototype shows that about 40% of tasks provided by a user familiar with the system are understood by Almond.

C. Natural Language Interfaces to Databases

Natural language interfaces to databases (NLIDB) have been studied since the late sixties; the associated conference (NLDB) is in the 24th iteration. Androutsopoulos et al. [5] give an introduction to the research area. Pazos R. et al. [6] review the state of the art. In the following, we briefly present representatives for common approaches.

Many NLIDB systems use specialized grammars. Rao et al. [7] use a *semantic grammar* to translate natural language to SQL queries. With customized production rules SQL queries are directly derived from the words in the utterances. Some NLIDB systems employ intermediate representations to grasp the intent of the natural language query. C-Phrase [8] uses an intermediate representation based on first order logic supplemented by additional higher-order predicates. It uses synchronous context-free grammars and lambda calculus expressions to convert natural language queries into the intermediate representation. Then, the intermediate representation is converted to an SQL query. More recent NLIDB approaches use machine learning techniques. Neelakantan et al. [9] use neural networks to map from language to SQL. Zhong et al. [10] employ reinforcement learning to improve quality.

All the above need developer-generated information: sample sentences, specialized grammars, or rules sets. We derive AOs directly from the database with minimal human effort.

IV. AUTOMATIC GENERATION OF ACTIVE ONTOLOGIES

We aim to create CIs for virtual assistants, chatbots, and the like (semi-)automatically. This way, we lower the effort for service providers to make their data accessible through a natural language interface. The sole precondition for our approach is that the service provider stores all information it wants to provide through the CI in databases. For example, if a service provider wants to publish information about touristic attractions it must store addresses, ratings, and the like of restaurants, museums, or galleries in accessible databases.

As underlying technology we use Active Ontologies. Usually, AOs are built manually. However, we have shown that it is possible to create AOs (semi-)automatically from web forms [11], [12]. In this work, we leverage the information provided by databases.

In contrast to web forms, databases always provide values, i.e. instances of concepts. We use the database values and synonyms to raise the linguistic competence of our AOs. Moreover, if sample utterances are present, we are able to add even more linguistic competence through an automatic extraction of common phrases. Our AOs are able to react to previously unseen user requests. Furthermore, they reply to composed requests.

Figure 2 shows an overview of our approach. We use an internal representation that is populated step by step. First, we extract the database structure and infer the concept hierarchy. Then, we create basic leaf nodes from the values in the database tables. Next, we add synonyms from Wiktionary, where applicable. If utterance samples are present, we add common phrases to the respective concepts. Finally, we generate the Active Ontology from the internal representation.

In the upcoming subsections we first describe the extraction of the concept hierarchy of the AOs from database schemes (subsection IV-A). Then we show how we increase the linguistic competence, i.e. how we add the leaf nodes to the AOs (subsection IV-B). Finally, we discuss the limitations of the approach, i.e. what a developer must review or add to the automatically generated AOs (subsection IV-C).

A. Taxonomy Extraction from Database Structures

AOs are hierarchic domain models. Inner nodes typically join information (gather nodes) to create a more complete view to the user’s request. We observed that database schemes follow the same intuition. For example, a database table *restaurant* may store information about *addresses*. The *addresses* again may be composed of a *ZIP*, a *city*, and a *street*. The *restaurant* table itself maybe used in different contexts. Thus, the *restaurant* table defines a concept that includes the sub-concepts *address*, *ZIP*, *city*, and *street*. For our prototype we use deductive databases.⁹ However, our approach can also be applied to relational databases as both database types store data in a structured way.

The structure is used to create the concept hierarchy of the Active Ontology, i.e the hierarchy of inner nodes. The database type only affects the way the database structure is extracted. Deductive databases contain triples that consist of an internal ID, the name of the property, and the property value. A property value may refer to another internal ID. For example, information about a restaurant is represented as follows:

```
[id01, @type, restaurant]
[id01, name, The Golden Eagle]
[id01, address, id01.address]
[id01.address, city, Karlsruhe]
[id01.address, ZIP, 76131]
```

We collect all property names and create a concept for each. Through the references in property values we infer hierarchies. For the above example the hierarchy in Figure 3 arises. Concept nodes can either be converted into gather or selection nodes. For our prototype we decided to only create gather nodes, because this is the best choice in most cases. Even though we found that for some concepts selection nodes would be the better choice, we were not able to come up with a generic rule to make this decision.

B. Leaf Node Generation

Now that we have created the hierarchy of concepts we need to extend the AO with linguistic competence. Up to now, the AO can join information only (and create a service call). However, it can not gather any information from a natural language request at all. Therefore, we create leaf nodes that match certain words or phrases in the utterance. We connect these leaf nodes to the respective inner nodes. For example, to create a leaf node that recognizes restaurants by their names

⁹A deductive database is a database equipped with a rule set. The rules are written in dialog, a simplified variant of logic programming [13], [14]. The deductive component of the database deviates additional knowledge from the data via rule executions. Queries are also composed in datalog. Ramakrishnana and Ullman describe deductive database systems as, “[...] database management systems whose query language and (usually) storage structure are designed around a logical model of data. As relations are naturally thought of as the ‘value’ of a logical predicate, and relational languages such as SQL are syntactic sugarings of a limited form of logical expression, it is easy to see deductive database systems as an advanced form of relational systems. [15]”

Fig. 3. A hierarchy extracted from database property names.

we can use the list of restaurants obtained from the database and attach it to the inner node *name*.

Besides vocabulary nodes, we generate all kinds of common node types (see section II), e.g. pre- and postfix nodes and specialized nodes such as date nodes. We use information from different sources to create leaf nodes. Next, we describe the sources, which kind of information we extract, the strategies to create leaf nodes, and which type of leaf nodes we create respectively.

1) *Database Values*: We create vocabulary, regex, and date nodes from database (property) values. For all string-valued properties we create vocabulary nodes. We join all values that belong to the same property (name). Thus, all names of restaurants are joined in a single vocabulary node. For numeric database values, e.g. phone numbers, ZIP codes, lengths, and the like, we use regex nodes. This way, we are able to extract any numeric information from the natural language input. Finally, to cope with specific phrases that contain date or time information such as “the day after tomorrow” we use date nodes. Date nodes recognize such phrases in the input and transform them into a machine-readable format.

2) *Lexical Databases and Dictionaries*: To amplify the linguistic competence of Active Ontologies one can add synonyms from lexical databases or dictionaries such as WordNet [16], [17], Wiktionary, or OpenThesaurus¹⁰. For our prototype we used Wiktionary for two reasons. First, as the values in our test databases are from Austrian service providers we need to recognize German utterances; Wiktionary provides the most extensive collection of German synonyms. Second, synonyms listed in Wiktionary are of high quality.

To retrieve synonyms, we first query Wiktionary for synonyms of the respective word. For each synonym we again look for synonyms. If no synonyms are available, we extract the so-called *similar words*. For each similar word we also search for synonyms. The list of synonyms and similar words is stored in a leaf node. Note that the leaf node does not pass the synonym to its parent nodes. Instead, the value of the associated property is used. For example, the leaf node that is supposed to recognize the word “Gaststätte” (German for “restaurant”) and all its (German and English) synonyms, e.g. “inn”, “restaurant”, or “eatery” passes the value *Gaststätte* to its parent nodes even if it recognizes the word “restaurant”

¹⁰OpenThesaurus: <https://www.openthesaurus.de>

in an utterance. This also relieves us from the issue that some values are German and others are English.

3) *Utterance Samples*: So far the generated AOs are capable to match keywords (or phrases) and their synonyms; they additionally detect dates and other regex-specified values. However, some user queries do not mention keywords directly. For example, a user might ask, “Where can I get pasta and tiramisu?” The utterance neither mentions restaurants directly nor the keyword “address”. However, obviously the user is interested in the address of an Italian restaurant. To overcome this limitation we automatically add common phrases that hint at a concept. Technically, such phrases form pre- and postfix nodes. We extract the phrases from sample utterances.

We are aware that sample utterances are not available for all domains/services. Thus, this step is optional. Alternatively, a developer can manually add pre- and postfix nodes to the AO.

For our prototype we use sample utterances from Dialogflow agents. Therefore, we extract all sample utterances from an agent and use the *intent* and *entities* as labels. With the help of the intent we are able to discover the appropriate AO part, e.g. restaurant requests. The entities have been linked to the respective database properties by the developer of the Dialogflow agent. Thus, we can determine the according concept in the AO. Additionally, often synonyms for entities are given. We add these to the synonym vocabulary nodes attached to the respective concept.

To extract pre- and postfixes we consider all entities in an utterance. We use all words preceding an entity as prefix and all succeeding as postfix. Of course, we stop discovery at the next entity. We consolidate all pre- and postfixes from all utterances for the same entity. Then we create one pre- and one postfix node per entity and attach them to the respective concept node. Given the Dialogflow sample utterance, “[Find me a [place to sleep]_{ent:type} in [Lisbon]_{ent:city}]_{int:hotel}”, we can identify the synonym *place to sleep* for the concept *@type* of the hotel AO part. Additionally, we extract the prefixes *find me a* (concept *@type*) and *in* (concept *city*) as well as the postfix *in* (concept *@type*).

C. Limitations

To automatically generate AOs, we have to make design decisions. For example, since we cannot automatically decide between selection and gather nodes, we create gather nodes for all concepts. However, in rare cases selection nodes are more appropriate. A developer can determine which node type is most suitable and select it accordingly. Another design decision concerns database values. We create word lists (for vocabulary nodes) for all string-valued properties. However, regex nodes might be more suitable to extract particular words or phrases, e.g. sub-strings.

In some cases, the extracted pre- and postfixes are either too specific or not specific enough. Modifying the phrases could improve matching with utterances. Entirely missing prefixes cause false positive matches and consequential conflicting hypotheses. Therefore, we expect that adding missing pre- and postfixes improves the accuracy of the AOs considerably. The

same applies to synonyms; a manual review improves accuracy since an automatic extraction of synonyms is error-prone.

V. EVALUATION

We evaluate our approach in three domains: tourism, hotels, and webcams. For each we have a deductive database and Dialogflow agents. The tourism dataset comprises information about local restaurants, ski rentals, events and the like. The hotel and web cam datasets contain information about the names and locations of hotels and web cams. In total, we included 3,861 data elements: 1,873 elements from the tourism, 1,303 from hotel, and 685 from web cam dataset.

We generate AOs for each domain in different variants. The basic AOs are created from the databases and synonyms only. All other configurations use sample utterances from Dialogflow agents to add pre- and postfix nodes. We use phrases from individual domains and all possible combinations of domain. For each domain we use all available samples provided by the agents for phrase extraction.

Note that any AO is enriched with pre-/postfixes where applicable. In other words, if we extract phrases from the web cam domain only but the other domains share concepts (e.g. locations) the respective phrases are added to all AOs. With that, we assess the impact of phrase extraction (the more the better?) and synergy effects (can we employ phrases from other domains?).

The database values are a mixture of English and German words. However, the sample utterances are in German. During AO generation we translate database values in the synonym mapping step (see subsection IV-B2). The generated leaf nodes are defective in some cases due to incorrect translations. However, we cannot measure the effect (if existing).

To assess the quality of our generated AOs we compare them to the Dialogflow agents. Therefore, we match the replies for a request returned by the AOs against Dialogflow. We assume that replies given by the Dialogflow agents are always correct, since all sample utterances have been manually annotated with intent and entity labels by developers. The Dialogflow agents contain 1,652 sample utterances (tourism: 1,140, hotels: 378, web cams: 134) with 4,597 entities (tourism: 2,430, hotels: 727, web cams: 1,440). To limit the effort, we analyzed a randomly sampled subset. We used 100 test utterances per domain for the configuration with no sample utterances, i.e. AOs built from databases and synonyms, and for the configuration with samples from *all* domains. For the other configurations we used 50 samples each.

The results of our study are depicted in Table I; the highest values for each configuration and per measure are highlighted. The first column shows the configuration for the phrase extraction, i.e. from which domain we took samples during AO generation: (T)ourism, (H)otel, and (W)eb cam. For all configurations we determine accuracy, recall, precision, and F_1 for the test utterances for individual domains (T, H, and W) and all domains (\forall). Note that we determine accuracy on a per-reply level, i.e. we count only answers that exactly match the Dialogflow result as correct. For precision, recall, and F_1

TABLE I
EVALUATION RESULTS FOR DIFFERENT PHRASE EXTRACTION SETTINGS. WE EITHER USED NONE, PHRASES FROM TOURISM (T), HOTEL (H), AND WEBCAM (W) AGENTS, OR VARIOUS COMBINATIONS.

Phrase Extr.	Accuracy				Recall				Precision				F ₁			
	T	H	W	∅	T	H	W	∅	T	H	W	∅	T	H	W	∅
none	0.11	0.00	0.16	0.09	0.12	0.06	0.29	0.18	0.34	0.60	0.79	0.58	0.18	0.11	0.42	0.27
T	0.30	0.02	0.22	0.18	0.50	0.22	0.29	0.35	0.72	0.45	0.42	0.55	0.59	0.30	0.34	0.40
H	0.14	0.00	0.06	0.06	0.04	0.10	0.26	0.17	0.13	0.40	0.75	0.48	0.06	0.16	0.39	0.25
W	0.14	0.02	0.24	0.13	0.19	0.31	0.51	0.34	0.42	0.63	0.84	0.66	0.26	0.42	0.63	0.45
T+H	0.26	0.04	0.22	0.17	0.43	0.25	0.55	0.28	0.71	0.47	0.45	0.52	0.55	0.35	0.37	0.36
T+W	0.32	0.02	0.40	0.24	0.44	0.33	0.55	0.46	0.78	0.52	0.96	0.79	0.57	0.40	0.70	0.58
H+W	0.02	0.14	0.34	0.16	0.18	0.24	0.55	0.33	0.26	0.50	0.78	0.51	0.21	0.32	0.65	0.43
T+H+W	0.30	0.08	0.28	0.22	0.45	0.35	0.50	0.45	0.74	0.62	0.79	0.78	0.54	0.43	0.61	0.57

we compare each element (i.e. *entity* in Dialogflow, *concept* in the AO) of the service call separately.

If an element is identified correctly, it is considered a true positive. Elements that were extracted mistakenly, i.e. they do not match an element extracted by the Dialogflow agent, are false positives. Any missing elements account for false negatives. Assuming that the service call elements for the exemplary request, “Find me a hotel in Lisbon,” are:

- Dialogflow: [hotel]_{ent:type}, [Lisbon]_{ent:location}
- Active Ontology: [hotel]_{ent:type}, [sauna]_{ent:feature}

In this example, *hotel* is a true positive, *Lisbon* a false negative, and the *sauna* accounts for a false positive.

The results indicate that our approach is feasible. Using the databases and synonyms for values only we achieve a precision of 58% (recall 18% and F₁ 27%). However, the accuracy (9%) shows that there is still much room for improvement. The evaluation also shows that enriching the AOs with sample utterances improves the quality in almost all cases. The best accuracy (40%), recall (55%), precision (96%), and F₁ (70%) are achieved for web cam requests when we use sample utterances from both the tourism and web cam domains. This clearly shows that phrases from other domains improves the linguistic competence of AOs. The effect can be further assessed with the results from the tourism domain with phrases extracted from the web cam domain (row *H*). Accuracy, recall, and precision improve in comparison to the configuration without any phrase extraction. This is due to shared concepts in both domains and similar sample utterances. For example, our approach extracts the prefixes *are there* for the concept @type and *in* for location from the web cam sample: “Are there [live pictures]_{ent:type} in [Salzburg]_{ent:location}?”¹¹ The prefixes can be applied to requests from the tourism domain such as, “Are there ski schools in Seeberg?”¹²

However, extracting sample utterances from the hotel domain often degrades the results as one can see, e.g. in the rows *H* and *H+W*. This is due to requests with many enumerations that occur frequently such as, “I am looking for a designer hotel with free parking, sauna, whirlpool, wifi, tennis court,

and a restaurant voucher.”¹³ Pre- and postfixes extracted from such samples produce both false positives and false negatives. For example, if the sample does not have an entity annotation for *free parking* our approach extracts the prefix *with free parking* for the concept *feature* (instance *sauna*) that causes false positives. Vice versa, if *free parking* has an annotation our approach misses the (correct) prefix *with* as we discontinue phrase extraction at the next annotation.

The best results for the hotel domain are achieved if we extract phrases from the web cam domain (see rows *W*, *T+W*, *T+H+W*). The results for tourism and web cams both improve when phrase samples from their own domain are used.

Accuracy values are low. However, using any kind of sample utterances increases the accuracy in all domains in almost all cases and reaches 40% in the best case.

We identified three errors classes that primarily affect the results. Rare errors are false positive elements due to missing pre-/postfixes. Concepts never mentioned in sample utterances are still part of the AO. These concept nodes have vocabulary, regex, or date nodes attached. Therefore, they might match requests even though the request have different intents. For example, a hotel might have a laundry but no sample mentioning it. The hotel AO then has a vocabulary node that reacts to any “laundry” in user requests. This may create false positives from requests such as, “I’m looking for laundries.”

Another error class is the incorrect selection of service calls. Our approach consolidates all concepts from each domain in a single AO. This way, we assure that only one service call is created from all hypothesis (combinations of elements). In some cases correct hypothesis have lower confidences than incorrect ones. If so, the root node chooses the wrong hypothesis and creates an incorrect service call.

Missing or incorrect synonyms form the third error class. Missing synonyms cause false negatives, while incorrect synonyms may produce false positives. An example for the latter is the German synonym *Haufen* (engl. *pile/bunch*) for the word *Berg* (engl. *mountain*) that is often used in colloquial idioms. This causes the AO part responsible for information on ski tours (to particular mountains) to react to phrases such as “ein Haufen Leute” (engl. “a bunch of people”).

¹¹Original: “Gibt es [Live Bilder]_{ent:type} in [Salzburg]_{ent:location}?”

¹²Original: “Gibt es Skischulen in Seeberg?”

¹³Original: “Ich suche ein Designerhotel mit gratis Parkplatz, Sauna, Whirlpool, WLAN, Tennisplatz und einem Restaurantgutschein.”

VI. CONCLUSION AND FUTURE WORK

We have presented an approach to automatically create virtual assistants from databases. Our virtual assistants use Active Ontologies to model the problem domain and process user utterances.

To generate AOs we first infer a concept hierarchy from database schemes and create word lists and regular expressions from extracted database values. We extend the word lists with synonyms from Wiktionary. Additionally, if sample utterances are present, we build pre- and postfix nodes to enhance the linguistic competence of our AOs.

Our evaluation in the domains tourism, hotel, and web cams shows that our approach successfully generates AOs that extract relevant information from user utterances. When we use sample utterances, precision and recall increases. Our approach successfully learns phrases from a domain (e.g. tourism) and uses it for queries from another (e.g. hotel).

We plan to improve the AO generation process. For the time being, we create one AO per domain. We experiment with smaller AOs, that may extract intents with higher confidences. This also evades the duplication of subtrees (e.g. for addresses of restaurants and cinemas).

Another improvement involves the general structure of the AOs. In some cases multiple pre- and postfix nodes fire at the same time, which makes intent extraction ambiguous. An additional layer of selection nodes that selects the most reasonable pre-/postfix may be beneficial.

We observed that some phrase segments are more meaningful than others. Therefore, we have implemented an alternative to pre-/postfix nodes. Instead of using full pre-/postfix phrases we extract single words and create a vocabulary node for each. We attach all of them to an additional layer of gather nodes that represent the original pre-/postfixes. This way, we create subtrees that capture bags of words. We calculate the TFIDF for each word per intent (each intent is a document and all intents correspond to the document set). The TFIDF value is used as confidence for the new vocabulary nodes.

A first case study shows the potential of this approach. We used 239 sample utterances from Dialogflow agents for the intent “request opening hours”. Additionally, we created 13 synthetic requests for addresses (e.g., *What is the address of the restaurant The Toothless Shark in Cologne?*).

We created bag-of-words subtrees for both intents and integrated them into the AO. On the test set the AOs answered opening hours request with an accuracy of 65% and addresses with an accuracy of 23%. The low accuracy for the latter is due to the small number of sample utterances.

With the bag-of-words subtrees the AOs can extract multiple intents from single user utterance. For the time being, virtual assistants such as Dialogflow cannot combine different intents. Thus, our approach improves the state of the art. Composed requests such as, “Give me the address and the opening hours of the hotel Tivoli Oriente in Lisbon,” achieve an accuracy of 40%. In the future, we plan to further investigate the bag-of-words-approach and evaluate it on a larger data set.

VII. ACKNOWLEDGEMENT

The evaluation of our approach was partially supported by Onlim GmbH¹⁴ that provided the data for testing. We thank Dr. Ioan Toma (Onlim GmbH) who greatly assisted our research.

Email: [priscilla.neuhaus, julia.couto, jonatas.wehrmann]@edu.pucrs.br, [duncan.ruiz, felipe.meneguzzi]@pucrs.br

Abstract—Creating an optimal amount of indexes, taking into account query performance and database size remains a challenge. In theory, one can speed up query response by creating indexes on the most used columns, although causing slower data insertion and deletion, and requiring a much larger amount of memory for storing the indexing data, but in practice, it is very important to balance such a trade-off. This is not a trivial task that often requires action from the Database Administrator. We address this problem by introducing GADIS, A Genetic Algorithm for Database Index Selection, designed to automatically select the best configuration of indexes adaptable for any database schema. This method aims to find the fittest individuals for optimizing both query response time, and disk required for the indexed data. We evaluate the effectiveness of GADIS through several experiments we developed based on a standard database benchmark, compare it to three baseline indexing strategies, and show that our approach consistently leads to a better resulting index configuration.

Index Terms—Database, Indexing, Artificial Intelligence, Genetic algorithms, Learning system.

I. INTRODUCTION

Creating indexes is the main action to improve database query performance [7, Chap. 15], since the indexes are the most used technique to speed up queries response [9]. However, it is important to properly choose the columns to be indexed, given that it also affect time to insert and update data and increase disk consumption. The Database Management Systems (DBMS) optimizer is responsible for analyzing queries and choosing the most efficient way to access information. The goal of an optimizer is to find options for running a given query and evaluate the cost of each choice, so that the chosen one would provide the best performance for retrieving the data.

Achieving the best indexing configuration for a database is not a trivial task [6]. Ideally, all the frequently queried columns should be indexed for a faster data retrieval. However, it is quite complex to find a balanced trade-off between performance and storage required. It is quite often the case when the cost-based optimizer is not able to find a proper solution, requiring the DBA to make a final decision on the database architecture regarding indexing strategies.

In this paper we developed GADIS, an approach based on Genetic Algorithms (GA) to help finding an optimal index configuration. We use two fitness functions: 1) an optimization objective to maximize the database performance considering INSERT, DELETE and SELECT queries; and 2) designed to

optimize the query response time by search for faster index configurations when compared to the initial one.

We perform a set of experiments using TPC-H, a well known database benchmark [11], and we compare our results with three baseline approaches: (i) the initial index configuration; and (ii) indexes derived from a random-search algorithm. Results show that GADIS outperforms the baselines, allowing for better index configuration on the optimized database. Finally, we observe that our approach is much more prone to find a proper solution that the competitive methods.

II. BACKGROUND

A. Genetic Algorithms

Holland [3] developed the concept of Genetic Algorithm inspired by the evolutionist theory. GA simulates the principles of biological evolution by repeatedly modifying a population of individual using rules modelled on reproduction and gene combinations. In this simulation of evolution, it leverages the best genes from the fittest individuals of a population to continue across the next generations. GA models individuals in terms of their genome, typically represented as strings of bits. Each generation replaces the previous population by its fittest *offspring*, where fitness is computed by a fitness function that assigns a score to each individual. Fitness typically measures how well an individual solves the problem at hand. The algorithm initializes with a random population and works through *selection*, *crossover*, and *mutation*. That process continues until the optimize criterion is satisfied or a certain number of generations is reached. Due to its random nature, GA improves the chances of finding a global solution.

B. TPC-H Benchmark

TPC¹ is a a non-profit corporation that produces database benchmarks. We chose TPC-H because it models a business database having realistic ad-hoc queries. TPC-H has a database schema, a workload and performance metric tests. The database size varies according to a constant named scale factor (SF). The workload is composed of 22 queries of varying complexity, and 2 refresh functions, that simulate data insertions and deletions in the two larger tables (`orders` and `lineitems`). In the performance test, the benchmark executes a power test and then a throughput test. The power

TABLE I
GA DEFINITIONS APPLIED IN THE CONTEXT OF THE DBMS

GA Definition	DBMS Application
Gene	0 if the column is not indexed; 1 otherwise
Individual	a database state represented by a vector that refers the columns of the schema
Population	collection of database states
Parents	two database states selected to be combined and next create a new database state
Mating pool	a collection of parents that are used to create the next population
Fitness	a function that tells us how good each database state is by running the benchmark
Mutation	a way to introduce variation in our population by randomly swapping the genes (0 - 1) of two individuals
Elitism	a way to carry the best individuals into the next generation

test (POWER@SIZE), calculates how fast the system computes answers to single queries. It executes a function to insert data, then it runs all queries in parallel, then it executes another function to delete data. The throughput test (THROUGHPUT@SIZE) measures how many queries were executed in the elapsed time for parallel query streams to simulate multiple users. It computes the ratio between the total number of queries and the total time spent to run the queries. TPC-H also presents the query-per-hour metric (QPHH), obtained from the geometric mean of power and throughput test. It captures the overall performance level of the system, both for single-user and multi-user mode.

III. METHOD

We already saw that indexes can speed up the data access. However, when we create or delete indexes we must verify which combination of indexes is the best one for queries selection. Specifically, for optimizing the TPC-H database, there are 2^{45} possible combinations for column indexing. Our approach is based on GAs trained directly on a running database, designed to evolve individuals that represent the whole index structure (i.e., all the columns on the database). We map GA definitions to the DBMS context in Table I.

A. Individual Representation

We use a straightforward individual representation that is based on binary vectors. In this strategy, each vector position denotes whether a column is indexed or not. Formally, we represent an individual as a binary vector \mathbf{x} , where $|\mathbf{x}| = C$ and C is the number of all columns in the whole database schema. Hence, x_i denotes whether the i^{th} column should be indexed by the DBMS. Naturally, both primary and foreign keys are always indexed, and therefore not affected by any crossover, mutation or additional random-based action on \mathbf{x} .

The initial population with n individuals is randomly created by sampling bits from an uniform distribution. Each bit corresponds to a specific gene having two possible actions: *create* or *drop* one index. Each individual is a concatenation of the binary representation of all columns from all tables. TPC-H contains 61 columns across 8 tables, with 16 primary

and foreign keys indexed by default. From the remaining columns, only 24 are used on the benchmark queries. Hence, each individual is comprised by $C = 24$ mutable genes, which generates a search space containing $2^{24} = 16,777,216$ possible combination of indexes.

B. Fitness Function

During the evolutionary process, we use a fitness function to estimate the degree of adaptation to the environment for each individual in the population. We first use the QPHH as fitness function that aims to optimize the performance for running queries while being computationally cheaper for data insertion and removal. We also propose a simpler approach, which optimizes the speed-up time for running all the 22 select queries in the benchmark.

More specifically, we want to find an individual represented by a genome that is capable of achieving high QPHH, but using the very least memory as possible. Formally, let $\mathcal{Q}(\mathbf{x})$, $\mathcal{H}(\mathbf{x})$ and $\mathcal{P}(\mathbf{x})$ be the functions that estimate the QPHH, THROUGHPUT@SIZE and POWER@SIZE for a given \mathbf{x} . Note that the estimate of $\mathcal{P}(\mathbf{x})$ is calculated by running all the queries in the benchmark, including delete and insert ones that are quite slow in heavily indexed databases. Thus, a database in which most of the columns are indexed would most likely yield lower POWER@SIZE values. The QPHH-based fitness function would be hereby referred as $\mathcal{Q}(\mathbf{x})$, calculated by Eq. 1.

$$\mathcal{Q}(\mathbf{x}) = \sqrt{\mathcal{P}(\mathbf{x}) \times \mathcal{H}(\mathbf{x})} \quad (1)$$

Our second fitness function optimize the time performance for running the SELECT queries in the benchmark. In this case, we want to find individuals that are capable of retrieving data efficiently, without considering data insertion and removal. This is achieved by optimizing the speed-up of the current individual when compared to a baseline one, namely, the initial state of the database. In this case, we refer to the function that calculates the total query time for a given individual as $\mathcal{T}(\mathbf{x})$. Finally, the speed-up-based fitness function is given by

$$\mathcal{S}(\mathbf{x}) = \frac{\mathcal{T}(\mathbf{x}_I)}{\mathcal{T}(\mathbf{x})} \quad (2)$$

where \mathbf{x}_I denotes the individual for the initial state of the database. Therefore, individuals with lower values of $\mathcal{T}(\mathbf{x})$ have higher fitness values than those that take more time to run the benchmark. In this case, we are necessarily optimizing the database storage requirements for index data. In summary, the proposed fitness functions are two-fold: (i) $\mathcal{Q}(\mathbf{x})$, which optimizes the performance for INSERT, DELETE and SELECT commands, and by transitivity, it also helps to lower memory requirements for indexes; and (ii) $\mathcal{T}(\mathbf{x})$ that directly optimizes the running time for all queries.

C. Selection

Our approach uses the popular and effective tournament method as selection technique, developed by Horn et al. [8]. It is a strategy for selecting the fittest candidates from the current generation in a GA. The process initiates with two candidate

points selected randomly from the current population, that compete for survival in the next generation. The next step is to compile points randomly to compose a tournament set, where each member is compared with other members. We need to specify the size of the tournament set as a percentage of the total population. Hence, the tournament set size implies the degree of difficulty in surviving. If the tournament size is larger, weak candidates have a smaller chance of getting selected as it has to compete with a stronger candidate. We use the selection pressure to determine the rate of convergence of the GA. This is a probabilistic measure of a candidate likelihood of participation in a tournament. Here, the convergence rate is proportional to the selection pressure, and the GA is capable of identifying optimal or near-optimal solutions over a wide range of selection pressures. The tournament selection works either for positive or negative fitness values.

D. Crossover and Mutation

After obtaining the individual from selection method, we apply the crossover genetic operator on population. In this phase, two individuals exchange information to produce the offspring. Both crossover and mutation occur only with respect to some probability previously defined. The main goal of the use of crossover is to make it possible for the genes of two individuals to generate an improved individual. Higher crossover values lead to in-depth exploitation of the current population individuals, but constraining the exploration of the search space. We employ the two-point operator [10], that determines two random crossover points to mark at which points of the two parents will occur the split. Next, the tails of their two parents are swapped to get a new offspring, which would integrate the population. It is important to define the crossover probability (cp), which controls the frequency of the application of the crossover operator on the individuals. For instance, when using $cp = 1.00$, crossover is applied over the entire population. On the other side, when $cp = 0.00$, the entire new generation is made from exact copies of individuals from old population (which can suffer mutation as well).

The next step is the mutation operator, that introduces random changes into the characteristics of the individuals. Mutation plays a critical role in GA, as crossover leads the population to converge by making the individuals in the population alike. Mutation reintroduces genetic diversity back into the population. In this phase, we need to set the mutation probability and the mutation rate. The first parameter sets the chance of each individual to be mutated, whilst the second one refers to the number of genes that would be changed.

Frequently, the mutation rate is rather small and depends on the length of the individuals. Therefore, new individuals produced by mutation will not be very different from the original one. Since we set each individual as a bit vector, the mutation operator is responsible to change the bit value of 1 to 0 or vice-versa. We also provide some experiments using a linear decay for the mutation probability. Such a decay allows for larger exploration during the initial generations, increasing

the genetic diversity, while allowing for in depth exploitation during the latter stages of the optimization procedure.

IV. EXPERIMENTAL SETUP

We carried out all experiments in hardware with Intel(R) Xeon(R) Platinum 8175M CPU @ 2.50GHz, 30GiB RAM and Non-Volatile memory controller (SSD), running Ubuntu Linux 16.04. We used DEAP [2], an open-source Python package, to implement the genetic algorithm. To evaluate all approaches, we use the TPC-H benchmark with scale factor of 1GB. We run the performance test and calculate the $POWER@SIZE$ and $THROUGHPUT@SIZE$ metrics for each execution of TPC-H. Then we calculate the QPHH for each individual ($Q(x)$).

A. Baselines

For evaluating our approaches we defined three main baseline strategies for database indexing. We compared our approach with the following strategies: (1) TPC-H initial state (only primary and foreign keys are indexed); (2) results achieved via a random-search algorithm that optimizes the proposed fitness functions. We run the random search using the same number of individuals as in our optimization algorithm.

B. Evaluation Measures

In our experiments, we run the final evaluation using a different set of query streams to the database, in order to make sure that our GA was not overfitting the training examples. First, we set the best indexing configurations found during the whole training phase, in order to run the complete benchmark. For quantitative evaluation, we used QPHH and the storage required by the index data (in MB).

C. Parameters

The first three experiments were designed to optimize the fitness function $Q(x)$, in order to maximize the QPHH metric. The two latter ones focused on minimizing the second fitness function, namely the benchmark runtime given by $T(x)$. For all experiments we used a initial population of 50 individuals, evolved during 50 generations, with mutation rate of 0.05 and elite size of 4. Parameters such as fitness function, mutation probability (mp), crossover probability (cp) and mutation decay (md) are defined as follows: $GADIS-[Q, mp=0.9, cp=0.8, md=0.05]$ and $GADIS-[T, mp=0.9, cp=0.6]$. The complete training procedure for each of those experiments (including random search) took about a week.

V. RESULTS

Figure 1 shows the performance of our approaches during the training phase. The chart shows values of QPHH as fitness for all evolved individuals; and the second chart depicts values of time required to run the test benchmark (only with SELECT queries), by using our second fitness function, namely $T(x)$. GADIS have shown to be much better in terms of consistency, once it can find several good database configurations with ease when comparing to the baseline. It is clear that both $GADIS-[Q]$ $GADIS-[T]$ present similar performance during

Fig. 1. QPHH and Time during training procedure.

TABLE II
RESULTS IN TERMS OF QPHH, TIME AND INDEX SIZE

Methods	QPHH	Time	Index Size
Initial State	1678	149.3s	599 MB
Random Search	1864	145.3s	1196 MB
GADIS-[Q]	2631	71.2s	1193 MB
GADIS-[T]	3077	60.6s	1600 MB

the training phase, though the latter presents itself as a much faster approach.

Table II shows quantitative results in terms of QPHH, Time and Index Size for each one of the approaches. Note that the best performing approach as measure in QPHH and Time is achieved by GADIS-[T]. Additionally, both versions of GADIS were able to achieve top results in all used metrics. GADIS-[Q] also requires roughly the same disk space when compared to the baseline, though with 40% better QPHH performance.

VI. RELATED WORK

In the past years, other researchers have used GA to improve database performance. Korytkowski et al. [4] present an automatic way to find the best set of indexes for a database, using GA. Different from our approach, their fitness function is based on time spent in insert operations and a single query, and they make experiments with just one table.

Pedrozo et al. [5] modelled an index tuning architecture applied to hybrid storage environments using GA to create indexes in the DBMS. They also use TPC-H benchmark to evaluate their approach, but unlike us, they did not apply the performance test provided by the benchmark.

Boronski et al. [1] propose a model to optimize the response time of a set of queries by creating indexes in a relational database. Unlike us, they use the response time of each group of queries to measure their performance and then compare it with the Oracle advisor.

VII. CONCLUSIONS

In this paper we developed a Genetic Algorithm-based approach for automatic index selection in databases called GADIS. This approach can find database configurations that outperform all the baselines in most of the scenarios, while saving storage requirements. We have observed that the training procedure of GADIS is very consistent, which allows us to find proper database configurations within only a few generations. In addition, GADIS is easily suited to be implemented on any database system. The main limitation of our work is that to find a good solution one has to run several distinct database configurations and evaluate them by using a benchmark. Such a procedure is somewhat costly, and required about a week of processing to optimize the indexes for the used database. For future work, we plan to improve GADIS so we can learn general rules for database agnostic indexing using metadata rather than performing a per-database optimization.

Research on Page Object Generation Approach for Web Application Testing

Yimei Chen, Zheng Li, Ruilian Zhao and Junxia Guo*

College of Information Science and Technology,
Beijing University of Chemical Technology, Beijing, China

*Corresponding: gjxia@mail.buct.edu.cn

Abstract—Test code generated by using the page object design pattern during web testing is easy to maintain. Page clustering is an essential stage of the page object approach. However, existing methods only consider the DOM structure in page clustering, which leads to inaccuracy when generating page objects. A state with the same DOM structure may result in an entirely different migration. The method of considering only the DOM structure cannot accurately generate page object classes. In order to improve the accuracy of page object generation, this paper not only considers DOM structure information but also considers CSS styles and the attributes of DOM elements in page clustering. Based on the experimental evaluation results, our method can automatically generate page objects that cover most of the application functions, which is more effective for the creation and maintenance of web test cases.

Index Terms—Web applications, Automated testing, Page object.

I. INTRODUCTION

As an essential stage of software development, software testing can be described as the process of identifying the correctness of programs. The primary purpose is to find possible errors in programs [1]. The cost of software testing is about 50% of entire software development cycle [2]. With the faster step of business, the software development cycle also becomes shorten and shorten. As a result, software testing needs to be finished in limited time, especially for quick-updated web applications. Because of cost constraints, software companies want to test their software as quickly as possible. Thus, research on automated testing has received significant attention in both industry and academia. Automated testing can run frequently, shorten the test cycle, quickly respond to changing requirements, and make the development process more agile.

The existing end-to-end automated test tools have a similar problem of maintaining test scripts during software evolution. Although those test tools can make testing easier, they cannot help testers write well-structured test scripts. To adapt to changing web applications, testers need to change test suites, which represents a considerable workload. Thus, the techniques for both test suite generation and maintenance are needed.

The page object pattern [3] is an effective mode on enhancing test suite maintenance and can reduce code duplication. A page object is an object-oriented class that acts as an interface

to the web page of applications under test. Individually, all element attributes and element operations of a page object are encapsulated in a class. Whenever testers need to interact with elements of the user interface, the test case will use the approaches of the page object class. The test code is separated from the page elements and its methods of operation, in order to reduce the impact of changes in page elements on the test code. If page elements are changed, we only need to modify the code of the corresponding page object (the corresponding class) without modifying the test code. Therefore, it is beneficial to adopt the page object mode in maintaining web test suites.

However, the existing tools based on page object mode have their limitations. Only the DOM state is used for page clustering, which leads to the inaccuracy of generating page objects. Two web pages with the same DOM structure can show different visual effects and trigger completely different events, which should be divided into two page objects. To address this problem, we propose an approach for automatically generating page objects for web application testing, which is more accurate and efficient.

In this paper, we conduct in-depth research on page object generation and use it in web testing. Its main contributions are listed as follows.

1. Oriented to the automated generation of page object, we theoretically analyze influence factors related to page clustering. Based on the consideration of the DOM structure of two pages, we also consider CSS styles and attributes of DOM elements. According to the multiple influence factors, we propose a two-stage clustering algorithm.
2. We implement a prototype tool for automatically generating test cases for web applications, which combines multiple influence factors we propose in page clustering. In this way, we effectively solve the problems of repeated inaccurate testing in the automated testing process and improve the efficiency of the test.
3. We do a series of experiments with several kinds of web applications to evaluate the approach of this paper.

The organization of this paper is as follows. Section II presents the motivation. Section III introduces our approach, theoretically analyzing influence factors on page clustering and also proposes a clustering algorithm of multiple influence fac-

Fig. 1. A simple DOM tree of pageA.

Fig. 2. A simple DOM tree of pageB.

tors. Section IV presents the experimental results to assess the effectiveness of our approach and its limitations. The relevant research is presented in Section V. Section VI concludes and presents the future works.

II. MOTIVATION

Generally, generating page objects starts from a state-based model (graph) of the web application. The model consists of nodes and edges, where nodes are dynamic DOM states of web pages and edges are attribute-based transitions between nodes. The information of nodes and edges can be crawled from the web application. Then, the similar web pages are grouped into an abstract representation by the page clustering algorithm. Consequently, the related interactions between the web pages may change according to the clustering results. Finally, a set of page objects is generated for the abstract web pages and their interaction.

From the above analysis, we can find that the accuracy of page clustering is a crucial aspect when generating page objects. Page clustering relies on the similarity between web pages. However, the existing studies focus on structural features only, such as tag frequency, URL, DOM elements and so on, ignoring CSS styles and the attributes of DOM elements, to measure the similarity between web pages. This leads to the inaccuracy of page clustering and page object generation.

As an example, assume that two web pages with the same DOM structure can show different visual effects and trigger completely different events, which should be grouped into two page objects. However, the existing tools which only use the DOM structure information for clustering web pages will classify these two pages into one category, causing the inaccuracy of page objects. For instance, as shown in the Fig.1 and Fig.2, different attribute(i.e. id) values are set to the <div> tags with the same DOM structure. Meanwhile, different attribute handlers *button1* and *button2* are set to

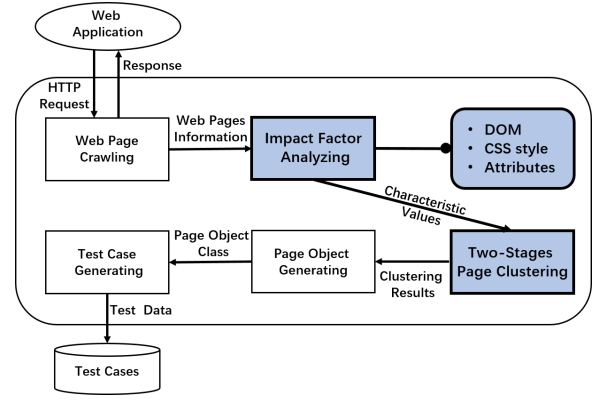

Fig. 3. An overview of the approach.

different ids. Even if their tags and structures are identical, pageA and pageB represent different states, and they should be divided into two page objects.

For measuring the similarity between web pages, the features which are using in existing approaches are insufficient. To solve this problem, we conduct an in-depth analysis of page information and raise a novel set of features considering the structure, CSS styles and attributes of pages, as well as the corresponding similarity measurement to distinguish pages with the same DOM structures but different functions.

III. OUR APPROACH

A. Approach Overview

The overview of our approach is shown in Fig.3. This paper design an automated testing framework which has five main steps. In the first step, by using a specific crawler, we can simulate user actions to get information. Then, we theoretically analyze factors that affect page clustering, including DOM structures, CSS styles and attributes of DOM elements. In this step, we get their respective characteristic values. In step three, according to the two-stages clustering algorithm mentioned in this article, web pages are clustered. Next, page objects can be generated for every clustered page. Finally, test cases can be generated by calling page elements in corresponding page object classes.

B. influence factors related to page clustering

1) *influence factors of DOM structure*: DOM is a neutral interface between platform and language that allows programs or scripts to dynamically access content, styles and structure of updated documents [4]. The DOM structure represents the hierarchical structure of a web page and is very important for quantifying the similarity degree of web pages. In this paper, we use tree edit distance (TED) [5] to calculate the similarity of DOM. The Tree Edit Distance is the minimum number of tree editing operations that convert tree T to tree T'.

2) *influence factors of CSS styles*: In web applications, HTML tags not only display information about the structure and content of the page but also show some information about performance. Cascading Style Sheets (CSS) define how HTML

elements are displayed. Web developers nowadays put the information not only in the HTML tag hierarchy but also in the style sheets. CSS styles of web pages are also important information for page clustering.

In CSS, each style is usually named by a class value. The HTML elements in a web page are rendered by referring to the class values. The HTML elements with the same class value have the same style. Therefore, we consider using information on class attributes as a kind of assist for page clustering when generating page objects. This may avoid the misclustering case where the DOM structure of two pages is the same, but different CSS styles are used, which should not be classified into one category.

The process of building a style matrix between two pages is as follows. Firstly, we parse the HTML document of the web page and get a collection of all class values used in this page. We can record the class value information of the two web pages into two sets A and B. Then we can use Jaccard distance to calculate the distance between the class value matrix of two pages. The calculation method is listed in Equation 1.

$$D_j(A, B) = 1 - J(A, B) = \frac{A \Delta B}{|A| + |B| - |A \cap B|} \quad (1)$$

When $A = B$, $D_j(A, B) = 0$. The smaller the value, the more similar the two pages are. We use the calculation result of Jaccard distance as the style matrix values. According to the above steps, the style matrix values of any two pages can be respectively calculated and stored in the corresponding vectors.

3) *influence factors of the attributes of DOM elements*: If the structure of the two pages is the same, but the attributes of DOM elements bound on the nodes are different, different functions will be triggered. So the attributes of DOM elements may be helpful in clustering. HTML pages contain different HTML elements which may have different attributes and different functions. If all the attributes are taken into account, it will not only significantly increase the complexity of the method, but also reduce the accuracy of comparison, for example, the src attributes of nodes.

The id value in a web page is a kind of unique identifier for a DOM node. Usually, scripting languages use id as a tag to find the node where id is located. So id value is significant for migration between states. We can distinguish different events bound to a node by id. Therefore, we consider that id value is a useful attribute in clustering and state migration.

We use Jaccard distance of id values to construct an attribute-based matrix between two pages. We get a collection of all the id values of a web page and use Equation 1 to calculate the id-distance of two web pages.

4) *Using tag filter to reduce the DOM state*: There are a large number of tags in HTML pages. Different tags have different effects. Not all tags in the HTML document are helpful in page clustering. We propose a tag filter method to reduce the pending tags in the HTML document, which focus on the effective tags and improves the usability and accuracy of the discovered tags. So that in page clustering, tag filter

can remove some interference, which can improve accuracy and speed.

In HTML pages, tags like <head>, <style>, <script> and <link> contain data that is not displayed to the user as content, which is a factor in clustering with DOM structures. In theory, by removing these tags that are not used for structure analysis, not only will the DOM structure will become smaller and simplified, but also the consumption time will be reduced. DOM is the foundation of web application display. The more accurately the page structure is analyzed, the more completely its functions are understood. Based on the DOM structure, tag filter optimizes the clustering approach and indirectly improves the accuracy of subsequent operations.

C. A two-stages clustering algorithm using multiple influence factors

The factors affecting page clustering mentioned above have their pros and cons. They have different effects on different types of websites. If we only use one of them to measure all types of web pages, there will be inaccurate classification problems that affect the accuracy of page object generation.

Algorithm 1 A two-stages clustering algorithm using multiple influence factors

Input: HTML pages P_n crawled by crawler

Output: A set of clustering results S_j of HTML pages

```

1: Get  $P'_n$  by using tag filter on  $P_n$ 
2: Calculate DOM tree edit distance matrix  $M_{DOM}$  of  $P'_n$ 
3: Generate  $S_i$  using hierarchical clustering on  $M_{DOM}$ 
4:  $n$  = number of crawled HTML pages in  $P'_n$ 
5:  $i$  = number of clustering results in  $S_i$ 
6:  $j$  = number of clustering results in  $S_j$ 
7: for all  $(s_1, s_2, \dots, s_i) \in S_i$  do
8:   if Consider CSS styles then
9:     Get class values sets  $S_{CSS}$  of  $P'_n$ 
10:    Calculate  $M_{CSS}$  of  $S_{CSS}$  based on Equation 1
11:    Generate  $S_j$  using hierarchical clustering on  $M_{CSS}$ 
12:    return  $S_j$ 
13:   else if Consider attributes then
14:     Get id values sets  $S_{id}$  of  $P'_n$ 
15:     Calculate  $M_{id}$  of  $S_{id}$  based on Equation 1
16:     Generate  $S_j$  using hierarchical clustering on  $M_{id}$ 
17:     return  $S_j$ 
18:   else if Consider CSS styles and attributes then
19:     Calculate  $M_{Cid}$  based on Equation 2
20:     Calculate  $M_{Cid}$  based on Equation 1
21:     Generate  $S_j$  using hierarchical clustering on  $M_{id}$ 
22:     return  $S_j$ 
23:   else
24:     return  $S_i$ 
25:   end if
26: end for

```

Therefore, we propose a two-stage clustering algorithm using multiple influence factors as shown in Algorithm 1. We use tag filter on the pages crawled for preprocessing

TABLE I
TEST SUBJECTS.

Application	states	URLs	edges	DOM length
Aminer	12	4	17	58.714 kB
Termonline	57	3	56	26.194 kB
Musicbible	27	7	42	185.73 kB
BUCT	13	5	12	46.917 kB
DBLP	8	8	14	31.698 kB
CBA	17	17	51	31.156 kB
Chinacoop	55	49	108	18.26 kB
Xinxishibao	49	15	48	196.542 kB
Wanshifu	35	27	79	49.965 kB

to simplify the DOM structure. In the first stage, we use hierarchical clustering to cluster pages based on the DOM tree edit distance matrix of two pages. According to the clustering results of the first stage, we re-cluster the pages that are grouped into the same category. In the second stage, we consider different influence factors for clustering, CSS style and id attribute. Finally, the clustering results are returned according to different factors. This algorithm can correctly classify most different types of websites with better accuracy.

For any two web pages obtained by the crawler, the matrix M_{CSS} based on the influence factor of CSS styles can be obtained by calculating Jaccard distance of class value sets based on Equation 1 and the attribute matrix M_{id} can be gotten by computing Jaccard distance of id value sets. The final matrix value M_{Cid} of multiple influence factors according to a certain weight is calculated using Equation 2.

$$M_{Cid} = \omega \times M_{CSS} + (1 - \omega) \times M_{id} \quad (2)$$

ω and $(1 - \omega)$ respectively represent the weight of the matrix value of CSS styles and the attributes of DOM ids. Setting reasonable weights in the final calculation is necessary. In order to determine the value of the above two weight parameters, this paper performs parameter adjustment experiments on several web applications.

IV. CASE STUDIES

In order to study the effectiveness of page object generation approach proposed in this paper, we selected thirty web applications in six fields as test objects, which contains the fields of information search, arts, portals, sports, governments and life services. Due to the limited space, we chose one or two of each category for display. In this section we list the result of nine web applications, including Aminer, Termonline, Musicbible, BUCT, DBLP, CBA, Chinacoop, Xinxishibao and Wanshifu. Then we use a two-stage clustering algorithm using multiple influence factors on these applications and analyze its impact on the accuracy of page object generation.

A. Test subjects

Table I gives the information about the nine experimental objects, including each application's name, the number of states, the number of visited URLs, the number of edges and the average length of the DOM.

TABLE II
COMPARISONS OF EIGENVALUES OF USING TAG FILTER OR NOT.

HTML	Tag Fliter	The Value of Eigenvector
index	N	0,731,0,697,719,734,742,772
	Y	0,727,0,693,715,730,738,766
state6	N	731,0,731,151,79,65,80,1195
	Y	727,0,727,151,79,65,80,1184
state14	N	697,151,697,0,128,145,147,1151
	Y	693,151,693,0,128,145,147,1140
state23	N	772,1195,772,1151,1183,1192,1211,0
	Y	766,1184,766,1140,1172,1181,1200,0

Fig. 4. Comparison of time consumption (in ms) in generating DOM-based feature matrix with or without tag filter.

B. Experimental results

1) *Research on the effectiveness of tag filter on DOM states reduction:* We compare page objects generated by using tag filter or not. We find that the page states generated before and after tag filter are the same.

Table II is the data of feature vector based on the DOM tree edit distance extracted from test subject DBLP. The first column shows the labels instead of different HTML pages. The second column shows whether tag filter is used to reduce DOM states. The remaining columns are the experimental value of the feature vector.

In Table II, the size of the number represents the degree of difference between DOMs. By observing experimental data, we find that tag filter can simplify DOM structure and make it more similarity.

Fig.4 shows a comparison of the time consumption of generating a DOM-based feature matrix using tag filter or not. It shows that the times using the tag filter are shorter.

Therefore, We can say that using tag filter will not only produce more reasonable page objects but also reduce time consumption. So we use tag filter to simplify DOM structure before generating a feature matrix.

2) *Research on the effectiveness of two-stages clustering algorithm using multiple influence factors and weight setting:* We compare generated page objects with different influence factors for test subjects and manually analyze page objects generated of each web application. The analysis results are used as criteria for judging the effects of each influence factor.

TABLE III
COMPARISON OF THE EFFECTS OF VARIOUS INFLUENCE FACTORS.

Application	DOM	DOM+CSS	DOM+ID
Aminer	1.52%	0.00%	0.00%
Termonline	0.88%	0.88%	0.00%
Musicbible	6.55%	6.55%	5.13%
BUCT	12.82%	0.00%	12.82%
DBLP	14.29%	0.00%	14.29%
CBA	13.97%	6.62%	8.82%
Chinacoop	14.41%	0.00%	5.39%
Epaperxxsb	0.00%	1.70%	1.70%
Wanshifu	2.52%	2.18%	1.01%
total	66.95%	17.93%	49.15%

Table III shows the result of the two-stage clustering algorithm proposed in this paper with the percentage of the mis-classified page combination number vs. the total page combination number. The first column is web applications under test. Second column shows the results that only using the DOM structure for page clustering. The third column shows the results that consider the DOM structure and CSS style for page clustering. The fourth column shows the results using DOM structure and attribute influence factors. The last line is the sum of the error rates for each method on all test subjects.

Through the data in Table III, we can find that for the application Aminer, the result of page objects generated when considering CSS style and DOM attribute for page clustering is the same as the result of the manual analysis. Moreover, they are both better than only considering the DOM structure. For the application Termonline, Musicbible and Wanshifu, the results that use DOM attribute have the lowest error rate when generating page objects. For the application BUCT, DBLP, CBA and Chinacoop, page objects generated by DOM structure and CSS styles have the lowest error rate. In addition to application Epaperxxsb, results of CSS-assisted DOM or ID-assisted DOM are better than using only DOM.

Therefore, we conclude that the generating accuracy of page object generated using our clustering algorithm is better than the method that only considering the DOM structure. However, the results of DOM structure with CSS styles and DOM structure with attribute have different performance for different applications. Therefore, we also do experiment that combine those two influence factors with different weights to achieve the best classification accuracy.

To set reasonable weights for CSS styles and DOM attributes in the final calculation, we did experimental research. In addition, we need to find the suitable condition for starting the second stage. If the result of first stage shows that the two pages are quite different, the second stage need not to be started. Therefore, We set the trigger threshold of the second stage in page clustering to be 0.5. When the distance between two pages exceeds the threshold in first stage, the clustering algorithm will start the second stage's processing.

The weights of the CSS style and DOM attribute values are set based on Equation 2. Then we raise the threshold of starting the second stage and adjust the weight of two influence factors. Through manual analysis, we get a reasonable threshold and

TABLE IV
COMPARISON OF EFFECTS OF DIFFERENT WEIGHTS.

Threshold	$\omega=0.2$	$\omega=0.4$	$\omega=0.6$	$\omega=0.8$
0.5	6.55%	6.55%	6.55%	6.55%
0.6	6.55%	6.55%	6.55%	6.55%
0.7	6.55%	6.55%	6.55%	6.55%
0.8	6.55%	6.55%	6.55%	6.55%
0.9	6.55%	6.55%	6.55%	3.13%

weight set. The result of the manual analysis is used in our experiments.

The experimental results are shown in Table IV. Here we show the result of test subject Musicbible. The first column is the threshold of starting the second stage in page clustering. It is incremented from 0.5 to 0.9 to determine which weight has the best effect. The lines show the weight of CSS style influence factors based on Equation 2. The numbers in the table indicate the pages that are the percentage of the mis-classified page.

When the threshold of starting second stage is 0.9 and the respective weights of M_{CSS} and M_{id} are 0.8 and 0.2, the result of generating page object is most similar to the result of manual judgment results. Therefore, the best effect of two-stages clustering algorithm using multiple influence factors is to take 0.9 as the threshold of starting the second stage in page clustering, with the weight of 0.8 for M_{CSS} and 0.2 for M_{id} .

V. RELATED WORKS

There are a number of testing approaches for web applications. Some of those approaches are suitable for the early days of Web applications, while others are more suitable for solving modern web technologies, such as AJAX and node.js [6], [7]. Some technologies are based on service-oriented framework, for example research [8]. Some use web page information extraction techniques. As a commonly used approach, the DOM similarity is used to judge the location of the required information, and the location information can be extracted directly without being disturbed by the noise information [9].

Web applications are different from traditional application software. web applications use BS structures and communicate with servers through browsers. However, local applications can run off the network. The difference is that web applications can only be run in various forms of browsers. In the traditional test [10], the web test is divided into two different test forms: black box and white box. Researchers use the corresponding models, such as control flow graphs or navigation maps, to conduct web application system testing studies. For example, Arcuri A [11] proposes a automated white-box testing method, in which test cases are generated automatically using evolutionary algorithms. Tests will be rewarded based on code coverage and fault finding metrics. Binkley D proposed a functional road map for testing web applications [12]. Liu X combined statement-based fault classification with spectrum-based software fault location in order to improve the accuracy of fault location and provide more possible fault information

for programmers [13]. In the research of Milani and Mirzaaghaei [14], by mining the human minds contained in the manually written test cases, they generate test cases for those points that are not found in the program under test. However, when the same function has multiple possible outcomes, a considerable amount of redundant test cases are generated. In the research of Yu Bing [15], a method based on a page object model for automatically generating web application testing is proposed. In this approach, the same function has multiple possible results, resulting in a significant probability that the generated page object is repeated, and finally, a redundant test case is generated.

When facing massive data information, it is possible to obtain incomplete or irrelevant information even through search engines, but with the development of web data mining, the problem is alleviated [16], [17]. Web data mining analyzes web page content to measure the importance of one page. Many algorithms have been proposed to extract content using the DOM tree. For example, in the method proposed in the research of Elyasov A [18], the DOM of the page is analyzed as an input to propose a testing framework of Javascript evolutionary. In the method proposed by Pagi V B [19], by using the embedded semantic tree kernel they can extract opinion content from web pages. In order to address repairing Internationalization Presentation Failures problems in web pages, Mahajan S [20] uses clustering to group stylistically similar elements in a page. It then performs a guided search to find suitable CSS fixes for the identified clusters.

Web pages contain a considerable amount of content that is not related to the web page theme. When acquiring information, this irrelevant information will affect efficiency and accuracy. It is often necessary to do some preprocessing on the web page. Uma [21] proposes an approach that cleans up and displays important information from web pages in standard format by eliminating noise and using unsupervised technology.

VI. CONCLUSIONS AND FUTURE WORKS

The existing generated page object tools only consider the DOM structure as the influence factor, which causes incorrect classification. In order to solve this problem, this paper theoretically analyzes the influence factors, which considers not only DOM structure, but also CSS styles and the attributes of DOM elements, and uses tag filter to simplify DOM structure. We propose a two-stage clustering algorithm using multiple influence factors when generating page objects. Therefore, the problem of incorrect classification of page objects is optimized. Moreover, we implement a prototype tool to automatically generate test cases for web applications to improve test efficiency based on page object. With experimental research, we find a suitable weight set for influence factors and threshold and verify the validity of our approach.

In future, we would like to analyze more factors. For example the type of events in client side scripts, which can handle different triggerable events. Moreover, in order to get more available information, we may use machine learning to

determine whether state and function are related. Besides, we will extend tested objects into other types of applications.

Abstract—Continuous Integration (CI) is an important practice in agile development. With the growth of integration system, running all tests to verify the quality of submitted code, is clearly uneconomical. This paper aims at selecting a proper test subset towards full coverage of all changed and affected code so as to reduce the cost of CI testing. We propose FEST, a novel approach, which searches for the full dependencies of changed code at the class level and then selects test classes related to the changed and affected classes. We assess FEST from fault detection efficiency and cost effectiveness based on 18 open source projects with 261 continuous integration versions from Eclipse and Apache communities, and compare it with the state-of-the-art approach ClassSRTS (as baseline). Results show that FEST (1) can not only cover all faults detected by actual CI testing and baseline, but also find new faults in 25% and 18% versions respectively. (2) shows better or equal test scale benefits than actual CI testing (in 98% versions) and baseline (in 99% versions); and can compensate risk of omitting necessary tests for actual CI testing (in 62% versions) and baseline (in 73% versions).

I. INTRODUCTION

Continuous Integration (CI) is a widely-applied development practice which requires developers to integrate their code into the master codebases frequently. It can improve the productivity, facilitate fast feedback of quality problems, and help projects release more often [1], [2]. One of the best practices in CI is to make your build self-testing, called CI testing. Each programmer must do a complete build and run (and pass) all or eligible unit tests before submitting work [1], [3]. With the growth of integration system, running all tests to verify the quality of submitted code, is clearly uneconomical. The big challenge of CI testing is how to optimize the test set to reduce test size as much as possible without sacrificing quality. These are many test case selection techniques proposed to tackle this problem [2], [4]–[16].

Generally speaking, the methods of test case selection can be split into static and dynamic techniques. Dynamic selection technique collects test dependencies by dynamically running tests on the previous revision, and selects a test set that may reach the code changes [7]–[9], [15], [17]. However, dynamic test dependencies for large projects may be time-consuming to collect, and for real-time systems, dynamic selection techniques may not be applicable, because code instrumentation for obtaining dependencies may cause timeouts or interrupt

normal test run [5], [15]. Besides, for programs with non-determinism (e.g., due to randomness or concurrency), dependencies collected dynamically may not cover all possible traces, leading to omission of necessary tests [5], [6]. Static selection technique does not require to execute tests; it uses static program analysis to infer the dependencies between changed code, affected code and test code [4], [5], [13], [18], [19]. It is easier to manipulate than dynamic technique thus draws more and more attention. However, the drawback of existing static approaches is that the selected test sets either cannot fully cover the necessary tests or are too redundant due to inefficient static analysis techniques [4]–[6], [13], [20].

In this paper, we propose a novel test selection approach called FEST (i.e., Full dEpendency based class-level test SelecTion) to select a proper test subset for CI testing based on class-level static dependencies. FEST first locates the changed classes of submitted commits, and generates full dependencies of source code at the class level. It then searches a complete set of affected classes and identifies affected test classes. Finally, it extends the test classes based on recently failed tests.

We experimentally evaluate FEST from fault detection efficiency and cost effectiveness on 261 CI versions of 18 projects from two large open source communities (i.e., Eclipse and Apache). For comparison, we refer the real-world practice of CI testing as the *actual CI testing* and apply the state-of-the-art approach ClassSRTS [5], [13] as baseline. The results show that (1) FEST can cover all faults detected by actual CI testing and baseline, and find new faults in 25% and 18% versions respectively; (2) compared with baseline, FEST shows better or equal test scale benefits in 99% versions, and higher risk compensation in 73% versions.

The main contributions of the paper are as follows:

- We design a new class-level test selection approach (FEST) to select a proper test subset towards fully covering all changed code and affected code. It can resolve full dependency relations at the class level, which improves previous work by capturing the dependencies of hidden references; and design an algorithm to incrementally and iteratively search the affected tests.
- We conducted experiments on 261 integration versions of 18 open source projects to evaluate the fault detection efficiency and cost-effectiveness of our approach, and results are promising.

II. APPROACH

This paper proposes an approach, called FEST (i.e., Full dependency based class-level test SelecTion). There are four major steps in FEST (shown in Figure 1), the following subsections will explain the details of the four steps.

Fig. 1. The overview of FEST

A. Locating the changed classes of submitted commits

For each CI, we have three phases to analyze and locate the changed classes. Firstly, we look for the **names of changed files** from the log message of the commits. Secondly, we look for the **changed lines of each changed file** by applying “*git diff*”, and filter the blank lines and annotation lines. Thirdly, we locate the changed code on associated classes. In detail, an improved open source tool Doxygen (named as Doxygen#) is applied to analyze the structure and dependencies of source code. We further parse the *xml* files generated by Doxygen# to obtain the code structure information of each file, including class names, the start line and end line of each class, and annotation information of each method (e.g., *@Test*, *@BeforeClass*, *@Before*). Based on the code structure information, we map the changed lines to their corresponding classes, and then label them as changed classes. Note that the commits can involve both program code and test code. We also locate changed test classes for better selecting the related tests. After this step, FEST will output a set of changed classes (C_Set).

B. Generating the full dependencies of code version

To ensure the full dependencies of code captured, we refer to the relations defined in *UML*. There are six relations among classes or objects defined in *UML*. Table I presents these relations and their representation in code (refer Orso’s work [21]), as well as the corresponding relations in code. There are two categories of relations in code: inheritance and invocation [22]. Some of the invocation types can be directly obtained with code dependency analysis tools (e.g., Doxygen#), and we call it as direct reference (short for *R*). Other invocation types can not be directly obtained with existing tools, and we call it hidden reference (short for *HR*). These hidden reference relations are usually ignored in the existing approaches [5], [20] or tools for code dependency analysis (e.g., Doxygen) because they are hard to resolve. We carefully consider and resolve the relation.

For inheritance and reference relations of invocation category, we directly capture them using the tags (e.g., *derivedcompoundref*, *referencedby*) in *xml* files outputted by Doxygen#. For hidden reference, we parse the *xml* files based on its representation in code (as shown in Table I) and the code structure information of class files obtained in Step 1. Take the first *dependency* relation as an example (i.e., the invocation

TABLE I
MAPPING OF RELATIONS BETWEEN RELATIONS IN *UML* AND IN CODE

Relations in UML	Representation in code	Relations in code
Generalization	A subclass $e1$ extends its superclass $e2$.	Inheritance
Realization	Class $e1$ implements an interface $e2$	Inheritance
Dependency	A Method of Class $e1$ uses Class $e2$ as an argument, e.g., the invocation by “ <i>Class.forName(‘P.e2’)</i> ” in reflection	Invocation (HR)
	A Method of Class $e1$ uses Class $e2$ in a cast operation.	Invocation (HR)
	Class $e1$ instantiates Class $e2$ in $e1$ ’s methods, then invokes its methods or variables.	Invocation (R)
Association	Class $e1$ uses Class $e2$ as a member variable.	Invocation (HR)
	A method in Class $e1$ invokes methods or member variables of member Class $e2$.	Invocation (R)
	Class $e1$ defines a member variable, and initiates it by invoking Class $e2$ ’s methods or variables, or using $e2$ in a cast operation.	Invocation (HR)
Aggregation	Class $e1$ uses Class $e2$ as an argument to instance.	Invocation (HR)
Composition	If Class $e2$ is a component of Class $e1$, it can only be instantiated in Class $e1$.	Invocation (R)

by “*Class.forName(‘P.e2’)*” in reflection), for each *xml* file, we check whether there is such hidden reference relation by its representation in code. If there is “*Class.forName*” in the *xml* file, we regard it as this case, and obtain the information of the referenced class (i.e., $e2$ as the name of referenced class, P as the name of $e2$ ’s package), and record its position (i.e., line of code); then we map the position to corresponding class based on the code structure information, and obtain the reference class and its information (e.g., class name). Finally, the hidden reference can be built with the obtained information of reference and referenced classes.

For convenience of step 3, FEST outputs an inheritance relation graph (*HRG*) and an invocation relation graph (*VRG*).

C. Searching affected classes and identifying related test classes

In this section, we design a BFS-based (i.e., Breadth-First Search) search algorithm to incrementally and iteratively look for a complete set of affected classes and identify related test classes. Note that since our approach considers the class-level dependency relations, the *tests* in this paper means the test classes.

In detail, for each changed class C_i in C_Set , firstly, we use BFS to search its all subclasses from *HRG*, and all referenced classes from *VRG* which invoke class C_i or its subclasses, and add them to the set of affected classes A_Set . Then, for the changed class C_i or each affected class, we check whether it is a test class. Note that we also check the changed class C_i , which ensures to select the newly-added tests or changed tests. Following existing work [6], [20], if it contains at least one method (the method name started with “test” or the method has the annotation “*@Test*”, “*@BeforeClass*”, “*@Before*”), we regard it as a test class. If it is a test class, we will add it to the set of related tests T_Set . Finally, when this loop is over, and A_Set is not null, for each class a_i in A_Set , we apply BFS iteratively to search its subclasses and referenced classes until there is no new class found, and identify new test classes, add

them to T_Set . After the above process, we search affected classes and identify the set of related tests T_Set .

D. Extending test classes

In this section, we aim to complement some tests to re-detect the deferred faults. These faults detected in the previous versions might have not been fixed and deferred to subsequent versions. This strategy has also been applied in existing studies [2], [11], [23]. In detail, we look for the failed test classes in recent n versions, then check whether they run again. If not, we add them into T_Set . We have experimented n from 1 to 30, and results showed that the performance is better and more stable when n is 10. Hence, we apply the recent 10 versions in the following experiments. Finally, we obtain a final test set (T_Set).

III. EXPERIMENT DESIGN AND EVALUATION METRICS

A. Subject projects and data preparation

According to the activeness and CI testing history availability, we chose 12 Eclipse projects and 6 Apache projects to evaluate our approach presented in Section II. We collected the CI testing history from November 2017 to January 2018 for the chosen projects, which contains test classes, test methods, results, etc. From which we can obtain the failed test information for each CI version. Then we collected commits from the *Git* repository by executing “*git log*”, checked out source code by executing “*git checkout*”; and built the relationship of the three datasets by the commit *id* of CI versions. Finally, we chose the versions for our experiment, in which the number of changed classes and the number of executed CI tests are greater than 0; and obtained 261 versions from the 18 projects.

We ran all experiments on a 3.40 GHz Intel Core i7-3770 machine with 8 GB of RAM, running Ubuntu Linux 14.04.3 LTS and Java 64-Bit sever version 1.8.0_73.

B. Baseline approach

To further evaluate the performance of our approach, we take ClassSRTS [5], [13], the state-of-the-art class-level static selection technique, as baseline. Besides, we also compare FEST with the selected tests of actual CI testing, which are recorded in the repositories.

We did not select any dynamic approach as baseline because in the most recent work [5], ClassSRTS is compared to the state-of-the-art dynamic approach, and results show that ClassSRTS is comparable with the dynamic approach. The reason we did not compare with dynamic selection is because it needs to run tests to obtain the dependency information, which is costly and limits its realization in our study.

C. Evaluation metrics

Following existing work, faults denote failed test classes where a test class is regarded as fail if at least one of the test cases in the test class fails, otherwise, it is regarded as pass. For each CI version, we compare the selected tests and the failed tests in the CI testing history, and count the failed test classes contained in the set of selected tests to get the

TABLE II
BASIC METRICS USED IN THE STUDY

Metrics	Description
Ct	A set of actual CI tests (i.e., actual tests ran during CI testing).
St	A set of selected tests by FEST or ClassSRTS (marked by $St@F$ and $St@C$ respectively).
Cft	A set of faults detected by actual CI testing.
Tft	A set of total faults detected by FEST or ClassSRTS (marked by $Tft@F$ and $Tft@C$ respectively).

number of detected faults. Regarding a new test class which is not included in the current set of actual CI testing, it will be labeled as a detected fault if its first run in the subsequent versions fails by following previous work [24]. It is because it should be detected in the previous version, but it was omitted by actual CI testing. **To facilitate understanding, we present basic metrics used in this paper in Table II.**

1) *Fault detection efficiency*: In this dimension, we define two metrics to evaluate fault detection efficiency.

(a) **Fault coverage** ($Fcovg$) means the percentage of the faults found by test selection approach (i.e., FEST or ClassSRTS) compared with the faults detected in actual CI testing. Following existing work [4], [12], [20], [25], it is defined as Equation 1.

$$Fcovg = \frac{|Tft \cap Cft|}{|Cft|} \times 100\% \quad (1)$$

In it, Tft is the faults detected by the measured approach, it can be $Tft@F$ (for FEST) or $Tft@C$ (for ClassSRTS). This metric is also used to evaluate the coverage of the faults detected by FEST compared with the faults detected by ClassSRTS, where Cft will be replaced by $Tft@C$. When $|Cft|$ is 0, we treat $Fcovg$ as 100%.

(b) **Fault detection enhancement** ($Fenhm$) means the new faults which are detected by the measured approach compared with actual CI testing or ClassSRTS. It is defined as $NewFt$.

2) *Cost effectiveness*: In this dimension, we evaluate the cost effectiveness from test scale benefits and risk compensation ability.

(a) **Test scale benefits** ($Testscal$) evaluates the return on investment (ROI), i.e., the number of detected faults divided by the number of running tests, as the existing work [9], [26], [27]. As we could not obtain the exact set of all faults, we use the union set of the faults detected by all investigated approaches and actual CI testing, as previous work [12], [20]. Therefore, we apply a penalty coefficient to adjust ROI, which is the proportion of the number of faults detected by current approach to the number of all faults. Hence, $Testscal$ is defined as Equation 2. The higher value of $Testscal$ the better.

$$Testscal = \frac{|Tft|}{|St|} \times \frac{|Tft|}{|Cft \cup Tft@F \cup Tft@C|} \quad (2)$$

Here, Tft is the fault set of the measured approach, i.e., it can be Cft (for actual CI testing), $Tft@F$ (for FEST) or $Tft@C$ (for ClassSRTS). When $|St|$ or $|Cft \cup Tft@F \cup Tft@C|$ is 0, we simply treat $Testscal$ as 0.

(b) **Risk compensation ability** ($Riskcomp$): Running insufficient tests for CI could lead to omit some potential faults, while running necessary and sufficient tests will decrease the

quality risk even if sometimes they did not find more faults. We define risk compensation ability to evaluate the ability of compensating the omitted necessary tests by actual CI testing. It is defined as Equation 3.

$$Riskcomp = \frac{|St| - |(St@F \cup St@C) \cap Ct|}{|St@F \cup St@C|} \quad (3)$$

Here, St is the test set of the measured approach, it can be $St@F$ or $St@C$ (for $Riskcomp$ of FEST or ClassSRTS). $St@F \cup St@C$ means the union set of tests selected by FEST and ClassSRTS respectively. $(St@F \cup St@C) \cap Ct$ is the test set running in actual CI testing and also selected by FEST or baseline. The positive $Riskcomp$ means that the measured approach can compensate risk for actual CI testing, the higher value of $Riskcomp$ the better. In contrast, the negative $Riskcomp$ means it can not compensate risk. When $|St@F \cup St@C|$ is 0, we simply treat $Riskcomp$ as 0.

IV. EXPERIMENT RESULTS AND ANALYSIS

Based on the number of faults detected by actual CI testing and FEST, we divide the experiment project versions (261) into four categories. The following subsections will present their results and analysis respectively.

- Category *Dual_F* (9%:23): both actual CI testing and FEST detected faults.
- Category *FEST_F* (20%:51): actual CI testing did NOT detect faults, while FEST detected faults.
- Category *Dual_NF* (70%:184): both actual CI testing and FEST did NOT detect faults.
- Category *CI_F* (1%:3): actual CI testing detected faults, while FEST did NOT detect faults.

A. Category *Dual_F*

In Figure 2, the size of bubbles refers to the number of tests. We order versions by reduced test size between FEST and actual CI testing, then assign the ID sequentially.

Fig. 2. Number of selected tests and number of detected faults for Dual_F

We can easily see that blue bubbles are either higher or inside other bubbles. It means that FEST can find more or equal number of faults than ClassSRTS or actual CI testing. Particularly, in some versions, the difference is quite large.

1) *Fault detection efficiency*: In Figure 3, FEST can not only cover all faults detected by actual CI testing and ClassSRTS, but also find new faults in 65% (15/23) and 83% (19/23) versions respectively. While ClassSRTS can cover the faults detected by actual CI testing only in 43% (10/23) versions, and find new faults in 48% (11/23) versions.

Fig. 3. Fault coverage and detection enhancement compared with actual CI testing for Dual_F

2) *Cost effectiveness*: In Figure 2, we observe that FEST selects slightly more tests than ClassSRTS in some versions. We further analyze the cost effectiveness of FEST.

Test scale benefits: From Figure 4, we can see that FEST shows better *Testscal* than actual CI testing in 96% (22/23) versions. Only in one version (v21), both FEST and ClassSRTS show slightly lower *Testscal* than actual CI testing. Compared with ClassSRTS, FEST shows better or equal *Testscal* in 87% (20/23) versions; in other three versions (v2, v19, v20), FEST shows lower *Testscal*. For these 4 versions where FEST shows lower *Testscal*, it has higher *Riskcomp* (see the next paragraph), which indicates our proposed approach can mitigate the risk of omitting necessary tests.

Fig. 4. Test scale benefits for Dual_F (the enlarged figure on the right shows the details)

Risk compensation ability: In Figure 5, compared with actual CI testing, FEST has positive *Riskcomp* in all versions, while ClassSRTS shows negative *Riskcomp* in 35% (8/23) versions. It means that in these 35% versions, ClassSRTS omits some necessary tests, which might lead to omit faults.

Fig. 5. Risk compensation ability for Dual_F

Compared with ClassSRTS, FEST shows higher *Riskcomp* in 96% (22/23) versions. It indicates that FEST can compensate more necessary tests than ClassSRTS, even though FEST selects more test in some cases. Only in 1 versions (v5), FEST shows lower *Riskcomp* than ClassSRTS. This is because when computing *Riskcomp*, we treat the union set of tests selected by FEST and ClassSRTS as ground truth of necessary tests. However, ClassSRTS has selected some unnecessary tests. In detail, it treats the selected tests as the difference between the set of all tests and the set of non-affected tests (tests not affected by changed code). However, the set of all tests could include some unnecessary classes, e.g., the basic classes which

do not have test cases. Hence, the lower $Riskcomp@FEST$ does not indicate the low effectiveness of our approach.

B. Category FEST_F

Similar to category Dual_F, in Figure 6, the size of bubbles refers to the number of tests.

1) *Fault detection efficiency*: In Figure 6, all green bubbles lie on X-axis due to $|C_{ft}| = 0$. It indicates that compared with actual CI testing, the fault coverage of both FEST and ClassSRTS are all 100%. More than that, FEST can cover all faults detected by ClassSRTS and detect more new faults in 57% versions.

Fig. 6. Number of selected tests and number of detected faults for FEST_F

2) *Cost effectiveness*: In Figure 6, test size of FEST is smaller than actual CI testing, and similar or slightly larger than ClassSRTS.

Test scale benefits: In this category, $Testscal@CI = 0$ in all versions. From Figure 7, we can observe that FEST shows better $Testscal$ than actual CI testing, and better or equal $Testscal$ than ClassSRTS in all versions. Especially, in 8 versions, $Testscal$ of FEST is more than three times as large as that of ClassSRTS.

Fig. 7. Test scale benefits for FEST_F (the enlarged figure on the right shows the details)

Risk compensation ability: In Figure 8, FEST has positive $Riskcomp$ in 90% (46/51) versions and none negative $Riskcomp$, while ClassSRTS shows negative $Riskcomp$ in 24% versions. Meanwhile, compared with ClassSRTS, FEST has better or equal $Riskcomp$ in 96% (49/51) and 2% (1/51) versions respectively. The reason of lower $Riskcomp$ in other 1 version (v63) is similar with the discussion in Section IV-A2.

Fig. 8. Risk compensation ability for FEST_F

C. Category Dual_NF

In all versions of this category, neither actual CI testing nor FEST or ClassSRTS detected faults (i.e., $Fcovg$, $Fenhm$ and $Testscal$ are 0). Therefore, we only discuss risk compensation ability for this category.

Risk compensation ability: In Figure 9, FEST has positive $Riskcomp$ in 49% versions and none negative $Riskcomp$, while ClassSRTS shows positive and negative $Riskcomp$ in 28% and 47% versions respectively. Compared with ClassSRTS, FEST presents higher or equal $Riskcomp$ than ClassSRTS in 91% (118/261) versions, among which $Riskcomp$ of FEST is twice as large as that of ClassSRTS in 109 versions. The reason of lower $Riskcomp$ in 9% versions is similar with the discussion in Section IV-A2.

Fig. 9. Risk compensation ability for Dual_NF

D. Category CI_F

1) *fault detection efficiency*: In all three versions (i.e., v259, v260 and v261) of this category, actual CI testing detected a few faults while ran a large size of tests. Both FEST and ClassSRTS selected very small test sets while detected no faults. We further examine the detail of these 3 versions.

In the 3 versions, the faults which are not covered by FEST do not have any dependencies with the changed and affected code, and have no failed test history in recent 10 versions. In other words, these faults were committed in earlier versions, and should be detected earlier. Hence, detecting these faults is not the responsibility of current CI testing. This indicates that the bad performance does not due to the drawback of FEST.

2) *Cost-effectiveness*: In this category, both FEST and ClassSRTS did not detect any faults, $Testscal$ of both FEST and ClassSRTS are zero, lower than actual CI testing.

Risk compensation ability: Regarding risk compensation ability, both FEST and ClassSRTS positively compensate risk in all versions, but FEST can get much higher $Riskcomp$ for all of them even though it did not find any faults. It is because actual CI testing ran some redundant tests while omitting necessary tests which results in a high risk of omitting faults. Meanwhile, FEST presents better or equal $Riskcomp$ than ClassSRTS in all versions.

Summary: Based on the detailed results and analysis of the 4 categories, we obtain the summary of FEST across all categories: (1) FEST can cover all faults detected by actual CI testing and baseline, and find new faults in 25% and 18% versions respectively; (2) FEST shows better or equal $Testscal$ than actual CI testing (in 98% versions) and ClassSRTS (in 99% versions); can compensate risk of omitting necessary tests for actual CI testing (in 62% versions) and baseline (in 73% versions).

The **internal** validity of our study arises from the implementation of baseline and FEST. We implemented baseline by strictly following the steps described in the original paper [13]. For both baseline and FEST approaches, we have employed 213 test cases to test their functionality. For the suspicious results, we have manually checked the code, and found they do not due to the defect in code.

The **external** validity concerns about our experimental dataset. We can not guarantee that our results can be fully generalize to other projects. However, the size of the dataset (18 projects with 261 versions) and the diversity of domains relatively reduce this risk.

VI. RELATED WORK

CI test selection based on dynamic dependency: Gligoric et al. [7] and Vasic et al. [19] implemented a test selection approach based on dynamic dependencies at the file level for *Java* and *.NET* respectively, and analyzed the strengths and drawbacks of file-level and module-level test selections. Because of that, Zhang [15] proposed a hybrid test selection technique that combined file-level and method-level analysis. Furthermore, Celik et al. [8] designed a file-level test selection across *JVM* boundaries, which can find more dependencies and improve precision of selection.

CI test selection based on static dependency: Soetens et al. [25] and Parsai et al. [4] proposed an approach to select tests on method-level static dependencies and improved it to deal with invocation in polymorphism. Legunsen et al. [5], [13] implemented class-level and method-level test selection techniques based on static dependencies. But the class-level approach would still omit some tests because it can not obtain all dependencies (e.g., the dependencies in reflection and cast operation), while the method-level approach shows worse performance in fault detection and time cost.

Generally speaking, the drawbacks with existing dynamic selection approaches are long running tests, non-determinism, and real-time constraints; while the drawbacks of existing static selection approaches lie in omitting some tests or selecting some unnecessary tests [4]–[6], [13], [20]. Our approach belongs to static test selection which improves existing approaches by resolving full dependency relations and selecting a test set towards fully covering all changed and affected code.

VII. CONCLUSION

In this paper, we propose FEST to select a proper test subset towards full coverage of all changed and affected code so as to reduce the cost of CI testing. Evaluations are conducted on 18 projects with 261 CI versions from Eclipse and Apache communities. Results show that FEST can outperform actual CI testing and the state-of-the-art ClassSRTS in terms of fault detection efficiency and cost-effectiveness in most cases.

Abstract—Cross-platform app development has achieved meaningful results in practice with frameworks like React Native, Xamarin, and Apache Cordova. Unlike native apps, such frameworks support the development of a mobile app that can run in different platforms. Nevertheless, the literature lacks techniques to test cross-platform apps since most of the existing works focus on native Android apps. A promising strategy for native apps is to amplify test suites so that the specific characteristics of mobile apps can be tested. This paper aims to investigate the test amplification of cross-platform apps. To do so, we apply four test patterns that verify well-known characteristics of mobile computing and amplify existing test suites. The proposed approach has been implemented in a tool capable of generating Appium test scripts and was evaluated with nine cross-platform apps. The amplified test suites exercise new scenarios, uncovering 23 unique bugs in eight out of nine apps.

I. INTRODUCTION

Smartphones, tablets, e-readers, and wearables have dominated the consumption of digital information and data traffic; the number of these devices has grown exponentially over the years [1]. The software running in such devices, so-called *mobile apps* (or just *apps* for short), radically changed the lifestyle of billions of people around the world, being used for several hours every day and helping users to perform a wide variety of activities [2]. To meet the ample range of users, millions of apps have been developed and are available for download [3]. Currently, the dominant operating systems (OSs) for mobile devices are Google’s Android and Apple’s iOS; they provide their own software development kits, characterizing the single-platform native development.

In order to reach more end users, the software industry has shown an upward trend in adopting cross-platform mobile app development. In such a paradigm, a unique code base is used to deliver the same app in different platforms (e.g., Android, iOS, Windows) and their versions [4], [5]. This is aided by several open source and commercial cross-platform development frameworks and tools; the most notable examples are React Native, Xamarin, and Apache Cordova. Developed by Facebook, React Native leverages the well-known web library React to generate mobile apps with native user interfaces (UIs) and coded in Javascript [6]. Acquired by Microsoft in 2016, Xamarin offers C# or F# as a common programming language to develop apps for the three main platforms: Android, iOS and

Windows. According to Microsoft, 75% of the code is shared among the platforms on average; this figure can be close to 100% if the UI toolkit Xamarin.Forms is employed [7]. Finally, Apache Cordova fosters the development of hybrid apps using standard web technologies like HTML5, CSS3, and Javascript [8]. As such, it is popular among web developers and has supported other mobile frameworks like Ionic and PhoneGap [9], [10].

Apart from this trend, research efforts in engineering high-quality mobile apps have focused on native development for Android [11], [12]. The demand for quality in mobile apps has grown along with their spread; the users want the apps to be reliable, robust, and efficient. As a consequence, mobile software engineers must adopt adequate quality assurance techniques [2]. Software testing is the primary activity to reduce risks and minimize the presence of bugs in the software. In a nutshell, testing involves the process of running a software system with the purpose of uncovering bugs [13].

As mobile apps possess specific features to be checked, *Test Amplification* [14] has been investigated in literature to go beyond functional test cases. Test amplification can be defined as the extension of existing test cases to verify other properties of the software under test. This is a promising strategy for mobile apps that are susceptible to bugs related to device rotation, interruptions, loss of resources, unique UI events/components, and so on. The verification of such specific features can be described in a well-defined set of generic actions and expected behavior called *test pattern* [15], [19]. The amplification by test patterns has been explored in native Android apps and results have shown effective bug detection [15], [16], [18], [19]. However, little is known on how test amplification performs in mobile apps developed with cross-platform frameworks.

This paper introduces an approach for test amplification of cross-platform apps. In particular, we describe four test patterns that aim to verify well-known characteristics of mobile computing and amplify test cases. The proposed approach has been implemented in a tool, called x-PATeSCO, capable of producing test scripts for cross-platform apps. We evaluated the approach and its supporting tool with nine real-world apps, developed with frameworks React Native, Xamarin, and Cordova.

This paper is organized as follows: Section II presents the

background and related work. Section III brings the test amplification approach proposed for cross-platform apps. Section IV presents the evaluation setup and the results are analyzed in Section V. Finally, Section VI makes the concluding remarks and sketches future work.

II. BACKGROUND AND RELATED WORK

Mobile computing brings a diverse set of features that may cause failures in the software developed for such platform. Holl and Elberzhager [22] propose a failure classification based on a literature review and a study with developers and testers of mobile apps. They list events that might make apps to fail, namely, temporarily disconnected network, network change (3G - WiFi), GPS temporarily disconnected, weak battery, globalization (localization, language, date or time differences between clients and servers), UI changes due to orientation, screen changes, OS-specific native functionality, interruptions via incoming calls or text messages, unexpected termination of an app process, and permissions. Similarly, Linares-Vázquez et al. [21] manually searched for bugs in Android apps related to specific features like GPS failures, loss of access to network data, slow data reception, and device rotation. The authors used this bug set to elaborate Android-specific mutation operators and developed a mutation testing tool for Android apps.

These well-known features have also been used to amplify existing test cases in a systematic way. Zaeem et al. [16] also performed a study with bugs from the most popular open source app projects, identifying feature interactions that might cause errors. The authors proposed an approach to verify automatically the feature interactions and a tool was developed to exhaustively test them. Morgado and Paiva [15] introduce a catalog of behavioral principles of the Android UI elements. Such behavioral principles are described as test patterns related to UI menu elements (drawer style) and device rotation. They also propose patterns related to features like GPS and 3G connection. Adamsen et al. [18] explore the injection of adverse conditions in existing test suites. The adverse conditions are related to common usage of apps like pause-stop-resume, rotation, as well as missing or changed resources such as loss of GPS accuracy, change of mobile network, and transition between Internet networks (3G-WiFi-3G). Their results show that the approach is effective in finding critical flaws and the additional cost in the test time is low, compared to the number of bugs found.

While test amplification and test patterns have been investigated [15], [16], [18], the state of the art in mobile app testing is focused on native Android apps [11], [12]. On the other hand, cross-platform app development has gained momentum by winning a meaningful market share, and being supported by big players of the software industry like Facebook, Microsoft, and Apache Software Foundation. In this context, one might wonder if the testing techniques developed for native apps are seamlessly applicable to cross-platform apps. In this paper, we inquire into test amplification for cross-platform apps; to our best knowledge, this is the first study on the topic.

III. TEST AMPLIFICATION APPROACH

This section describes the approach we define to test amplification of cross-platform apps; Figure 1 shows an overview of the approach. There is a component called Test Amplification Generator that receives as input a set of system-level test cases TC_1, TC_2, \dots, TC_n and a one or more test patterns. Then, it produces as output a combination of test cases and test patterns, the *amplified test script*. Such scripts can then be executed in the *app under test* (AUT).

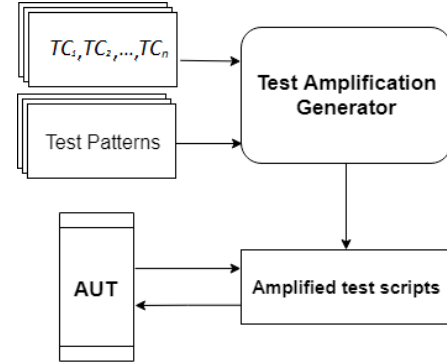

Fig. 1. Overview of the proposed approach.

The following sections explain how we implemented the approach. Section III-A details how a test case and a test pattern are combined to amplify the tests. In particular, we leverage four test patterns that verify well-known characteristics of mobile apps. Section III-B focuses on the Test Amplification Generator, describing how we made the approach applicable to cross-platform apps.

A. Test Patterns

We herein describe the four test patterns adopted in this work. All test patterns assume that a test case is provided as a sequence of system-level events, mostly UI actions like clicking a button, selecting an item, or filling a text field. The test pattern contains not only a pre-defined sequence of specific events that should be executed, but also a mechanism to identify a potential bug (i.e., a test oracle). To simplify the presented algorithms, we do not treat exceptions that can be thrown when a given event is executed in the app (e.g., a crash). Nevertheless, our tool deals with it by capturing the exception and recording the bug information in a log (further details in Section III-B). The literature on Android app testing reports different strategies to amplify test suites [4], [16], [18], [21]; this study adopts four test patterns, well-known in literature and that we found relevant to cross-platform apps.

1) *Lost Connection (LC)*: This pattern aims to verify how the AUT behaves when the Internet connection is lost [15], [21], [22]. As mobile devices are susceptible to unstable networks, the AUT is supposed to be aware and react when a connection is lost. By reacting, we assume that some feedback is provided to the end user, like an error message or a warning [17], [20].

Algorithm 1 describes how a test case is amplified to verify a lost connection. It receives as input a test case as an array of events, and a map of states recorded during the original execution of the test case. First, the procedure turns the connection off and starts the app (Lines 4-5). In each iteration, it checks if the current state is different from the original state (Line 8); i.e., the connection lost had an impact on the UI. If the current state has no sign of feedback for the user (like an error message) (Line 9), we record the scenario as a bug (Line 10). To resume the verification in the following events of the test case, we turn the connection on (Line 12), execute the events normally until the current state (Line 13). The connection is then turned off (Line 14) and the iteration continues to the next event (Line 16).

Algorithm 1 Lost Connection Test Pattern

```

1: procedure LOSTCONNECTION(allEvents[], origStates[])
2:   input allEvents[] - Test case as an array of events
3:   input origStates[] - Map of states collected from the original execution
4:   connection( OFF );
5:   startApp();
6:   for each event ∈ allEvents do
7:     currentState = getActualState();
8:     if currentState != origStates[event] then //changed GUI
9:       if ! existLostConnectionMsg(currentState) then //no feedback
10:        RecordBugInfo();
11:       end if
12:       connection( ON );
13:       bringAppTo( currentState );
14:       connection( OFF );
15:     end if
16:     executeEvent(event);
17:   end for
18: end procedure

```

2) *Back Event (BE)*: This pattern aims to verify how the AUT behaves when the Back event is triggered during a test case [16], [22]. We assume that when running, the Back event must go to a previous screen of the application [17], [20].

Algorithm 2 describes how the test case is amplified to verify the execution of the Back event. It receives as input a test case as an array of events. Initially, the procedure starts the application (Line 3). In each iteration, we execute the corresponding event, then it is checked if the state after the event execution is equal to the state before execution (Line 8). The procedure executes the Back event, and validates whether the application has returned to the previous state (Lines 9-11). If the states are different after running the Back event, we record this scenario as a bug (Line 12). If the states are equal, the procedure follows the verification for the next event.

3) *Side Drawer Menu (SDM)*: This pattern aims to verify how AUT behaves when having a side menu [16], [22]. The menu opens when the user slides from the screen to the center or clicks in a menu icon or label [15]. We validate if all the menu items take the app to a different screen.

Algorithm 3 describes how the test case is amplified to validate the application menus. It receives as input a test case as an array of events. Initially, the procedure starts the application (Line 3). For each iteration, we check whether the application has a menu (Lines 6-23). If there is a menu in

Algorithm 2 Back Event Test Pattern

```

1: procedure BACKEVENT(allEvents[])
2:   input allEvents[] - Test case as an array of events
3:   startApp();
4:   for each event ∈ allEvents do
5:     beforeState = getActualState();
6:     executeEvent(event);
7:     afterState = getActualState();
8:     if beforeState != afterState then //there is a screen transition
9:       ExecuteBack();
10:      afterBackState = getActualState();
11:      if beforeState != afterBackState then //bug detected
12:        RecordBugInfo();
13:      end if
14:      bringAppTo( afterState );
15:    end if
16:  end for
17: end procedure

```

the AUT, the procedure checks the menu items empirically by clicking on them and checking if the application changes the screen after entering a menu item (Lines 28-33). If the application does not change screen, we record this scenario as a bug (Line 31). If no menu item is found, the procedure proceeds to the next iteration (Line 35).

Algorithm 3 Side Drawer Menu Test Pattern

```

1: procedure SIDEDRAWERMENU(allEvents[])
2:   input allEvents[] - Test case as an array of events
3:   startApp();
4:   for each event ∈ allEvents do
5:     beforeMenuState = getActualState();
6:     haveMenu = false;
7:
8:     //Try do detect menu by horizontal swipe
9:     initialState = beforeMenuState;
10:    Swipe();
11:    finalState = getActualState();
12:    if initialState != finalState then
13:      haveMenu = true;
14:    else
15:      //Try do detect menu by menu button
16:      initialState = getActualState();
17:      LocateAndClickMenuButton();
18:      finalState = getActualState();
19:
20:      if initialState != finalState then
21:        haveMenu = true;
22:      end if
23:    end if
24:
25:    if haveMenu then
26:      menuState = getActualState();
27:      for each item ∈ getMenuItems() do
28:        tap( item );
29:        afterTapItemState = getActualState();
30:        if afterTapItemState ∈ {beforeMenuState, menuState} then
31:          RecordBugInfo();
32:        end if
33:        bringAppTo(menuState);
34:      end for
35:      bringAppTo(beforeMenuState);
36:    end if
37:    executeEvent(event);
38:  end for
39: end procedure

```

4) *Don't Change State (DCS)*: This pattern aims to verify how the AUT behaves when external events triggered by the user occur during the test case [15], [16], [18]. As mobile devices are susceptible to these actions, the AUT is supposed

to be aware and prevent failures because of external events. We assume that after the execution of external events, the app should return to the state it was before [17], [20].

Algorithm 4 describes how a test case is amplified to verify the external events performed by users. It receives as input a test case as an array of events, and the type of the external action to be executed. The types currently supported are Rotate, Pause-Stop-Resume, Zoom, Swipe, and Scroll. First, the procedure starts the application (Line 4). For each iteration, it records the state before and after the external event (Lines 7-9). If the states are different (the AUT did not return to the same screen) (Line 10), we record the scenario as a bug (Line 11). The procedure then continues to the next event (Line 12).

Algorithm 4 Don't Change State Test Pattern

```

1: procedure DONTCHANGESTATE(allEvents[], type)
2:   input allEvents[] - Test case as an array of events
3:   input type ∈ {Rotate, PauseStopResume, Zoom, Scroll, Swipe}
4:   startApp();
5:   for each event ∈ allEvents do
6:     executeEvent(event);
7:     beforeState = getActualState();
8:     execute( type ); //execute one of the 5 types
9:     afterState = getActualState();
10:    if beforeState != afterState then //didn't come back to the same screen
11:      RecordBugInfo();
12:      bringAppTo( beforeState );
13:    end if
14:  end for
15: end procedure

```

B. Test Amplification Generator

We developed a tool named x-PATeSCO (*cross-Platform App Test Script reCOder*) to support cross-platform mobile app testing. The tool is built on top of Appium [23], an open source framework to automate UI tests in native, Web and hybrid apps. Moreover, Appium is cross-platform and makes it possible to automate tests for iOS and Android platforms, using a Selenium WebDriver API. x-PATeSCO is able to read the elements of an app's UI and assist the tester in selecting these elements to design automated test cases.

The Test Amplification Generator component has been implemented within x-PATeSCO. The four test patterns aforementioned are embedded into the tool as code templates, that are integrated with the recorded test cases. Such integration is realized when the test scripts are generated; currently, x-PATeSCO produces scripts coded in C#. These scripts are capable of executing the four test patterns in the original test case automatically, therefore no manual effort is required to apply test amplification in cross-platform apps.

IV. EVALUATION SETUP

To evaluate the proposed approach, we set out the following research questions (RQs):

- **RQ₁**. Can test amplification detect bugs in cross-platform apps?
- **RQ₂**. What is the impact of test amplification on test execution?

- **RQ₃**. Are the results replicable in different settings (e.g., OS version)?

To answer **RQ₁**, we record the number of unique bugs detected as a consequence of the test amplification. As our approach may show false alarms, the number of tests presenting failure (failures) and false positives are also collected. So, for each failure, we try to reproduce it by manually performing the test steps. For a successful reproduction, we have a bug, otherwise a false positive. As for **RQ₂**, we measure the overhead of the amplified tests in test execution time. Given that T_{orig} is the runtime of the original test cases and T_{amp} is the runtime of the amplified tests, the overhead is calculated by T_{amp}/T_{orig} . Finally, **RQ₃** analyzes the results collected in **RQ₁** from the perspective of different configurations. In this study, we only considered different versions of the OS Android.

Table I lists the nine apps evaluated; for each app, it shows the project size in number of lines of code (LOC), the cross-platform app development framework, the number of test cases (#TCs) and their events (#Ev.). Such cross-platform apps' size ranges from around 400 LOC to up to 178 KLOC, and are implemented in different cross-platform development frameworks (namely, Apache Cordova, React Native, and Xamarin). Two apps are industrial (namely, MemesPlay and Bargains) and have been provided by partner IT companies. The other seven are open source projects obtained from GitHub. Each app has two or three test cases (with nine to 20 events each), designed by independent participants.

TABLE I
APPS UNDER TEST.

App	Size-LOC	Framework	#TCs (#Ev.)
Fresh-Food-Finder	13824	Cordova	3 (20)
OrderApp	71565	Cordova	3 (16)
MemesPlay	5484	Cordova	3 (12)
Agenda	1038	Cordova	3 (18)
ToDoListCordova	9304	Cordova	3 (10)
MovieApp	2088	React Native	3 (10)
ToDoList	405	React Native	3 (13)
Tasky	654	Xamarin	3 (9)
Bargains	178266	Xamarin	2 (10)

x-PATeSCO was used to support the experimental evaluation; it connects to Appium which, in turn, connects to mobile devices to run the test cases and log pieces of information to answer **RQ₁**, **RQ₂**, and **RQ₃**. The apps were installed in two devices, one with Android 6.0 and another with Android 7.0, and all tests were executed in both devices. Besides the mobile devices, the test projects were run from a computer with an Intel Core i5 dual-core (2.5 GHz) processor and 8 GB of RAM without any further processing or communication load in order to avoid CPU and memory saturation. An Appium server was also installed in this machine.

To foster future replication and overcome possible threats to this study, we make the tool and the experiment objects available as an open source experimental package in <https://goo.gl/7CF4oZ>

V. ANALYSIS OF RESULTS

a) *Bug detection*: Table II shows the number of bugs found, failing test cases (Fail), and false positives (FP); rows identify the apps and OS version (OS V.), while columns group the test patterns: *Back Event (BE)*, *Lost Connection (LC)*, *Side Drawer Menu (SDM)*, and *Don't Change State (DCS)*. Column *DCS* takes into account the results of Rotate, PauseStopResume, Zoom, Scroll, and Swipe. Symbol '-' indicates that the test pattern is not applicable in a given app. For instance, Agenda does not use Internet connection, so *LC* is not applicable. In this part, we focus our analysis on the OS version that had more bugs revealed (namely, Android 6.0).

As for *BE*, this pattern revealed seven bugs in seven different apps. We did not observe false positives since all failures were caused by the identified bugs. In general, this pattern finds a faulty scenario in which the app does not return to a previous screen using the back button. Instead, the app terminates, goes to the background, or returns to a different screen. Concerning *LC*, this pattern revealed five bugs in four out of five apps in which is applicable. It shows a smaller number of failures and no false positives. This is likely due to the low number of events that depend on an Internet connection to properly execute. For instance, OrderApp does not give a feedback on a lost message due to a failing Internet connection. MovieApp presents the same bug, and in other scenario of connection lost the app crashes.

There is no bug, failure or false positive for *SDM*. While four apps have menus, all menu items are accessible and navigate to different screens correctly. We surmise that menus are built with well-tested UI components and developers pay special attention to them due to their relevancy in the app. As a consequence, menus are more tested and less susceptible to bugs. The *DCS* test pattern uncovered 11 bugs in eight apps. Notice that this pattern showed a high number of failures and false positives. This occurred due to issues related to the Appium framework. Actions like Zoom, Scroll and Swipe caused exceptions during the automated test execution, but we failed to reproduce these scenarios manually. As for the bugs, the OrderApp, TodoList, Bargains, and Memesplay apps restarted after a Pause-Stop-Resume action. Agenda, Fresh-Food-Finder, MovieApp, TodoList, and Bargains slowed down when performing the zoom action.

The amplified tests detected 23 unique bugs in eight out of the nine cross-platform apps. Among the four test patterns, only *SDM* did not reveal a bug. A reasonable number of false positives has been observed, except for *DCS*. We believe that new Appium versions and adjustments in x-PATeSCO can reduce the presence of false alarms in future. The results give evidence that supports a positive answer for **RQ₁**.

b) *Overhead in test execution*: Table III shows the overhead of the amplified tests in test execution time. The overhead of the test patterns shows some variation among the apps. For

instance, the *BE*'s overhead ranges from 0.71 to 4.5 times in comparison with the original test suite. On average, *BE* also poses the highest overhead (2.97x), while *SDM* shows the lowest average (2.06x). *DCS* and *LC* had intermediate averages, 2.42x and 2.68x, respectively.

TABLE III
OVERHEAD IN THE TEST EXECUTION TIME.

App	OS V.	BE	LC	SDM	DCS
Fresh-Food-Finder	6.0	4.50	1.70	1.71	2.59
	7.0	4.55	1.72	1.70	2.69
OrderApp	6.0	4.25	3.37	-	3.91
	7.0	3.36	2.66	-	3.09
Memesplay	6.0	4.25	5.56	3.09	4.47
	7.0	2.40	3.58	1.96	2.70
Agenda	6.0	3.44	-	1.82	2.07
	7.0	3.42	-	1.64	2.29
TodoListCordova	6.0	3.71	-	-	2.62
	7.0	4.17	-	-	2.87
MovieApp	6.0	2.20	2.54	3.10	2.04
	7.0	0.71	0.82	1.02	0.65
TodoList	6.0	1.43	-	-	2.40
	7.0	1.39	-	-	1.99
Tasky	6.0	1.97	-	-	2.38
	7.0	2.00	-	-	2.43
Bargains	6.0	2.22	3.04	-	1.77
	7.0	2.50	2.31	-	1.99
Max		4.50	5.56	3.10	4.47
Min		0.71	0.82	1.02	0.65
Avg		2.97	2.68	2.06	2.42

The results show that amplified tests execute from 0.65 to up to 5.56 times the runtime of the original test suite. Answering **RQ₂**, the impact can be reasonable depending on the app and test pattern, though the (low) cost of CPU time might be compensated by the bug detection capabilities of the proposed approach.

c) *Different settings*: Due to space limitations, we analyze the results using two settings: Android 6.0 and Android 7.0. As we used two devices with different hardware configurations, variations in the runtime were expected and natural (see Table III). So, we focus on the results summarized in Table II. Notice that there is no discrepancy between the OS versions for test patterns *BE*, *LC*, and *SDM*. So, the 12 bugs detected by them were detected in both devices. From the 23 bugs found in Android 6.0, 11 were not observed in Android 7.0. Fewer failures were also noticed in Android 7.0, yet the number of false positives was slightly higher.

As all false positives were caused by Appium's issues, newer versions of Android seem to be more robust for automated tests. Surprisingly, all bugs found by *DCS* in Android 6.0 were not detected in Android 7.0. We believe that Android policies for background processes (app not in focus) may differ between the OS versions. This might cause a faulty behavior in a specific version.

The different results obtained in Android 6.0 and Android 7.0 give initial evidence that supports a negative answer to **RQ₃**. This motivates further investigation on different Android versions and other target OSs like iOS and Windows.

TABLE II
NUMBER OF BUGS, FAILURES (FAIL), AND FALSE POSITIVES (FP).

App	OS V.	BE			LC			SDM			DCS			Total		
		Bug	Fail	FP	Bug	Fail	FP	Bug	Fail	FP	Bug	Fail	FP	Bug	Fail	FP
Fresh-Food-Finder	6.0	1	10	0	0	0	0	0	0	0	1	31	15	2	41	15
	7.0	1	10	0	0	0	0	0	0	0	0	16	16	1	26	16
OrderApp	6.0	1	15	0	1	6	0	-	-	-	1	9	0	3	30	0

VI. CONCLUSION

This paper presented and evaluated an approach to generate amplified test scripts for cross-platform apps. To do so, we employed four test patterns that check well-known features of a mobile application: namely, *Lost Connection*, *Back Event*, *Side Drawer Menu*, and *Don't Change State*. We developed a supporting tool called x-PATeSCO and nine apps were used in the experiments. The results gave evidence that test amplification is capable of uncovering new bugs in cross-platform apps, though there exists a reasonable overhead in the test execution time. We also noticed variations between different versions of Android; this motivates further investigation on automated tests in multiple configurations of hardware, OSs, and so on.

Abstract— It is an empirical observation that Software Engineering and Knowledge Engineering seem to converge to a single discipline which may be suitably called *Software-Knowledge*. However, mere empirical observations are not satisfactory. These should be justified by plausible arguments. There are three convergence aspects, semantic, algebraic and topological, and this paper focuses on the algebraic aspect. Linear algebra is the basis for Linear Software Models, a rigorous theory of software systems composition from sub-systems, recently developed. Linear algebra, with added non-linearity, is also the basis for Deep Learning, a successful Artificial Intelligence domain. This work suggests and analyzes *Deep Software Learning*, i.e. Deep Learning specific to Software development problems. We then conjecture on deep reasons for Software-Knowledge convergence.

Keywords: *Linear Software Models; Software Composition; Laplacian Matrix; Deep Software Learning; Software-Knowledge Convergence; RNN; LSTM; Sequential and Structured Data.*

I. INTRODUCTION

It has been observed empirically that the Software Engineering and Knowledge Engineering disciplines seem to converge along their relatively short histories. Convergence is interesting theoretically and in practice. This paper analyzes Deep Software Learning as a mutual Software and Knowledge interaction for Software Development problems.

This work ultimate goal is to point out concrete directions to the rationale of Software-Knowledge convergence, starting from plausible conjectures. It offers a discussion roadmap for the Theory of Software Engineering special session on Software-Knowledge convergence, within the SEKE'2019 conference.

A. Concise Historical Overview

Software as a discipline starts in 1956 with Backus' Fortran a *high-level* programming language. Software Engineering itself was coined only in the celebrated NATO 1968 conference. Software history is since then a continuous increase in abstraction level of languages and design techniques. From structured programming, to object-oriented languages, as Java, to modeling languages, as UML, and model-driven-engineering

up to ontologies as conceptual refinement of classes and inheritance by subclasses.

Knowledge, an Artificial Intelligence (AI) field, started in 1950, with Shannon's [15], and Turing's [16] pioneer papers. Next appear classical AI expert-systems, e.g. Dendral to resolve chemical structural formulas. These systems separated inference engines from knowledge bases. Ontologies resulted from this research thread.

An early algebraic learning theory is the 1969 Perceptrons by Minsky and Papert [13]. A neural networks sub-field developed, remaining in research laboratories, for the lack of computing power. They were renamed "Deep Learning" with the industrial applications surge, due to added computing power (e.g. GPU), big data sets, and algorithmic improvements.

B. Aspects of Software-Knowledge Convergence

This paper is motivated by the following conjecture:

Software-Knowledge Conjecture

Software Engineering and Knowledge Engineering are converging to a single discipline which we call *Software-Knowledge*.

Software-Knowledge convergence consists of three aspects:

- 1) **Semantic** – the importance of concepts and ontologies in both software and knowledge fields;
- 2) **Algebraic** – mostly linear algebra as the basis of software composition theory and Deep Learning in diverse knowledge domains; this paper's focus;
- 3) **Topological** –graphs (planar or upon manifolds), with meaningful entities in nodes linked by edges.

Semantics got prominence within Software Engineering with the claim by Frederick Brooks in his books [1] [2] that "Conceptual Integrity is the most important consideration for software system design". This has been followed by recent research, e.g. by Jackson [8] and Exman. Semantics within Knowledge Engineering is prevalent since classical AI research, somewhat eclipsed by Deep Learning. Ontologies (e.g. the Protégé tool) are an important facet of it.

The Algebraic Software Engineering aspect, recognizing the importance of Software mathematical theory, e.g. that Linear Software Models [3], [4] gradually gains traction. The Algebraic Knowledge aspect, recognizing Deep Learning's applied surge.

II. RELATED WORK

A. Deep Learning for/by Software Engineering

Relevant neural networks are Recurrent Neural Networks (RNN), proposed in 1986 by Rumelhart, Hinton and Williams [14], and Long Short-Term Memory (LSTM) a special kind of RNN, proposed by Hochreiter and Schmidhuber [7] in 1997.

Software Engineering applications of Deep Learning for higher abstraction levels include: program generation from user intention (Lili Mou et al. [12]); program comprehension, to generate comments to Java code. (Xing Hu et al. [20]); API functions extraction from annotated code snippets collected from GitHub (Xiaodong Gu et al. [19]); and software modeling for various tasks (Hoa Khanh Dam et al. [6]).

Practical tools deal with software Traceability (Jin Guo et al. [11]), and fixing of C program errors (Rahul Gupta et al. [5]). Wei Fu and Tim Menzies [17] combine classical AI with Deep Learning to shorten training tasks.

B. Algebraic Software Theory: Linear Software Models

Software composition algebraic theory formalizes Brooks' Conceptual Integrity idea. Software is a hierarchical system, where each level is represented by a Modularity Matrix [3], [4]. Matrix columns stand for structural units, object-oriented *classes*, and matrix rows for functional units, i.e. class *methods*.

Brooks' principles translated into linear algebra demand that all matrix column vectors be *linearly independent* and similarly all the row vectors be linearly independent, obtaining a square matrix. If vector subsets are disjoint to other subsets, the matrix displays a block-diagonal form, i.e. the modules are *orthogonal*.

Modularity matrices may have outliers coupling between modules. Spectral methods for the Modularity Matrix [3], or the respective Laplacian Matrix [4], resolve couplings. A Laplacian obtains the same modules as the Modularity Matrix. The Fiedler vector, fitting the lowest Laplacian non-zero eigenvalue, allows locating outliers and splitting of too sparse modules.

III. DEEP SOFTWARE LEARNING: THE PROBLEMS

Deep Software Learning has to assume that software is a collection of diverse assets: requirements, class diagrams, statecharts for design, a variety of graphs, models and code.

A. Software Problems to be Solved

Software problems dealt with by Deep Learning can be classified by their abstraction levels (Fig. 1). Higher abstraction activities, such as API Extraction, Program Generation and Program Comprehension depend on a suitable underlying *software modeling*. Modeling is high-level abstraction, since many activities involve *translation between models*.

Figure 1. Deep Learning to Software Engineering applications, classified by abstraction levels. In between, the essential Linear Algebra Techniques.

Even lower abstraction level activities, such as correcting program errors, as done in DeepFix [5] need modeling. Every programmer has experience with accumulated bugs that result from misinterpretation (by the compiler!) of only a few bugs.

Linear algebra techniques are essential for Deep Learning. Richard Wei et al. [18], in their Compiler Infrastructure for Deep Learning, emphasize linear algebra representation in their system, such as a first class tensor type, algebraic operators such as “dot” and “tanh” (a typical sigmoid-like activation function).

B. Software Characterization: Sequential but not Consecutive, and Structured

Often program feature pairs are sequential but not appearing in each other neighborhood. Examples are: left and right parentheses (or braces); open and close a file; Java try and catch. Code modeling is sequential, but not of consecutive tokens. Dealing with such sequences, demands specific Deep Learning (DL) networks. Software also has more complex structures such as abstract syntax trees, dependency graphs, design diagrams. Sequences are not enough for software DL.

IV. RECURRENT NEURAL NETWORKS

Recurrent Neural Networks (RNNs) are dedicated to continuous data, such as text, audio and video. It reuses previous information about a word in a sentence or video frame to understand the next word or frame. RNNs handle tasks, like free text comprehension and text sequences generation from scratch. To reuse previous information to handle the next input, RNN has recourse to persistence loops. RNNs have difficulty applying prediction of long-distance natural language dependencies. Most translation, voice recognition, and image classification successes, are due to LSTM a special class of RNNs.

A. LSTM = Long Short-Term Memory

LSTMs remember information for long periods. Forgetting must be explicitly handled. LSTMs also have a loop structure of repeating neural network units. The main difference of a typical LSTM unit from an RNN unit, is 4 layers instead of a single one. A hidden state Z is the key to LSTMs functioning. It has an input z_{t-1} from its predecessor, runs throughout the chain of (unrolled loop) units, affected by controlled interactions, and outputs z_t to its successor unit. Three gates (in Fig. 2) update the hidden state Z in each cycle, filtering the output Y parts:

- **Forget gate f_t** – sigmoid taking y_{t-1} and x_t and producing a number between 0 and 1 for each z_{t-1} value; the part of the hidden state Z to (fully or partially) discard;
- **Input gate** – has 2 layers: *sigmoid* i_t sets which values will be updated; *tanh* creates a new vector of values \hat{z}_t , multiplied by the sigmoid output giving candidate values actually added to Z: $\hat{z}_t = f_t * z_{t-1} + i_t * \hat{z}_t$
- **Output gate** – sigmoid o_t filters what will be the output and what remains the Z output: *tanh* normalizes z_t values between -1 and +1, then multiplied by the sigmoid o_t :
 $y_t = o_t * \tanh(z_t)$.

Figure 2. LSTM Deep Learning Network Schematic diagram - The upper (blue) horizontal line is the Z hidden state, with input z_{t-1} and hidden output z_t . The lower horizontal line passes the output y_t between consecutive units. The three vertical gates are: the (red) forget gate f_t ; the (green) input gate i_t with two parallel layers (σ and \tanh); the (violet) output gate o_t . (Color online)

A realistic LSTM test, keeping track of long-range attributes, takes a large source code and randomly concatenates it into a long file (e.g. Linux Kernel [9] about $6 \cdot 10^6$ characters). The LSTM network is trained to predict special source code symbols, as whitespace, quotation marks and brackets. To predict a *close* bracket, the model must be aware of a matching *open* bracket, appearing many time steps ago. LSTM performs much better than other learning models due to an additional state feature (hidden state Z) explained above, in contrast to the standard RNN single hidden state. Results can be improved with an attention mechanism [21] or bidirectional-LSTM [10].

V. DEEP SOFTWARE LEARNING IN PRACTICE

The Deep Learning (DL) mechanism in the Xing Hu [20] work deals with sequential code, and Abstract Syntax Tree (AST) structure, translating sequence-to-sequence, code to comments. The Encoder/Decoder (both LSTMs) architecture uses one Encoder pass to traverse the AST, learning the code relevant to the comments. A second Encoder pass composes the gathered comment pieces into meaningful sentences.

Rare tokens clutter a vocabulary with single instances. Practical projects exchange numerals/strings by generic tokens <NUM> and <STR>, and rare words by “unknowns” <UNK>.

VI. DISCUSSION

Today’s software and knowledge (DL) theories have two important characteristics: 1- they heavily involve linear algebra; 2- the algebra is totally independent of concepts’ semantics.

Remaining issues are: The algebraic software theory is up to now strictly linear, while Deep Learning involves non-linearity. Will there be a convergence also in this sense? The Laplacian matrix is central to the software theory, while not so prominent in Deep Learning; will it be important for Deep Learning too?

Abstract— Business models, organizational activities and corporate strategies are now being reshaped to meet the new needs of a challenging and evolving environment in which more up-to-date, secure, safer, cost-efficient and personalized software products and services must be timely delivered. This new digital context also represents an opportunity for the improvement and extension of existing software engineering methods. One of the current trends in Software Engineering development lies in boosting interoperability and collaboration between tools and people through the sharing of existing artifacts under common data models, formats and protocols to improve the practice and reuse of existing software artifacts. In this context, formal ontologies and data shapes play a key role to model and exchange data and to provide services for data validation (consistency checking) or type inference as part of a knowledge management strategy. In this document, an initial review of the different approaches to model and exchange data of software artifacts is done to finally evaluate and discuss the proper mechanisms to technically support the upcoming needs in the Software Engineering development lifecycle.

Keywords: *software development lifecycle; ontologies; data shapes; interoperability; knowledge representation*

I. INTRODUCTION

The Digital Age, the “Society 5.0” in Japan or the “4th Industrial Revolution” [1] has come to say that any industry, business or even our daily life will suffer a deep transformation being driven by software systems.

This new digital context also represents a challenge and an opportunity for the improvement and extension of existing software engineering methods. After 50 years [2], the Software Engineering (SE) discipline has focused on ensuring the efficiency, correctness, robustness and reliability of software systems. The development of some SE knowledge areas [3] have set the foundations of the discipline. Furthermore, the definition of methodologies, methods and models, software development lifecycles and their technological support have also represented a major step to improve the SE practice from both organizational and scientific/technological points of view[4] [5].

On the other hand, knowledge management techniques have gained enough momentum in the SE discipline to elevate the meaning of the implicit knowledge coded into software pieces. Software as a knowledge asset is becoming a commodity that is embedded in products, business or manufacturing processes. It

is a new kind of intellectual asset that can help us to reduce costs and time to market, and to generate competitive advantage. In this light, knowledge management techniques [6] can be applied to capture, structure, store and disseminate software artifacts to directly support methods such as software reuse.

However, one of the cornerstones in knowledge management lies in the selection of an adequate representation paradigm. After a long time [7], this problem still persists since a suitable representation format (and syntax) can be reached in several ways.

Obviously, different types of knowledge, such as those in the SE discipline (requirements, source code, test cases, etc.), require different types of representation [8] [9]. But, on the other hand, knowledge management also implies the standardization of data and information within the development lifecycle. Any bit of information must be structured and stored for supporting other application services such as business analytics or knowledge discovery.

One of the current trends in SE development lies in boosting interoperability and collaboration between tools and people through the sharing of existing artifacts under common data models, formats and protocols to improve the practice and reuse of existing software artifacts. In this context, OSLC (“Open Services for Lifecycle Collaboration”), model-driven approaches, etc. are defining a collaborative software development ecosystem [10] through the definition of data shapes that serve us as a contract to get access to information resources through standardized.

In particular, the Representational State Transfer (REST) software architecture style is commonly used to manage information and software resources such as requirements, test cases or even source code that are publicly represented and exchanged in standard formats such as RDF or just XML. Obviously, these approaches represent a big step towards the integration and interoperability between the agents involved in the software development lifecycle.

However, a knowledge management strategy to take advantage of software artifacts is beyond of the mere exchange of data. Consistency checking, type inference, data integrity, etc. are common operations expected in a knowledge-centric framework that can help us to improve the practice in the SE discipline.

In this paper, authors review and discuss the role of ontologies and data shapes as a mean to represent, exchange and consume software-related artifacts with the aim of improving and enriching software development methods providing capabilities for consistency checking, type inference or data integrity.

II. BACKGROUND

The Software Engineering discipline [11] [12] [13] initially focused on the definition of methodologies and methods to tackle the problem of reliability in software systems and to ease the reuse of working software products.

The notion of software engineering process was then defined, and different software development lifecycles (SDLC) such as the Structured Systems Analysis and Design Method (SSADM), the Waterfall model, the Rational Unified Process (RUP), the Rapid application development (RAD) or the Vee model were established as a method to manage the complexity of software development. Afterwards, new programming paradigms, standard notations (e.g. UML or OCL), languages and tools emerged as way of improving the abstract thinking in combination with a technological support providing better development environments.

Once, the methods and the supporting tools were available, the focus was the reuse of software assets, the quality management, the definition of maturity models and the automation of tasks generated during the software development process. More specifically, the software reuse area gained momentum through the definition of methods to reuse existing software components through the abstract description of different elements, e.g. architectural and design patterns, libraries, component models or services. Furthermore, coding practices [14] were also improved adding new foundations such as the SOLID¹ principles or new practices such as refactoring.

Initiatives such as Model-Driven Engineering [15] [16] (MDE) and Model-Driven Architecture (MDA) later posed the foundations to automate the production of software for specific domains. In the last decade, software product lines [17] have also been subject of study and application as a method for automating the creation of families of software products.

At the development level, the emerging use of Agile methods [18], inspired by the Spiral model, such as XP, Scrum or Kanban and, processes such as BDD (Behavior-Driven Development) or TDD (Test Driven-Development) have also led us to improve the software development practice in combination with approaches such as DevOps [19] (Development and Operations). The latter are often applying to ease the continuous transition of software systems from a development to a production environment as a mean for the early detection of “bugs” and the improvement of the maintenance and change management processes.

In summary, the Software Engineering discipline has reached a great maturity level. There is a huge body of

knowledge and practice that allow us to acknowledge which are, and which are not, the software engineering practices that really represent timeless scientific and technological foundations for a proper software development process. That is why, knowledge management techniques are aimed at enhancing existing SE methods by providing a knowledge layer on top of the data generated during the development lifecycle.

III. FORMAL ONTOLOGIES VS DATA SHAPES

In the early days of the Semantic Web, formal ontologies [20] designed in RDFS (Resource Description Framework Schema) or OWL were the key technologies to model and share knowledge.

From upper ontologies such as DOLCE (Descriptive Ontology for Linguistic and Cognitive Engineering) or SUMO (The Suggested Upper Merged Ontology) to specific vocabularies such FOAF (Friend Of A Friend) or SKOS (Simple Knowledge Organization System), the process to share knowledge consisted in designing a formal ontology for a particular domain and populate data (instances) for that domain. Although the complete reuse of existing ontologies was expected, the reality demonstrated that every party willing to share knowledge and data would create its own ontologies. Thus, the main idea behind web ontologies was partially broken since just a few concepts were really reused.

Once the Linked Data initiative (RDF + HTTP) emerged to unleash the power of existing databases, a huge part of the Semantic Web community realized that a formal ontology was not completely necessary to exchange data and knowledge.

Taking into account that ontologies were still present, the efforts were focused on providing methods for data consistency [21] through the execution of procedures such as: 1) reasoning processes to check consistency, and 2) rules, mainly in SWRL (Semantic Web Rule Language) or SPARQL [22] [23]. These procedures are not fully recommended, due to performance issues, when a huge number of instances are available. As a new evolution, then, the community realized that ontology-based reasoning was not the most appropriate method for data validation when data is being exchanged.

That is why in recent times the Semantic Web community has seen an emerging interest to manage and validate RDF datasets according to different shapes and schemes. A data shape can be defined as a resource, i.e. metamodel, that describes contents of, and constraints on, other resources. In this way, it is possible to not just improve but to overcome some of the well-known restrictions [24] of RDF encoded data: 1) lack of support to represent certain knowledge features N-ary relationships [25], 2) practical issues dealing with reification [26] and blank nodes [27]. New specifications and methods for data validation (consistency) are being designed to turn reasoning-based validation into a kind of grammar-based validation.

Process	Type	Creation	Scope	Refs.
Consistency check	Vocabulary-based	Semantic Web reasoner	RDF datasets	[21]
Data validation (integrity)	Query-based	Hand-made RDF templates	RDF datasets	[22]
	Vocabulary-based	Hand-made	RDF datasets	[23]
	Vocabulary-based	Hand-made or automatically generated by an OSLC API	OSLC Resource Shape	[28]
	Vocabulary-based	Hand-made	Dublin Core Description Set Profiles	[29]
	Query-based	RDF Unit (test creation)	RDF datasets	[30]
	Query-based (generated from ShEX expressions)	Automatic generation of SPARQL queries	RDF datasets	[31] [32] [33]
	Vocabulary and Query-based	Automatic generation of SPARQL queries	OWL and RDF under Closed World Assumption	[34]
	Query-based	SPIN language + SPARQL queries	RDF datasets	[35]

Table 1 Comparison of methods for RDF data validation.

These methods take inspiration from existing approaches in other contexts such as DTD (Document Type Definition), XML-Schema or Relax NG (REgular LAnguage for XML Next Generation) for XML, or DDL (Data Definition Language) for SQL (Structured Query Language).

The W3C launched in 2014 the RDF Data Shapes Working group having as main outcome the SHACL (Shapes Constraint Language), W3C Recommendation, and the ShEX (Shape Expressions) language [31] [32]. Both are formal languages for expressing constraints on RDF graphs including cardinality constraints as well as logical connectives for disjunction and polymorphism. OSLC Resource Shapes [28], Dublin Core Description Set Profiles [29], and RDF Unit [30] were also other constraint languages for data validation in the context of Linked Data.

Following a more classical approach for RDF data validation, the Pellet Integrity Constraints is an extension of the existing semantic web reasoner [34] that interprets OWL ontologies under the Closed World Assumption with the aim of detecting constraint violations in RDF data. These restrictions are also automatically translated into SPARQL queries. This approach has been implemented on top of the Stardog² database, enabling users to write constraints in SPARQL, SWRL or as OWL axioms. This approach has been reported as a method for data validation and type inference in some case studies (e.g. NASA Knowledge Graph)³ were logical models are translated into OWL instances and, then, a reasoning process (semantic web based or rule-based) is executed to find inconsistencies, infer types, etc. However, the complexity and time to make transformations between object models and Description Logics seems to be not very effective since the same information is being modelled at the same time under two different paradigms. Finally, the SPIN language [35] also makes use of SPARQL (mainly its syntax) to define constraints on RDF-based data that can be executed by systems supporting SPIN (SPARQL Inferencing Notation), such as the TopBraid's toolchain.

In conclusion, the relevance of data validation to exchange RDF-encoded data is clear. RDF Data Shapes in its different flavors, such as OSLC Resource Shapes, are becoming the

cornerstone for boosting interoperability among agents, see Table 1. It is also clear that ontologies are becoming less important although a combined approach (data shapes and a formal ontology) can provide important benefits in terms of data validation and knowledge inference (if needed). In the context of SE and reuse, as it has been previously outlined, software artifacts must take advantage of new technologies to enable practitioners the automatic processing of exchanged data.

IV. KNOWLEDGE MANAGEMENT WITHIN THE SOFTWARE ENGINEERING PROCESS

Software is becoming a commodity, knowledge that is embedded in every product, business and development or manufacturing process. Assuming that a software artifact is a knowledge asset, the ground truth about knowledge characteristics [36] is also valid for software artifacts:

- Use of knowledge does not consume it.
- Transfer of knowledge does not imply losing it.
- Knowledge is abundant; the problem lies on the proper use and exploitation.
- Much of an organization's valuable knowledge walks out the door at the end of the day.

According to the current SE context, it seems that graph-approaches based on a semantic network and deployed under a set of standards in a service-oriented environment, are the most appropriate candidates. Considering this environment, the following knowledge representation paradigms (focusing on web-oriented technologies) have been selected for comparison:

1-The **Resource Description Framework** (RDF) [37] is a framework for representing information resources in the Web using a directed graph data model. The core structure of the RDF abstract syntax is a set of triples, each consisting of a subject, a predicate and an object. A set of such triples is called an RDF graph. An RDF graph can be visualized as a set of nodes and directed-arcs diagram, in which each triple is represented as a node-arc-node link. RDF has been used as the underlying data model for building RDFS/OWL ontologies, gaining momentum in the web-based environment due to the explosion of the Semantic Web and Linked Data initiatives that

² <http://stardog.com/>

³ <https://www.stardog.com/blog/nasas-knowledge-graph/>

aim to represent and exchange data (and knowledge) between agents and services under the web-based protocols.

2-The **RDF Schema (RDFS)** [38, p. 1] provides a data-modeling vocabulary for RDF data. It represents a first try to support the creation of formal and simple ontologies with RDF syntax. RDFS is a formal and simple ontology language in which it is possible to define class and property hierarchies, as well as domain and range constraints for properties. One of the benefits of this property-centric approach is that it allows anyone to extend the description of existing resources.

3-The **OWL (Ontology Web Language)** [39] is an ontology language for capturing meaningful generalizations about data in the Web. It includes additional constructors for building richer class and property descriptions (vocabulary) and new axioms (constraints), along with a formal semantics. OWL 1.1 consists of three sub-languages with different levels of expressivity: 1) OWL Lite, 2) OWL DL (Description Logics) and 3) OWL Full.

4-The **OWL 2.0** [39] family defines three different profiles: OWL 2 EL (Expressions Language), OWL 2 QL (Query Language) and OWL RL (Rule Language). These profiles represents a syntactic restriction of the *OWL 2 Structural Specification* and more restrictive than OWL DL. The use of profiles is motivated by the needs of different computational processes. OWL EL is designed for enabling reasoning tasks in polynomial time. The main aim of OWL 2 QL is to enable conjunctive queries to be answered in LogSpace using standard relational database technology. Finally, OWL 2 RL is intended to provide a polynomial time reasoning algorithm using rule-extended database technologies operating directly on RDF triples. In conclusion, OWL 2.0 adds new functionalities regarding OWL 1.x. Most of them are syntactic sugar but others offer new expressivity [39]: keys, property chains, richer datatypes, data ranges, qualified cardinality restrictions, asymmetric, reflexive, and disjoint properties; and enhanced annotation capabilities.

3-The **RIF Core** (Rule Interchange Format) [40] comprises a set of dialects to create a standard for exchanging rules among rule systems, in particular among Web rule engines. RIF was designed for exchanging rather than developing a single one-fits-all rule language. RIF dialects fall into three broad categories: first-order logic, logic-programming, and action rules. The family of dialects comprises: 1) logic-based dialects (RIF-BLD) including languages that employ some kind of logic such as First Order Logic (usually restricted to Horn Logic) or non-first-order logics; 2) rules-with-actions (RIF-PRD) dialects comprising rule systems such as Jess, Drools and JRules as well as event-condition-action rules such as Reaction RuleML. RIF also defines compatibility with OWL and serialization using RDF.

5-The **SRL** (System Representation Language) [41] [42] is based on the ground idea that whatever information can be described as a group of relationships between concepts. Therefore, the leading element of an information unit is the relationship. For example, Entity/Relationship data models are certainly represented as relationships between entity types;

software object models can also be represented as relationships among objects or classes; in the process modeling area, processes can be represented as causal/sequential relationships between sub-processes. Moreover, UML (Unified Modeling Language) or SysML (System Modeling Language) metamodels can also be modeled as a set of relationships between metamodel elements.

SRL also includes a repository model to store information and relationships with the aim of reusing all kind of knowledge chunks. Furthermore, text-based information can certainly be represented as relationships between terms by means of the same structure. Indeed, to represent human language text, a set of well-constructed sentences, including the subject+verb+predicate (SVP) should be used. The SVP structure can be then considered as a relationship typed V between the S and the predicated P. In SRL, the simple representation model for describing the content of whatever artifact type (requirements, models, tests, maps, text docs or source code) is as follows:

SRL representation for artifact $\alpha = i_\alpha = \{(RSHP_1), (RSHP_2), \dots, (RSHP_n)\}$ where every single RSHP (relationship) is called RSHP-description and must be described using terms.

One important consequence of this representation model is that there is no restriction to represent a particular type of knowledge. Furthermore, SRL has been used as the underlying information model to build general-purpose indexing and retrieval systems, domain representation models [41], approaches for quality assessment of requirements and knowledge management tools such as knowledgeMANAGER.

Obviously, a plethora of other knowledge representation mechanisms and paradigms can be found as it is presented below. However, we focus here on comparing those that satisfy the three basic ideas of this study: 1) a language for representing any artifact metadata and contents; 2) a system for indexing and retrieval and 3) a standard input/output interface (data shape+REST+RDF) to share and exchange artifact metadata and contents.

The SBVR (Semantics of Business Vocabulary and Rules). It is an OMG standard to define the basis for formal and detailed natural language declarative description of a complex entity. The Ontology Definition Metamodel (ODM). It is an OMG standard for knowledge representation, conceptual modeling, formal taxonomy development and ontology definition. It enables the use of a variety of enterprise models as starting points for ontology development through mappings to UML and MOF.

ODM-based ontologies can be used to support: 1) interchange of knowledge; 2) representation of knowledge in ontologies and knowledge bases; and 3) specification of expressions that are the input to, or output from, inference engines. The Reusable Asset Specification (RAS), an OMG standard that addresses the engineering elements of reuse. It

attempts to reduce the friction associated with reuse transactions through consistent, standard packaging.

V. EVALUATION AND DISCUSSION

The previous section has reviewed the main approaches for knowledge representation in a web-oriented environment for exchanging software artifacts. As a result, Table 2 (in the Annex) shows the main characteristics and capabilities that can be found in RDF, RDFS, OWL and SRL with special focus on those regarding knowledge management and, more specifically knowledge representation. In order to select the proper mechanism for knowledge representation of software artifacts, the following points must be considered:

- RDF is based on a directed graph and it can only represent binary relationships (unless reification and blank nodes are used). As a representation mechanism, RDF presents some restrictions that have been outlined in several works [24]. For instance, N-ary relationships [25], practical issues dealing with reification [26] and blank nodes [27] are well-known RDF characteristics that do not match the needs of a complete framework for knowledge representation. Furthermore, RDF is built on two main concepts: resources and literals. However, a literal value cannot be used as the subject of an RDF triple. Although this issue can be overcome using a blank node (or even reification) and the property `rdf:value`, it adds extra complexity for RDF users. Finally, RDF has been designed to represent logical statements, constraining also the possibility of representing other widely used paradigms such as objects or entity-relationships models. Due to these facts, it seems clear that RDF can be used for exchanging data, but it is not the best candidate for knowledge representation.
- RDFS is a good candidate for modeling lightweight formal ontologies including some interesting capabilities close to object-oriented models. RDFS ontologies can be serialized as RDF, but this feature can also be a disadvantage due to expressivity restrictions of RDF. Again, RDFS has been designed for expressing logical statements that describe web resources, so its use for other types of information seems to be not advisable.
- Building on the previous discussion, OWL presents a family of logic dialects for knowledge representation. It is based on strong logic formalisms such as Description Logic or F-Logic. It was also designed for asserting facts about web resources although it can be used as a general logic framework for any type of knowledge. One of the main advantages of OWL is the possibility of performing reasoning processes to check consistency or infer types. However, reasoning can be considered harmful in terms of performance and most of times it is not necessary when data is being exchanged. Besides, OWL is not the best candidate for data validation, a key process in knowledge exchange.
- RIF Core and the family of RIF dialects have been included in this comparison due to the fact that most of

domain knowledge is embedded in rules. However, RIF was not designed for data validation and its acceptance is still low (just a few tools export RIF and less are capable of importing RIF files). On the other hand, RIF makes use of the web infrastructure to exchange rules, what means also that this environment is a very good candidate to exchange data, information and knowledge.

- SRL, based on relationships, allows domain experts to create relationships between terms, concepts or even artifacts (containers). It provides a framework for knowledge representation with capabilities for expressing any kind of cardinality and N-ary relationships. SRL is based on undirected property graphs, enhancing expressivity. Although it has not been directly designed for data validation, its metamodel allows the possibility of checking cardinality, value constraints, domain and range restrictions. One of the strong points of SRL is the native support of a tool such as knowledgeMANAGER and the possibility of automatically providing semantic indexing and retrieval mechanisms. Both have generated a relevant acceptance in the industry for authoring and quality checking.

Finally, as a general comment, there is also a lack of tools working natively on RDF. Furthermore, RDF was conceived to exchange information over the web. Although some RDF repositories can provide capabilities for indexing and searching RDF resources through an SPARQL interface, the experience has demonstrated that most of times RDF is translated into the native data model of a tool.

Based on this evaluation and considering the three basic requirements of this review, we conclude that RDF is a good alternative to exchange data. Since formal ontologies and reasoning processes are not completely necessary and, instead, data validation is a key aspect for boosting interoperability and reuse of software artifacts, it also seems clear that an approach like SRL can perfectly fit to the major objective of knowledge representation in the SE discipline. However, we recognize that the use of formal RDFS or OWL ontologies is not incompatible with data shapes, but possible. RDFS and OWL are languages for building domain vocabularies, while SRL is already a domain vocabulary for knowledge representation, so it is possible to define SRL in a formal RDFS/OWL ontology.

VI. CONCLUSIONS AND FUTURE WORK

The application of the Linked Data principles to exchange data in the software development lifecycle is gaining momentum. Software artifacts reuse via interoperability is a key enabler for boosting collaboration in the development of complex software systems. The concept of continuous engineering is becoming a reality since it is possible to integrate data and services under common protocols and data models.

In this context, the capability of reusing existing software artifacts is a key factor that can ease teams to develop systems faster and safer. However, software is not anymore, a piece of logical instructions but a kind of knowledge and organizational asset. That is why a proper environment for knowledge

management of software artifacts should provide the appropriate mechanisms for representing, storing, indexing and retrieving any kind of software artifact. However, some approaches such as OSLC relying on Linked Data principles cannot easily be deployed due to issues regarding expressivity in RDF or the need of tools for easily processing RDF (mainly from a developer perspective). In this context, the use of well-documented REST APIs (e.g. based on standards such as the OpenAPI Specification) are good enough to access and exchange data generated during the development lifecycle.

Abstract—Using advanced technologies is imperative to support quick decision-making in a hospital, where people work with complex and critical processes. An example of a complex and very important task is to make the best decision about in which room and bed a patient should be admitted to hospital, considering the patient needs, characteristics, and available resources. In this case, bad decisions can even compromise patient health. With this study, we aim to facilitate patient-related decisions related to bed allocation, based on an ontology. To do so, we developed an ontology that takes patients' information into account to help health professionals decide where to allocate them. Our main contribution is an ontology, with classes, relationships, individuals, and rules to be used in specific scenarios. Additionally, we exemplify some scenarios in which the rules could be applied.

Index Terms—Ontology, health care, hospital bed allocation.

I. INTRODUCTION

Hospital decision-making is an important and complex task, which demands a great deal of cognitive effort from health professionals [13]. In this way, tools and technologies that facilitate decision making are great alternatives to help health professionals reduce their cognitive load and possible errors caused by fatigue.

Information technology is widely adopted in modern medical practice, especially to support administrative tasks, patient electronic records, and data management [15]. Artificial Intelligence (AI) has also been highlighted in several applications in the medical field, e.g. to predict patient inflow [8], identify high-quality physicians based on big data [24], and estimate surgical time duration [21].

Ontologies provide the basis to establish an explicit formal concept specification in a specific domain, allowing the development of relationships between these concepts and the reuse and integration of domain knowledge [10]. In the hospital domain, ontologies provide information associated with a wealth of knowledge about clinical decisions [3], medication [2], diagnoses [19], medical records [11], and so on.

In this paper, we report the development of an ontology for bed allocation, which we developed for the Portuguese language. Our ontology is composed of classes, object properties, and individuals, enabling us to present real scenarios that can be tested using its rules. The main function of our ontology is to assist decision making about the place where patients will be allocated when being admitted to hospital, according to the patient's records, characteristics, and the bed allocation rules used in the particular hospital.

II. THEORETICAL BACKGROUND

The development, dissemination, and use of common communication standards, vocabularies, and ontologies are important for the development of health systems [13]. Therefore, in this section we explore some of the main concepts related to our work, such as hospital bed allocation and ontologies.

A. Hospital bed allocation

Hospital bed management is an important part of operational capacity planning and control, and it involves the efficient use of resources [17]. Each hospital has its own rules, but there are some factors that must be considered when choosing a bed for a patient, such as age, patient condition, and gender.

Effective management of beds has always been a challenge for managers, given that hospital settings are highly dynamic and uncertain. It is necessary to accommodate both scheduled and emergency patients, requiring multiple expertise in a wide range of hospital departments with various different constraints [4].

Furthermore, in a hospital there are many other resources that need to be allocated and many decisions that always need to be made as quickly as possible. An ontology-based decision support system can be useful to quickly make the right decisions, even helping save lives.

B. Ontology

An ontology is an explicit and formal specification of a shared conceptualisation made up of concepts or classes, relationships, instances, attributes, axioms, restrictions, rules, and events [20]. An ontology communicates what kinds of things exist and how they are related to each other [22]. A standard for representing ontologies that is widely used both in academia and industry is the OWL (Ontology Web Language), is a language for representing ontologies that is based on formal logic, a discipline that evolved from philosophy and mathematics [22].

For instance, Protégé¹ is an open source tool that implements OWL. A Protégé ontology consists of classes, properties, individuals, and rules. Classes are concepts in the domain of discourse. Object properties are slots that describe properties or attributes of classes. Individuals are class instances, and rules are axioms specifying additional constraints. The ontology and its class individual instances with specific values comprise a knowledge base on Protégé [14].

III. BED ALLOCATION ONTOLOGY

The inspiring approach [5] was used in the development of the ontology containing 95 classes, 85 object properties, and 78 individuals. We created the original version in Portuguese, but we translated the terms here for consistency with the study report. Next, we explain its components, and present and exemplify the rules we created based on the hospital bed management context. Due to space constraints, we are not able to present here all the details, properties, rules and ontology visual representation, so we provide it in a repository at GitHub: <https://github.com/DeborahEngelmann/Hospital-Bed-Allocation-Ontology>.

A. Classes

In this section, we detail the classes we created. Note that all the concepts described here refer to the scenario created by the researchers, and they can have different meanings in different contexts.

Attendance: The term *attendance* is used to refer to the whole period the patient attended any activity in a hospital, either ambulatorial or hospitalisation. *Ambulatorial* is the assistance that occurs via prior scheduling or by emergency need. It has *Elective* (when it is scheduled) and *Emergency* sub-classes (when it occurs without scheduling, because of an urgent need of the patient). *Hospitalisation* occurs when the patient needs to stay in hospital for more than one day, occupying a *Hospital_Bed*.

Risk_Classification: A risk category assigned to patients when they start being cared for, widely used in the emergency sector to prioritise patients in worst health conditions. We describe it based on Manchester protocol, defined by Mackway-Jones, Marsden, and Windle [9]. Sub-classes range from immediate to non urgent. A patient that has risk of death is classified as *Very_urgent*. Patients with immediate risk of limb loss or loss of organ function are classified as *Very_urgent*. Patients with conditions that can worsen if not helped soon are *Urgent*. Patients with low risk of health damage are *Standard*, and the ones without any immediate risk of health damage are *Non_urgent*.

Temporal_concept: Concepts related to the timing of events. It includes the following sub-classes: Now, Year, Date, Day, Today, Hour, Time interval, Month, and Week.

Document: It refers to the documents generated during or after a patient's attendance. It includes diagnosis, report, prescription, and medical records. (1) *Diagnosis*: made by a doctor, it determines the disease nature and cause, based on the patient history, symptoms, examination, etc. (2) *Report*: made by a specialist doctor, it usually contains the analysis of exams, such as radiology, laboratory, etc. (3) *Prescription*: made by a doctor, it includes drugs and treatments recommended to the patient. (4) *Medical_records*: it includes all the data related to the patient that can be accessed and stored by the hospital.

Disease: Biological alteration of a person's health state, manifested by a set of symptoms.

Speciality: Represents the medical specialisation or expertise that the doctor possesses or that the patient needs.

State: it represents patient conditions, and has 5 sub-classes: Coma, In treatment, Stable, Severe, and Vegetative.

Situation: it represents hospital bed conditions, and has 5 sub-classes: Blocked, Clean, Free, Occupied, and Dirty.

Local: places inside a hospital. Sub-classes are: Corridor, Pharmacy, Bed, Room, Reception, and *Hospitalisation_Unit*. The *hospitalisation_Unit* also has sub-classes named: *Speciality_Unit*, Nursery, Pediatrics, Intensive_Care_Unit, and *Special_Care_Unit*.

Medication: the drugs stored on the Pharmacy, which are meant to treat the patients.

Furniture: All the furniture that belongs to the hospital. For this study, we describe just two sub-classes: Bed and Stretcher.

Person: People who belong to the hospital ecosystem. Sub-classes are: *Companion*, *Man*, *Woman*, *Patient*, and *Employee*. *Employee* has the following sub-classes: *Administration*, *Cleaner*, *Receptionist*, *Security_Guard*, and *Health_Professional*. The last one comprehends *Nurse*, *Nursing_Technician*, and *Doctor*. *Doctor* also have sub-classes named: *Generalist*, *Resident*, and *Specialist*. *Specialist* has the following sub-classes: *Cardiologist*, *Dermatologist*, *Neurologist*, *Oncologist*, *Pediatrician*, *Pneumologist*, *Radiologist*, and *Traumatologist*.

Restriction: rules to restrict bed allocation. (1) *Routing*: Origin of the patient, for example if he came from the emergency or is an elective patient. (2) *Age*: person's age group, which can be adult, teenager, or child. (3) *Gender*: male or female. (4) *Isolation*: Refers to the cases where the patient cannot be in the a room with other patients. (5) *Puerperal*: Women who just gave birth. (6) *Length_Of_Stay*: Predicted time of patient stay in the hospital, can be turn-fast or long-stay. (7) *Hospital_Care*: Hospital care the patient needs, can be surgical or clinical. (8) *Type_Of_Care*: Type of care that the patient needs, can be minimal, semi-intensive or intensive.

Symptom: Signs to which the patient refers when talking about his illness (pain, fever, etc.).

Treatment: Set of instructions of procedures that the doctor recommends for the patient undergo.

B. Object Properties

We created 85 relationships between the classes, and some of them presented in Table I. The full list is available at GitHub. We have not included all possible relationships between classes, only those we consider interesting for this domain, so we could see clearly how the classes relate to each other, to help us test the rules.

C. Individuals

We instantiated 78 individuals, so we could use the reasoner to test our rules. Individuals we created include Patient, Room, Hospital_Bed, Symptoms, and so on. To create them, we used names such as Patient1, 100, 100A, Headache, and so forth.

D. Rules

Our ontology aims to help decision making about the beds where patients can be allocated according to the bed

TABLE I
BED ALLOCATION ONTOLOGY – OBJECT PROPERTIES

Domain	Object Property	Range	Inverse of

Bedroom	bedroom-is-care	Hospital_Care	
Bedroom	bedroom-is-routing	Type_Of_Care	
Bedroom	bedroom-is-routing	Routing	

allocation constraints. Thus, we establish rules that propagate information about restrictions by registered individuals. We are aware that a lot of rules can be created to help decision making related to bed allocation in hospitals. We present a sample of the ones we created for our ontology in Table II.

1) *First scenario*: For some hospitals, there are a number of bedrooms that have no preferential gender. It means one can allocate male or female patients to those bedrooms, but not both. Let us say there is a bedroom with two empty beds, and then a man is allocated to one of those beds. Thereafter, while there is a man in this bedroom, only another man can occupy the other bed. Nevertheless, as soon as the bedroom is empty, women can occupy it too, according to the priority in the queue of patients to be hospitalised. In this scenario, our rules work as follows. If a male patient is placed in a bed, RULE 1 infers that the patient is male, RULE 23 infers that the bed has become male only, RULE 29 infers that if a bed of the bedroom is for male patients, then the bedroom must also be male only, and finally, RULE 19 infers that if a bedroom is male only, all the beds in that room are too.

2) *Second scenario*: Patient disease and condition also influences bed allocation. For instance, when a woman is suspected to have a disease transmitted by air and highly contaminating, she must be isolated, having her own bedroom, and be attended by a Pneumologist doctor. In this case, when allocating this patient in a bed, RULE 21 infers that if the patient is of the Pneumology speciality then the bed where she was allocated is also of that speciality. RULE 9 infers that the bedroom where this bed is also is of the Pulmonology speciality. Finally, RULE 8 infers that if there are other beds in that bedroom, they all have that same speciality. In addition, because it is a patient in isolation, rule 20 infers that if the patient is in isolation, so is the bed. RULE 2 infers that if the bed is for isolation then the bedroom should also be. And

finally, RULE 27 infers that all beds in the bedroom should be of the same type of isolation.

3) *Third scenario*: Another important restriction related to bed allocation is age group. When a child has to be hospitalised, we can only allocate them in the same bedroom with people up to 12 years old. The rules we can apply in this case are: RULE 24 that infers that if the patient in a bed is of a certain age group then the bed is also; RULE 16 infers that the bedroom is the same age group as the bed that has a person allocated; and RULE 18 that infers that all other beds in the bedroom have the same age group.

4) *Fourth scenario*: When a healthy baby is born, its mother must be allocated in a bed in the Maternity Unit, because she needs a baby crib next to her bed. In this case, RULE 12 infers that if the patient is of a puerperal type, then the bed is of the same type. RULE 7 infers that the bedroom to which the bed belongs will be of the same puerperal type, and RULE 28 infers that in this case, the other beds in that bedroom must only be allocated women who just gave birth to a healthy child. In addition to these scenarios, we create rules with this same type of reasoning for all other constraints.

IV. RELATED WORK

A considerable number of papers studied ontologies on hospital domains. In this Section, we summarise some of them. Rubin [18] presents Radlex, a standard terminology widely used in the radiology field. Mhiri and Despres [12] use ontologies as indexing support to generate more accurate clinical reports. Kataria et al. developed HIWO [6], a formal description of an intelligent hospital domain, based on a ontology. The Nurse Call System (oCS) [15], developed by Ongenae et al., uses an ontology to manage context information about patient profiles and team members. An Ontology for Hospital Scenarios (OntHoS), created by Becker et al. [1], aims to establish a basis for a description of these

23. *Patient(?X), is - of - the - gender(?X, ?H), Hospital_Bed(?Y), occupy - one(?X, ?Y) → bed - is - of - the - gender(?Y, ?H)*
24. *Patient(?X), is - of - the - age - group(?X, ?G), Hospital_Bed(?Y), occupy - one(?X, ?Y) → bed - is - of - the - age - group(?Y, ?G)*
27. *Hospital_Bed(?Y), Bedroom(?Z), is - in(?Y, ?Z), bedroom - is - isolation(?Z, ?I) → bed - is - isolation(?Y, ?I)*
28. *Hospital_Bed(?Y), Bedroom(?Z), is - in(?Y, ?Z), bedroom - is - puerperal(?Z, ?Q) → bed - is - puerperal(?Y, ?Q)*
29. *Hospital_Bed(?Y), Bedroom(?Z), is - in(?Y, ?Z), bed - is - of - the - gender(?Y, ?H) → bedroom - is - of - the - gender(?Z, ?H)*

scenarios and facilitate their interoperability. We also found a UML-based ontology to describe hospital information system architectures [23], an ontology for intelligent assistants in patient management based on rules [16], and an ontology-based health context information model to implement omnipresent environments [7]. Different from our work, none of them focuses on bed allocation.

V. CONCLUSIONS

In this paper we presented the concepts, properties, and rules we developed for an ontology that can be used to help decision making about the place where the patients will be allocated when hospitalised, according to predefined bed allocation rules. We also present four different examples of scenarios in which the ontology could be used. Our ontology has not been used yet in a real scenario, although it is freely available online and we hope it can motivate people to use it. The full version of our ontology has 95 classes, 85 object properties, and 78 individuals. As future work we plan to evaluate our ontology with domain specialists. Our ontology can also be extended and explored in other directions such as the definition of the number of patients per nurse, distribution and classification of the patients in beds, among other possibilities.

A Software System is Greater than its Modules' Sum: Providers & Consumers' Modularity Matrix (TSE)

Iaakov Exman and Harel Wallach

Abstract— Modularity Matrices and their Laplacians enable finding software system modules by a rigorous algebraic procedure. However, Modularity Matrices have up to now focused mainly on structors as providers of functionals. This paper takes a broader view at the software system as a whole. The Software System Modularity Matrix, besides displaying *provider* relationships, also describes which structors *consume* functionals provided by other structors. This broader view improves software system design in two ways. First, consumer relationships set realistic expectations for consumer numbers and roles. Second, the Software System Modularity Matrix generates standard design criteria for interacting providers and consumers. This standard System matrix obeys linear independence of its constituent vectors, and block-diagonality of its recognizable modules. The novelty consists of modules being composed into a whole working Software System by means of a limited number of consumers playing the role of module *connectors*. Modules and their connectors are formally obtained by the same spectral method applied to the respective Laplacian, which obtained provider matrices. This is illustrated by case studies.

Keywords: Linear Software Models; Spectral Software Design; Modularity Matrix; Laplacian Matrix; Providers; Consumers; Modules; Connectors; Linear Independence; Block-Diagonality.

I. INTRODUCTION

Linear Software Models represent each abstraction level of a given Software System by means of a Modularity Matrix [8], [10] or its corresponding Laplacian Matrix [13], [14]. These models enable rigorous software design of any given system:

- **Standard Matrix** – is defined as an exact criterion to compare different proposed designs;
- **Matrices highlight the need of redesign** – pinpointing eventual coupling problem locations.

A Modularity Matrix is made of column *structors* – a generalization of classes in object-oriented programming languages – and row *functionals* – a generalization of class methods. A matrix element is 1-valued if its structor provides the respective functional. Otherwise, the element is zero-valued.

The meaning of a structor as a *provider* of a functional is e.g. a class containing the declaration/definition of a method, usable by other classes. Another structor using such a functional is called a *consumer* (e.g. a class calls a method of another class).

This paper's goal is to propose and deal with the broader sense of Modularity Matrix, and its corresponding Laplacian, displaying not only providers, but also matrix elements standing for consumers. This extended Modularity Matrix is a more complete representation of Software from the system perspective and is of practical interest for software design.

This Introduction concisely reviews concepts of Modularity and Laplacian matrices.

A. Software Modularity

A central problem to be solved by software engineering is the hierarchical composition of a software system from sub-systems, down to software architecture units, typically classes, considered indivisible by the designer.

Solving the software system composition problem involves software modularity. Applying Linear Software Models, one designs one or more Modularity Matrices, obtaining modules by spectral methods. One then compares their quality with a square and block-diagonal standard matrix, resolving eventual coupling problems, highlighted by the matrices.

A simple example of a schematic Modularity Matrix with providers only is shown in Fig. 1. It has five structors and five functionals. It displays three modules, the blocks along the diagonal. It is a standard Modularity Matrix as it does not have any outlier, a 1-valued matrix element outside the modules.

B. Modularity Matrices and their Laplacians

A Laplacian Matrix is easily generated from a Modularity Matrix in two steps:

- **Extract a bipartite graph** – with a structors' vertex set and a functionals' vertex set having edges corresponding to 1-valued matrix elements of the Modularity Matrix;
- **Generate the Laplacian Matrix** – from the bipartite graph, according to equation (1):

$$L = D - A \quad (1)$$

where L is the Laplacian matrix, D is the Degree matrix of the graph vertices and A is the Adjacency matrix of vertex pairs.

	S1	S2	S3	S4	S5
F1	1	1			
F2	0	1	All zeros		
F3			1		
F4	All zeros			1	1
F5				0	1

Figure 1. Schematic Providers Modularity Matrix – It has 5 structors (S1 to S5), 5 functionals (F1 to F5) and three modules, the (blue) blocks along the diagonal: upper-left and lower-right with 2*2 size and middle block of size 1*1. It is a standard matrix as it does not have outliers (1-valued elements outside modules). (All figures are in color online).

A bipartite graph, obtained from the Modularity Matrix in Fig. 1, is shown in Fig. 2.

Figure 2. Bipartite Graph from Modularity Matrix in Fig. 1 – It has two vertex sets: the upper set of structors (S1 to S5), and the lower set of functionals (F1 to F5). A bipartite graph only has edges linking vertices in different sets. Arrows pointing down mean that structors provide functionals. The (blue) rectangles separate vertices belonging to given connected components (the modules).

A schematic Laplacian Matrix, generated from the bipartite graph in Fig. 2, is shown in Fig. 3.

	F1	F2	F3	F4	F5	S1	S2	S3	S4	S5
F1	2					-1	-1			
F2		1				0	-1			
F3			1					-1		
F4				2					-1	-1
F5					1				0	-1
S1	-1	0				1				
S2	-1	-1					2			
S3			-1					1		
S4				-1	0				1	
S5				-1	-1					2

Figure 3. Schematic Providers Laplacian Matrix – This Laplacian is generated from the bipartite graph in Fig. 2. By equation (1) its diagonal is D the Degree matrix (in green) showing the degrees of each vertex of the Bipartite graph. The upper-right quadrant (and its reflection in the lower-left quadrant) is the negative of A the graph Adjacency matrix, which is identical to the Modularity Matrix.

C. Paper Organization

The rest of the paper is organized as follows. Section II mentions related work. Section III introduces Consumer Matrices to be included in the whole System Matrices, which is done in Section IV. Section V illustrates the provider and consumer matrices by means of a server case study. Section VI concludes the paper with a discussion.

II. RELATED WORK

Here one finds a concise review of the extensive literature about Modularity approaches, by spectral and other methods. Also shortly reviewed are some references to consumers.

A. Linear Software Models

Linear Software Models have been developed by Exman and collaborators (e.g. [8], [9]) as a rigorous theory to solve the hierarchical software system composition problem from sub-systems. Linear Software Models are based on linear algebra operations and theorems. One assumes that all structors should be mutually linearly independent and also all functionals are linearly independent, an assumption motivated by minimization of the number of structors and functionals needed to build the system. Given this assumption, a linear algebra theorem demands that the Modularity Matrix be square. This is not a trivial result for software systems; it demands some effort to understand the theorem's rationale and implications.

Moreover, if sub-sets of structors/functionals are disjoint to other sub-sets, a second theorem states that these sub-sets can be rearranged into a block-diagonal matrix. These diagonal blocks are recognized as the modules in that software system level (for detailed proofs and examples see the work by Exman [10] and references therein).

A given software system modularization may display undesirable provider outliers coupling between modules. A procedure to compare different designs of the same software system, and to improve design is given by spectral methods as described in [11]. The Perron-Frobenius theorem (see e.g. Gantmacher [17]) is central for the Modularity Matrix theory.

Exman and Sakhnini [13], [14] have shown how to generate a Laplacian Matrix from the Modularity Matrix. The Laplacian matrix obtains the same modules as the Modularity Matrix, by similar spectral methods. The Fiedler theorem [1], [15] is central for the Laplacian theory. The so-called Fiedler eigenvector fits the lowest non-zero eigenvalue of the Laplacian Matrix. It allows locating outliers and splitting of too sparse software modules.

B. Alternative Approaches to Modularity

There exist a variety of techniques applying matrices for modularity analysis. For instance, Baldwin and Clark describe a Design Structure Matrix (DSM) in their "Design Rules" book [2]. DSM has been applied to many systems, including software engineering, see e.g. Cai and Sullivan [5].

Conceptual lattices, another algebraic structure relevant to software design, were introduced by Wille in 1982 [21] as part of Formal Concept Analysis (FCA). They have been used for

software system design e.g. by Siff and Reps [19] and by Exman and Speicher [12].

Alternative clustering techniques to obtain software modules are found e.g. in Shtern and Tzerpos [18].

C. Theoretical Approaches to Consumers

There have been modelling systems in the literature representing provider and consumer interactions. Yau and Caglayan [22] use Petri Nets to design distributed software systems. One of their examples is a producer-consumer system.

Clark et al. [6] describe experiences with PEPA (Performance Evaluation Process Algebra) modelling tools. In particular they refer to Producer-Consumer relations.

Browning [4] suggests that system modelers often build two DSM matrices, one for information supplier and another for the consumer, similar to our providers/consumers pairs of matrices.

III. THE NATURE OF CONSUMER MATRICES

Consumer matrices display Structors and Functionals consumed by the referred Structors. This section describes assumptions needed to generate Consumer matrices.

A. Consumer Matrices Shape and Size

Consumer matrices are not by themselves the aim of this paper. The goal of consumer matrices, jointly with provider matrices, is a more complete description of a software system, showing the interactions between the given sets of Structors and Functionals, from a system perspective.

Given this goal, we assume that Structors and Functionals of the consumer matrices are identical to those of the provider matrices. Thus, a consumer matrix fitting a standard providers' matrix is also square. We emphasize that the reason for consumer matrices being square is essentially different from the provider matrices. As stated in section II standard provider matrices are square by algebraic considerations. Consumer matrices are square just to enable unification of providers and consumers into a single system matrix, as described below.

We often refer to sub-systems, to allow for the possibility that consumer matrices leave outside, e.g. service functionality, obtained from external libraries. Alternatively, functionals provided by our sub-system may be consumed by other sub-systems, not included in our provider/consumer matrices.

Modularity and Laplacian matrices are tools to solve software design problems resulting from coupling interactions between different architectural units – structors and their functionals – in a given hierarchical level. Functionals provided and consumed by the same Structor do not appear in either of the provider/consumer matrices, as these are not interactions between different structors at that level.

B. Theoretical Properties of Consumer Matrices

Given the above assumptions on Consumer Matrices, we state easily verifiable theoretical properties.

Property 1 – Complementarity to Provider Matrices.

Since Consumer Matrices have exactly the same Structors and Functionals as the Provider Matrices, and the matrices do

not display Functionals provided and consumed by the same Structor, consumer Matrices are complementary to Provider matrices of the same sub-system. In other words, there is no overlap of non-zero matrix elements of the consumer matrix with non-zero matrix elements of the provider matrix.

Property 2 – Consumer Matrices may have empty (totally zero-valued) columns or rows, while Provider matrices cannot.

This may happen since the Sub-system Under Design (SUD) may interact with other external sub-systems or libraries not represented in the matrices of the SUD. For example, if an SUD Structor in the Provider matrix provides a Functional consumed only by external sub-systems, the respective SUD Consumer matrix will have an **empty row** corresponding to the Functional consumed externally. Another example, if an SUD Structor appearing in the Provider matrix does not consume any Functional, the respective SUD Consumer matrix will have an **empty column** corresponding to the referred Structor. Provider matrices cannot have empty columns or empty rows, since they display only Structors actually providing Functionals.

Property 3 – Consumer Matrices per se generally neither display linear independence of their Structors/Functionals, nor have block-diagonal modules, in contrast with Provider matrices.

This happens, since besides the empty columns/rows already mentioned in the previous property, it may be that a single given Structor consumes several Functionals originating identical rows. In other words, the rank of a Consumer Matrix is generally less than its size would permit. This does not occur with Provider matrices as already mentioned in section II.

C. An Example of Consumer Matrix

Now we reveal that the provider modularity matrix in Fig. 1 refers to the Command Design Pattern code in CSharp found in [7]. We use the same Structors and Functionals to show the respective Consumer matrix (in Fig. 4). The Command Design Pattern serves as an introductory running example, and as a first case study, in this and in the next section.

Structors →		ICommand	Concrete File Command	File Operation Invoker	IFile Operator	Concrete File Operator
Functionals ↓		S1	S2	S3	S4	S5
Execute	F1			1		
Create Command	F2					
InvokeAll	F3					
File operations	F4		1			
Create Operator	F5					

Figure 4. Command Design Pattern, Consumers only Modularity Matrix – This consumers matrix fits the Providers Modularity Matrix in Fig. 1. Both matrices have the same Structors (S1,...,S5) and the same Functionals (F1,...,F5), and both comply with the Properties enumerated in sub-section B. The consumers matrix has just two 1-valued matrix elements (green hatched background), respectively (S3, F1) and (S2,F4) and is much sparser than the providers matrix.

IV. SYSTEM MODULARITY MATRICES: PROVIDERS AND CONSUMERS

This section finally deals with whole system modularity matrices including providers and consumers. The same algebraic techniques, previously used to identify provider-only matrix modules, are applied for the whole system matrices. This is done here for the Command Design Pattern Laplacian matrix.

A. System Weighted Modularity Matrices

We obtain the System Modularity Matrix by straightforward superposition of the provider matrix with the consumer matrix in a single overall matrix. This is possible as, by *Property 1* above, there is no overlap between non-zero matrix elements of these two matrices. But simple superposition would imply loss of “direction” information, i.e. whether a Functional is provided or consumed by a given Structor. To avoid this ambiguity one assigns a different weight to each direction: a functional *provided* by a structor is assigned a weight of “2” and a functional *consumed* by a structor is assigned a weight of “1”.

In this context, it is important to state that Fiedler [15] has extended the algebraic connectivity properties of Laplacians to those for weighted edge graphs (see e.g. de Abreu [1]).

A System Weighted Modularity Matrix for the Command Design Pattern is shown in Fig. 5, combining the provider matrix of Fig. 1 with the consumer matrix of Fig. 4.

Structors → Functionals ↓		ICommand	Concrete File Command	File Operation Invoker	IFile Operator	Concrete File Operator
		S1	S2	S3	S4	S5
Execute	F1	2	2	1		
Create Command	F2	0	2			
InvokeAll	F3			2		
File operations	F4		1		2	2
Create Operator	F5				0	2

Figure 5. Command Design Pattern, System Weighted Modularity Matrix – This matrix is obtained by superposition of the Consumers Matrix in Fig. 4 with weights of “1”, upon the Providers Matrix (blue modules) in Fig. 1 with weights of “2”, to distinguish the consumers from the providers *direction*.

The weighted bipartite graph obtained from the System Modularity Matrix in Fig. 5, is shown in Fig. 6.

Figure 6. Command Pattern Weighted Bipartite Graph from Modularity Matrix in Fig. 5 – It has two vertex sets: the upper set of structors (S1 to S5), and the lower set of functionals (F1 to F5). Structors providing functionals are shown by (black) arrows pointing down with weight=2. Structors consuming functionals are shown by (red) arrows pointing up with weight=1. The (blue) rectangles denote providers’ connected components (within the providers’ modules). Consumer arrows are *connectors* between providers’ modules.

B. Generation of the Weighted Laplacian

In order to identify the whole system modules including providers and consumers, we obtain from the Weighted Bipartite Graph (Fig. 6), the Weighted Laplacian Matrix in Fig. 7.

C. Connector Discovery from the Weighted Laplacian

As a last step towards the modules of the whole Command Pattern system, including both providers and consumers, we apply the same algebraic spectral method previously used (in [14]) for the providers-only Laplacian. It consists of:

- Calculate eigenvalues and eigenvectors – of the Laplacian Matrix;
- Obtain Modules from eigenvectors – whose eigenvalues are zero-valued;
- Discover Module connectors by splitting modules – using the Fiedler eigenvector.

	F1	F2	F3	F4	F5	S1	S2	S3	S4	S5
F1	5					-2	-2	1		
F2		2				0	-2			
F3			2					-2		
F4				5			1		-2	-2
F5					2				0	-2
S1	-2	0				2				
S2	-2	-2		1			5			
S3	1		-2					3		
S4				-2	0				2	
S5				-2	-2					4

Figure 7. Command Pattern Weighted Laplacian Matrix from bipartite graph in Fig. 6 – It weights (by 2) Laplacian providers in Fig. 3, and adds the consumer elements, with negative weight=1 and a hatched (green) background. Diagonal degrees are changed to guarantee that all rows and columns sum to zero.

Laplacian Matrix Eigenvalues

Eigenvalues are shown in Fig. 8. The only zero-valued eigenvalue is the sixth one: it shows *Modules* in the Laplacian by the fitting eigenvector. The lowest eigenvalue closer to zero is the seventh one and is the *Fiedler* eigenvector, which allows further splitting of the Module.

#1	2	3	4	5	6	7	8	9	10
8.15	7.11	5.00	4.27	4.00	0.00	0.24	0.67	1.35	1.22
Type	→				Modules	Fiedler			

Figure 8. Command Pattern Weighted Laplacian Matrix eigenvalues – these are shown in the middle row of the figure.

Laplacian Matrix Eigenvectors

Eigenvectors' in Fig. 9 fit the Fig. 8 eigenvalues: the 2nd row from the top *Modules* eigenvector has all equal elements, implying one big whole system module; the 3rd row *Fiedler* eigenvector splits the whole system into two modules, by its element signs. Negative signs cluster (F1, F2, F3, S1, S2, S3) into one module and positive signs the vertices (F4, F5, S4, S5) into another module. In this first splitting iteration, the single structor module (F3, S3) seen in Fig. 5 and in Fig. 6, is left inside the 1st module. The 2nd Fiedler vector splitting iteration, in the bottom row of Fig. 9, finally separates the smaller module (F3, S3), obtaining all the three modules in this system.

Laplacian eigenvectors obtain only modules (either directly or by Fiedler vector splitting), as modules are mathematically "connected components" [20] of the graph.

Consumers, as external "connectors", are the remaining positive elements of the Modularity Matrix *by exclusion*, after the modules were directly characterized. For instance, in the 1st splitting iteration the consumer (F1,S3) is left inside the 1st module, while the consumer (F4,S2) is outside both modules. In the 2nd splitting iteration which obtains all modules, also obtains by exclusion both external connectors.

F1	F2	F3	F4	F5	S1	S2	S3	S4	S5
0.32	0.32	0.32	0.32	0.32	0.32	0.32	0.32	0.32	0.32
-0.20	-0.06	-0.47	+0.28	+0.43	-0.23	-0.05	-0.41	+0.32	+0.38
0.12	0.47	-0.64	0.00	0.00	0.17	0.34	-0.47	0.00	0.00

Figure 9. Command Pattern Weighted Laplacian eigenvectors – the top row has vertex indices; the 2nd row from top has all *Modules* vector elements equal 0.32; the 3rd row *Fiedler* different sign elements split the system into two modules 3*3 (negative, blue) and 2*2 (positive, yellow); the bottom 2nd *Fiedler* iteration splits the previous biggest module into 2*2 (positive, green) and 1*1 (negative).

Connectors Discovery by Splitting Modules

The final iteration from the Laplacian eigenvectors is displayed in the System Modularity Matrix, with the referred modules enclosed within dashed rectangles, as seen in Fig. 10.

Structors →		ICommand	Concrete File Command	File Operation Invoker	IFile Operator	Concrete File Operator
Functionals ↓		S1	S2	S3	S4	S5
Execute	F1	2	2	1		
Create Command	F2	0	2			
InvokeAll	F3			2		
File operations	F4		1		2	2
Create Operator	F5				0	2

Figure 10. Command Design Pattern, System Weighted Modularity Matrix with Connectors – This matrix shows the provider modules as the result of the Laplacian eigenvectors, seen as delimited by the dashed (black) rectangles. These are the upper-left and lower-right modules of 2*2 size and the middle 1*1 module. The consumer (F1,S3) links the upper-left and middle modules. The upper-left module is also linked to the lower-right module by the consumer (F4,S2). Iterative splitting by the Fiedler vector obtains these two connectors.

The conclusion from this Command Pattern example is that consumers are *connectors* linking provider modules. This is seen in the bipartite graph (in Fig. 6), and corroborated by the partition by the Laplacian eigenvectors (in Fig. 10).

V. CASE STUDY: AN ASYNCHRONOUS SERVER SYSTEM

This case study is a larger system from the Boost library written in C++, viz. an Asynchronous Echo Server System [3]. The calculation steps were the same as in the Command Pattern example. Here are shown only the important steps' results.

A. Provider and Consumer Modularity Matrices

The Providers Modularity Matrix is strictly diagonal (Fig. 11). The Consumers' Modularity Matrix in Fig. 12 is very sparse and barely understood. Consumption is concentrated in "control" structors, viz. Main, Server and Session.

Structors →		Main	Io-context	Server	Acceptor	Endpoint	Socket	Session	Buffer
Functionals ↓		S1	S2	S3	S4	S5	S6	S7	S8
main	F1	1							
run	F2		1						
server-constructor	F3			1					
async-accept	F4				1				
v4(), port	F5					1			
read, write, is-open, close	F6						1		
start, do-read, do-write	F7							1	
to-stream	F8								1

Figure 11. Asynchronous Server System – Providers-only strictly diagonal Modularity Matrix.

B. Spectral Approach to System Modules

In order to obtain System Modules, we apply the spectral method as done previously with the Command Design Pattern. One superposes the providers and consumers in a single weighted Modularity Matrix, and obtains the bipartite graph. Then one generates its Laplacian Matrix and calculate its eigenvalues and eigenvectors, as shown in Fig. 13 and Fig. 14.

Structors →		Main	Io-context	Server	Acceptor	Endpoint	Socket	Session	Buffer
Functionals ↓		S1	S2	S3	S4	S5	S6	S7	S8
main	F1	1							
run	F2		1						
server-constructor	F3			1					
async-accept	F4				1				
v4(), port	F5					1			
read, write, is-open, close	F6						1		
start, do-read, do-write	F7							1	
to-stream	F8								1

Figure 12. Asynchronous Server System Consumers only Modularity Matrix – This consumers matrix fits the Providers Modularity Matrix in Fig. 11. Both matrices have the same Structors (S1,...,S8) and the same Functionals (F1,...,F8), and both comply with the Properties enumerated in sub-section III B. The non-zero consumers' matrix elements are marked (in green hatched background).

#1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
7.10	6.09	5.73	4.00	4.24	4.38	1.30	0.81	0.00	0.11	0.23	4.56	2.00	0.43	4.56	0.43
Type	→							Module	Fiedler						

Figure 13. Asynchronous Server System Laplacian Eigenvalues – The eigenvalue #9 is the only one zero-valued, implying one *Module* in this system. Eigenvalue #10 is the *Fiedler* vector allowing splitting of this overall module.

The Modules and the Fiedler eigenvectors are shown in Fig. 14. The Fiedler eigenvalue #10 splits the whole system into two modules of 5*5 and 3*3 sizes. The next iteration Fiedler vector (the lowest row) further splits the 5*5 module into two smaller modules of sizes 2*2 and 3*3 sizes.

F1	F2	F3	F4	F5	F6	F7	F8	S1	S2	S3	S4	S5	S6	S7	S8
0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25
0.28	0.38	0.04	0.06	0.06	-0.34	-0.24	-0.34	0.29	0.36	0.12	0.05	0.05	-0.32	-0.15	-0.32
-0.25	-0.48	0.17	0.33	0.33	0.00	0.00	0.00	-0.28	-0.43	0.03	0.29	0.29	0.00	0.00	0.00

Figure 14. Asynchronous Server System Laplacian Eigenvectors – From top row to bottom: the 1st row shows the vertices (on yellow); the 2nd row is the eigenvector fitting the single module eigenvalue #9; the 3rd row is the Fiedler #10 eigenvector splitting the 2nd row eigenvector into two modules according to the positive and negative signs; the lowest row is the next iteration Fiedler eigenvector, splitting the larger (green) module in the 3rd row eigenvector into two smaller modules of sizes 2*2 and 3*3 (light blue and orange background).

C. Connector Discovery in the System Matrix

Modules are discovered by looking at the eigenvectors of the Laplacian. These modules are the upper-left (F1,F2,S1,S2), the middle (F3,F4,F5,S3,S4,S5) and the lower-right (F6,F7,F8,S6,S7,S8) as shown in Fig. 15.

External consumers, the “connectors” between the three referred modules, viz. (S1, F3) and (S3, F7) are discovered by exclusion (i.e. outliers), as the remaining positive matrix elements of the System Modularity Matrix outside the three modules (Fig. 15). An interesting observation for this system is the existence of consumers as “internal connectors”, inside the three modules, where each consumer reasonably links a pair of provider structors.

Functionals ↓	Structors →							
	Main	Io-context	Server	Acceptor	Endpoint	Socket	Session	Buffer
	S1	S2	S3	S4	S5	S6	S7	S8
main	F1	2						
run	F2	1	2					
server-constructor	F3	1		2				
async-accept	F4			1	2			
v4(), port	F5			1		2		
read, write, is-open, close	F6						2	1
start, do-read, do-write	F7			1				2
to-stream	F8						1	2

Figure 15. Asynchronous Server System Modules – The three modules enclose the original Provider modules and respective internal connectors. The external connectors are found in the elements (S1,F3) linking the upper-left and middle modules, and (S3,F7) linking the middle and lower-right modules.

VI. DISCUSSION

A. Interpretation of System Matrix Results

A Consumer Matrix by itself is rather perplexing: it is very sparse and not easily interpreted. Consumer Matrices do not obey any apparent algebraic rules such as structors or functionals linear independence, or module block-diagonality, as for Provider Matrix. There are no obvious correctness criteria for Consumer Matrices by themselves.

When one superposes a Consumer Matrix upon its Provider Matrix the picture suddenly clarifies: **consumers are “connectors”** between pairs of provider modules. One could say that the Software System is greater than the sum of its modules, due to the interactions of the external consumer *connectors* with provider modules.

There are two slightly different situations with the case studies in this paper. The Command Design Pattern of the providers-only Modularity Matrix has the same number of three modules (Fig. 1) as the System Modularity Matrix with connectors (Fig. 10). The two connectors are external to the three modules and actually connect pairs of modules.

In the Asynchronous Server case study the providers-only Modularity Matrix (Fig. 11) is strictly diagonal and has 8 single-structor modules. In the System Modularity Matrix with connectors (Fig. 15) the providers-only modules were re-configured into three larger modules internally linked by connectors. In addition there are two external connectors. It is still true that connectors – both internal and external – link pairs of modules. The internal connectors link the original providers-only modules. The external connectors link the re-configured system modules (containing both providers and consumers, playing the internal connectors role).

We are led to the following conjecture as a summary of our currently empirical findings:

Conjecture: Software System Modularity Connectors

The *Minimal Number of System Module Connectors* is equal to the number of System Provider Modules minus one, i.e. each System module is connected to at least one other System module by a consumer Connector.

B. System Benefits for Software Design

First of all, it has been clear, before this work, that providers-only Modularity Matrix, the corresponding bipartite graph and its Laplacian Matrix, were incomplete descriptions of a software system. The addition of the consumers certainly improves the ability to judge the overall system design quality.

Once consumers are interpreted as “connectors” of provider modules, there are clear expectations on *consumers'* quantity and matrix element locations for their software system role.

Moreover, there are two System Matrix correctness criteria:

- a- **Algebraic** – the providers and consumers joint modules, excluding the external connectors, obey linear independence and block-diagonality;

- b- **Semantic** – system modules are semantically sound (e.g. the Fig. 15 lower-right module clusters *read*, *write*, and *stream* belong to the same category of messaging functionals).

C. Future Work

The paper's results, in particular the Software System Modularity Connectors conjecture, deserve formal proofs and extensive verification for a variety of software systems. These will be presented in an expanded version of this paper.

Although Fiedler (see e.g. [1]) extended the Laplacian spectral properties validity to weighted graphs, we need to investigate the specific weights' influence on modules calculations done with the Laplacian matrix.

D. Main Contribution

The main contribution of this paper is the introduction of Consumers in the software System Overall Modularity Matrix, and in the corresponding Laplacian Matrix, in the role of connectors between provider modules.

We have thereby shown that the same Linear Software Models that have been applied to providers-only matrices, is a generic algebraic theory of software composition, applicable to the overall system, including consumers.

ACKNOWLEDGMENT

The authors are grateful to the anonymous reviewers for incisive comments that helped to improve this version of the paper.

Abstract—Accurate effort estimation is an important part of the software process. In Agile Software Development, the techniques for predicting effort are mostly based on expert judgment, but there are approaches based on Machine Learning. The theme continues to be challenging and a subject of further studies given the difficulty of finding accurate solutions to the problem. This paper proposes and evaluates a tool based on the decision tree method for effort estimation in agile projects. We evaluated our tool given its accuracy and ease of use collecting data from four projects. To evaluate the accuracy, we compared the values of Magnitude of Relative Error from the teams' estimations with the values provided by the tool. To evaluate the ease of use, we used the Technology Acceptance Mode. The initial results show that the tool can be reliably used with minimal training. In terms of accuracy, the tool achieved lower error compared to the estimates provided by the teams (mean: 19.05% vs 33.32%), and the evaluation means in TAM were higher than 4.0 in ten of the eleven variables analyzed on a Likert scale. From this work, we conclude that estimation by decision tree is a viable technique that, at the very least, can be used by project managers to complement current estimation techniques.

Keywords—Agile Software Development; Effort Estimation; Machine Learning; Decision Tree.

I. INTRODUCTION

Since 2001, there has been an increasing interest in agile methodologies. Nowadays, these methods are widely used in software industry projects, especially, because of its volatility and flexibility. Agile software development (ASD) focuses on the needs of the rapidly changing environment by embracing the proposal of iterative and incremental development [7]. According to a recent study [2], Scrum stands out as an agile development process with 56% of preference. Scrum is a framework for developing and sustaining complex products [1]. One of its main events is the Sprint Planning Meeting in which occurs the task breakdown. During this process, the Scrum team defines tasks to be developed and estimates the effort to complete them.

In ASD context, effort estimation consists of predicting the effort needed to fulfill a given task [24], which is an important part of the development process, since it is one of the many steps that can lead to successful project completion. Due to

the dynamic nature of ASD [8] and limited documentation [36], effort estimation is considered a complex and critical task [4]. Traditionally, it depends heavily on the expert experiences [36] and the estimated values usually are far away from the real ones, resulting in low accuracy. On the other hand, accurate estimations can improve the development planning by enabling optimal assignments of both stories and developers [22]. Additionally, high accurate values can be used in different prediction models to improve the outputs. For instance, to increase project velocity [14], to optimize developer effort across different projects in the organization, and different projects inside the organization can be centrally coordinated to increase efficiency.

Over the past years, there has been a growing interest in effort estimation researches [21], [37], [32]. In previous work [9], we identified different approaches proposed to estimate effort using historical data and expert opinions based techniques. A significant amount of these used Artificial Intelligence or Machine Learning techniques to support effort estimation in ASD, which contributed to achieve higher accuracy. Despite the contributions of recent studies, low accurate prediction is still considered a gap in effort estimation.

In this study, we focus on the empirical evaluation of an effort estimation support tool for agile software development. The proposed tool is based on historical data and uses a Decision Tree to estimate effort during software development. In the evaluation, we aim to measure (i) the accuracy of the proposed tool and (ii) its usefulness and ease of use. To do so, we used Magnitude of Relative Error (MRE) to compare the estimations made by the project team members and those ones provided by the tool with the real effort (in hours). Furthermore, through a questionnaire based on the Technology Acceptance Model (TAM) [10], professionals with experience in software development used the tool and reported their perceived usefulness and perceived ease of use. As a result, the proposed tool achieved lower MRE values compared to ones provided by the teams (mean: 19.05% vs 33.32%). As also, most of the professionals who participated in the study found the approach to be useful and easy to use to support the estimation process (evaluation mean was higher than 4.0 in ten of the eleven variables analyzed on a Likert scale [16]).

The remainder of this paper is organized as follows: Section

II presents the background information. Section III details the proposed tool. Section IV presents the empirical evaluation, followed by the results and discussion in Section V. Finally, threats to validity and conclusions are described in Sections VI and VII, respectively.

II. BACKGROUND AND RELATED WORK

This section presents the background and related work on this paper. A considerable number of studies has been published on this subject. A Systematic Literature Review (SLR) [39] performed in 2014 aggregated and described the state of the art related to estimation techniques, effort predictors, accuracy measures and agile methods used. In 2018, Dantas et al. [9] updated this review and observed a strong indication of solutions based on Artificial Intelligence (AI) and Machine Learning (ML) methods for effort estimation in ASD. The purpose of the identified studies is to support human judgment during effort estimation. The main techniques observed were: Bayesian Network and Decision Tree.

In general, the studies use different factors in their approaches to estimate effort more accurately, either to support traditional estimation methods such as Planning Poker or in ML and AI solutions. These factors are known as Cost Drivers and represent personal or project factors that influence the estimated values [9]. For instance, to support Planning Poker, Lenarduzzi [19] considered technical ability, competence level, and managerial skill. While Grapenthin et al. [13] used factors related to the project: complexity and flexibility.

Artificial Intelligence is a branch of computer science formed by techniques that support activities of optimization or knowledge discovery [45]. A popular AI technique is the Bayesian Network which is used to estimate values considering the uncertainty of the variables (cost drivers) and can be constructed using historical data and experts. In the context of effort estimation, Mendes [25] proposed a Bayesian Network for Web effort estimation using knowledge from a domain expert. Karna and Gotovac [17] presented another model, including the relevant cost drivers with turnover, priority, and severity. Zahraoui et al. [46] adjusted story points using: priority, size, and complexity. The complexity and importance of a user story were considered by Lopez et al. [20], while Dragicevic et al. [11] considered the skills of the developers and requirements complexity. These approaches use historical data and expert knowledge to estimate effort with better accuracy.

Machine Learning is a current application of AI based on the idea that a system can learn from data rather than through explicit programming. Thus, the ML methods aim to improve the performance at certain tasks learning from the observed data. Many studies use ML to estimate effort in software projects. For instance, in Satapathy and Rath [32] Decision Tree, Stochastic Gradient Boosting and Random Forest were compared to assess effort estimation given a dataset composed by 21 projects. Porru et al. [29] used Support Vector Machine, K-Nearest Neighbors and Decision Tree for the same purpose given data from eight open source projects. Several Neural Networks were used in Panda et al. [27]. The purpose of these works is to support human judgment during effort estimation.

In this study, we use a Decision Tree which is a decision support method indicated for establishing classification or regression based on multiple covariates for developing prediction algorithms for a target variable [35]. This method constructs

prediction models by recursively partitioning the data and fitting a simple prediction model within each partition [6], till a halting paradigm is fulfilled [32]. For this purpose, it uses a sequential process to identify the predictor variables that best differentiate groups along with the outcome variable of interest.

Effort estimation is still attractive to researchers since a reliable estimation process is crucial for correct project planning and a good management of the resources [33]. Several other studies on the subject can be found in the literature, mainly focus on designing a good estimator [18], [3], new cost metrics [26] or other aspects [15].

III. PROPOSED TOOL

A. Overview

The effort estimation support tool presented in this paper uses historical data to construct a decision tree predictive model. The purpose of the tool is to support teams during task effort estimations. Therefore, it assists in the development process during the planning phase. The tool consists of a web application with an interface implemented in Angular that can be accessed from computers or smartphones. The key parts of the tool are discussed below.

B. Dataset

Agile projects often manage user requirements with models called User Stories (US). These artifacts are used to describe features that deliver value to the customer. USs are written in natural language, which makes it difficult to retrieve information [30]. Therefore, to build a dataset we have defined a model to represent the main features of software projects.

The model was built by specialists and is organized in a hierarchical structure of 03 levels to represent each feature. The first level is called *Module*, the second is *Operation*, and finally for each operation we have different types of *Tasks* in the third level. The whole model is composed by 03 *Modules*, 18 *Operations* and 131 *Tasks* types. Table I shows an example of operations defined to the "Authentication" module.

Table I: Examples of previously defined operations for Authentication module

Module	Operation
Authentication	Perform login with username and password
	Perform login with OAuth
	Password recovery
	First login
	Validate user permissions
	Update profile
	Create account
	Remove account

With the defined model, we analyzed the backlog of different organizations to create our dataset. All companies work with agile processes based on Scrum and develop projects on the web platform. We have analyzed 26 backlogs, containing a total of 530 USs and 1879 tasks. At the end, we were able to map 52% of tasks according to the model, which results in 977 items that form our dataset. For each record, in addition to the information representing the feature (*Module*, *Operation*, *Task*), we extract information from the following cost drivers: effort, human resource and technology. The information was taken from the teams during the planning meetings.

C. Prediction Algorithm

The proposed tool adopts the M5P algorithm for building the Decision Tree [43]. This algorithm represents an appropriate choice because it implements as much decision trees as linear regression for predicting a continuous variable. To train the algorithm, we used a 10-fold cross validation [5] and choose Effort (in hours) as the dependent variable. In Figure 1 we can see the relations of the cost drivers used to construct the predictive model. Category corresponds to the feature according to the model, human resource is the professional responsible. Finally, the predominant technology in the feature is also used to forecast the varying effort. Several Cost Drivers were analyzed using the Weka software, but these were chosen for achieving a result with the least error.

Figure 1: Cost Drivers Relation.

D. Design

The architecture of the proposed tool consists of a processing layer which executes the Decision Tree algorithm and a serving layer which exposes a REST API. The database has been implemented in MySQL and contains tables to store the historical data of the projects. To perform the processing, we used the class M5P¹ in Weka, version 3.8.0. Its interface was build using Angular framework, version 6.1.2. The tool is available² and can be accessed in any web browser.

The tool was developed for supporting agile teams during Sprint Planning. As shown in Figure 2, the tool has a view that shows all the tasks types and the structure is represented in three hierarchical levels (see the area of the screen indicated by 1). These tasks are in agreement with the model created in the construction of our dataset. Once selected the task type, the tool processes the decision tree algorithm and displays an effort estimation (see area of the screen indicated by 2). Finally, clicking on “detail”, the user can have access to the historical values of this task.

IV. EMPIRICAL EVALUATION

This section presents the case study performed to evaluate the proposed tool, which is detailed in the following sub-sections.

A. Case Study Planning

The evaluation is oriented towards design science in software engineering [42]. The improvement problem is the low accuracy from effort estimation tasks. The artifact used is a

Figure 2: Screenshot of tool.

historical data based tool to support decision making during planning meetings. Therefore, we seek to answer the following research questions:

- RQ1: *Category*, *Human resource* and *Technology* can be used to construct a decision tree predictive model capable to reduce effort estimation errors during planning meetings?
- RQ2: The perceived usefulness and ease of use have a positive impact on the tool adoption?

To investigate the research questions, we conducted an exploratory case study [28] in a Brazilian software development company. Four agile software projects, based on Scrum, were available to participate in the study. Each project was composed of six developers and one Scrum Master who also performs the project manager role, each developer works exclusively on one project. According to the company practice, the Scrum Master does not participate in the effort estimation process, only the developers. All the projects belong to web development platform and were implemented with similar technologies.

The study lasted six sprints with 15 days each, resulting in three months of evaluation. Before the beginning, the participants were submitted to 15 minutes of training to get familiar with the proposed tool. At this moment, they received instructions and examples of use to learn how to utilize the tool.

Most participants were graduate developers (84.61%), who worked full time at the company and had more than three years of experience in software development. The remaining participants (15.49%) were undergraduate students from a computer science course, who worked part-time and had at least a year of experience in software development.

B. Case Study Execution

During the case study, the tasks were created by the teams and recorded in a spreadsheet. The authors of this paper were responsible for analyzing each task and for mapping them to the corresponded category of the model presented in Section III-B. Thereafter, the project teams estimated the effort of the tasks. At this moment, they could estimate the values by their own or use the tool to assist in the process. At the end of the study, 76% of the tasks were mapped, which corresponds

¹<http://weka.sourceforge.net/doc.dev/weka/classifiers/trees/M5P.html>

²<https://mot-client-web.herokuapp.com/>

to 121 items. For each task, we recorded three values: (i) the team estimation, (ii) the tool estimation and (iii) the real effort.

To answer the RQ1, we choose the MRE (Equation 1) which measures the difference between real and estimated effort relative to the real one. Therefore, we compared the team MRE values with the tool MRE values, resulting in two value lists. Then, we use a confidence interval (with 95% confidence level) to do a statistical analysis. This procedure is recommended to characterize the uncertainty associated with a certain parameter estimated [41].

$$MRE = \frac{Real\ effort - Estimated\ effort}{Real\ Effort} \quad (1)$$

To answer the RQ2 we applied a questionnaire based on the indicators presented in the TAM [10]. The questionnaire aims at assessing users' beliefs about the usefulness and ease of use of a technology that is expected to support their work. It has been used extensively to explain and predict users' acceptance of information technology [34]. According to TAM, two variables impact adoption: perceived usefulness and perceived ease of use. Perceived usefulness refers to the degree to which an individual believes that using a particular technology would enhance his or her job performance. Perceived ease of use refers to the degree to which an individual believes that using a particular technology would be free of physical and mental effort [40]. Table II shows the applied questionnaire. The questions are divided by type: Perceived usefulness (PU), Perceived ease of use (PEoU), External variables (EV) and Attitude (AT). The type of response follows a Likert scale [16] with five possible answers ranging from strongly disagree (mapped to number 1) to strongly agree (mapped to number 5). The participants were asked to respond to each statement in terms of their own degree of agreement or disagreement [23]. The questionnaire was applied at the end of the six sprints and all the participants submitted their answers.

V. RESULTS AND DISCUSSION

This section outlines the results with respect to the research questions, which are answered in different sub-sections.

A. RQ1: Category, Human resource and Technology can be used to construct a decision tree predictive model capable to reduce effort estimation errors during planning meetings?

After collecting data from the case study, we were able to calculate MRE values from 121 tasks, resulting in two types of errors: team MRE and tool MRE. As mention before, we used the confidence interval to analyze the data. In several regression applications, these intervals are computed by supposing the errors follow a normal (Gaussian) distribution or another more general distribution with a number of parameters [31].

In Table III, are shown the mean, standard deviation and confidence intervals (with 95% confidence level) for the MRE values. We can observe that the tool has achieved lower MRE mean values when compared to each project team values. The overall result shows a 19.05% MRE mean value for the tool and 33.32% for the teams, i.e., the proposed tool can provide more accurate estimations. Also, the lower overall standard deviation obtained by the tool indicates that the estimated values tend to be close to the mean, generating more homogeneous

predictions. The overall confidence intervals (14.87% - 23.62% and 25.55% - 41.42%) do not intersperse, thus the two group values can be considered statistically different.

Regarded to the RQ1, we can conclude that the selected cost drivers can be used to construct a decision tree predictive model capable to reduce effort estimation errors during the planning meeting. Therefore, the proposed tool can provide accurate estimations when compared to the ones given by the project teams.

B. RQ2: The perceived usefulness and ease of use have a positive impact on the tool adoption?

In order to carry on a qualitative evaluation, we used the TAM. Table II shows the assigned variables for this study.

Table IV describes the values for median, mean, standard deviation (SD) for questions of the perceived usefulness. All average values were higher than 4.0, indicating that participants generally had positive attitudes toward the tool.

Table IV: Perceived usefulness

Variable	Definition	Mean	Median	SD
V1	Using the tool is useful for estimating task effort.	4.32	4	0.712
V2	Using the tool allows quick access to a historical basis	4.82	5	0.743
V3	The tool is accessed at all planning meetings	4.12	4	1.04

In Table V, all mean values related to the ease of use are above the midpoint and the standard deviations are within the range from 0.716 to 0.926 indicating a narrow spread around the mean.

Table V: Perceived ease of use

Variable	Definition	Mean	Median	SD
V4	Learning to use the tool was easy for me	4.74	5	0.786
V5	I often get confused in researching and understanding information in the tool	3.94	4	0.926
V6	Access to the tool is simple	4.78	5	0.716

The variable V9 in Table VI has the lowest mean value. This occur because the tool was recently adopted, thus the motivation among co-workers was expected to be low. Also, the standard deviation of V9 was greater than one, representing a high dispersion of the information.

Table VI: External variables

Variable	Definition	Mean	Median	SD
V7	The navigation features (menus, icons, links and buttons) are all clear and easy to find	4.34	4	0.696
V8	The tool has a nice interface	4.74	5	0.556
V9	My co-workers encourage me to use the tool	3.42	3	1.213

The results of Table VII show that the participants perceived the attitude of the information systems, since, for all variables, the average has resulted in more than 4.0, showing agreement on all the statements.

Table VII: Attitude

Variable	Definition	Mean	Median	SD
V10	I believe it's best to use the tool instead of traditional planning.	4.46	4	0.879
V11	My intention is to use the tool to better plan my project tasks	4.24	4	0.786

Table II: Questionnaire Statements on: Perceived usefulness, Perceived ease of use, External variables and Attitude

Type	Definition	Variables
Perceived usefulness (PU)	The level at which a person believes that using the tool improves the performance of their tasks.	V1: Using the tool is useful for estimating task effort. V2: Using the tool allows quick access to a historical basis V3: The tool is accessed at all planning meetings
Perceived ease of use (PEoU)	Level at which the person presents their perception of the tool in terms of ease of learning and operation.	V4: Learning to use the tool was easy for me V5: I often get confused in researching and understanding information in the tool V6: Access to the tool is simple
External variables (EV)	External variables provide a better understanding of what influences perceived utility and ease of use.	V7: The navigation features (menus, icons, links and buttons) are all clear and easy to find V8: The tool has a nice interface V9: My co-workers encourage me to use the tool
Attitude (AT)	Intention of the individual to use the tool	V10: I believe it's best to use the tool instead of traditional planning . V11: My intention is to use the tool to better plan my project tasks

Table III: Results of the MRE calculation

	Team MRE				Tool MRE			
	Mean (%)	Standard Deviation (%)	Lower Confidence Interval (%)	Upper Confidence Interval (%)	Mean (%)	Standard Deviation (%)	Lower Confidence Interval (%)	Upper Confidence Interval (%)
Project A	43.27	55.12	38.43	42.12	25.67	15.23	23.16	32.19
Project B	26.56	38.77	22.48	31.02	14.78	10.12	13.21	19.43
Project C	31.45	42.24	26.38	33.10	18.21	27.34	16.33	22.91
Project D	32.05	58.12	30.21	36.39	17.54	26.21	15.88	20.32
Overall	33.32	51.33	25.55	41.42	19.05	22.92	14.87	23.62

When using Likert-type scales it is imperative to calculate and report Cronbach's alpha coefficient for internal consistency reliability [12]. The Cronbach's alpha is an index of inter-item homogeneity that describes how related a set of items is as a group [38]. In table VIII, we can see the coefficient for each variable. All multi-item constructs should meet the guidelines for a Cronbach's alpha of greater than 0.70. Table VIII demonstrates that the coefficient values, for all constructs in the measurement model, exceeded the recommended threshold. Therefore, based on the presented results related to the RQ2, we can conclude that the tool is easy to use and has utility for the teams.

Table VIII: Descriptive statistics

Construct	Variables	Mean	Cronbach's
Perceived usefulness	V1	4.32	0.8829
Perceived usefulness	V2	4.82	0.9084
Perceived usefulness	V3	4.12	0.8779
Perceived ease of use	V4	4.74	0.8745
Perceived ease of use	V5	3.94	0.8238
Perceived ease of use	V6	4.78	0.8779
External variables	V7	4.34	0.8989
External variables	V8	4.74	0.8779
External variables	V9	3.42	0.8229
Attitude	V10	4.46	0.9208
Attitude	V11	4.24	0.8779

VI. THREATS TO VALIDITY

This section presents the main threats to validity identified in the study, according to Wohlin et al. [44]. The analysis of the threats aims to examine the relationship between the conclusions reached and the reality.

A threat to external validity identified is related to the platform of the selected projects. All of them were web development projects with similar technologies, thus our findings can not be generalized. To address this threat, we intend to conduct a new case study with projects from mobile and desktop platforms. Another identified threat refers to internal validity. The teams that participated in the case study were composed by graduate developers and undergraduate students, with different levels of experience, which can impact the error measurement. Therefore, the results from this study must be considered as indicators and further evaluation with different contexts must be conducted.

VII. CONCLUSION AND FUTURE WORK

This paper proposed and evaluated an effort estimation support tool for agile software development. The tool uses historical data to construct a decision tree predictive model to provide effort estimations during the planning meeting. To evaluate the tool, we performed a case study in a Brazilian software development company, in which four agile projects (based on Scrum) and 24 professional participated. The case study lasted three months and thereafter we performed a quantitative and qualitative analysis.

The achieved results indicate that the tool can support the planning meeting, reducing the errors related to the task estimation process. Also, we concluded that the majority of the professionals who participated in the study found the tool useful and easy to use for supporting the effort estimation, and they would regularly use the tool for future plannings in their job.

As a limitation, we realize that the low numbers of teams and the types of projects are prohibitive to generalize our findings. In the future, we plan to conduct another case study with more projects and different contexts. Additionally, we would like to evaluate the usage of the tool with more experienced teams.

Abstract—Software analytics supports data-driven decision making, which allows software practitioners to leverage valuable insights from software data to improve their processes and many quality aspects of the software. In this paper, we present an artifact designed from a set of patterns to support agile teams to plan and manage software analysis activities, named Software Analytics Canvas. Further, we report the study undertaken to evaluate the ease of use and the utility of our canvas from the practitioners’ viewpoint, and a participatory design session carried out to collect information about possible artifact improvements. In general, subjects found the artifact useful, but some of them reported difficulties in learning and understanding how to use it. In the participatory design, they pointed out improvement points and a new layout for the canvas components. The results of both studies helped us refine the proposed artifact, improving both the terms used in each element and the layout of the blocks to make more sense for its users.

Index Terms—software analytics, agile teams, decision making, software data

I. INTRODUCTION

An increasing number of companies around the world have used data analytics to make decisions about their businesses. Analytics refers to the use of analysis, data, and systematic reasoning to inform the decision making process [1].

Nowadays, researchers and practitioners already use analytics applied to software data for better decision making concerning many aspects of software quality and its development process [2]. Zhang et al. [3] coined the term “Software Analytics” (SA) to label research in this area. Since then, SA has been widely adopted by large companies. However, it has not yet reached its full potential for broad industrial adoption. For small companies, for example, SA is an open question and rarely addressed [4]. Furthermore, to the best of our knowledge, there is no consolidated approach on how to introduce software analytics concepts and practices into an agile development context.

By emphasizing short feedback cycles, agile teams regard changes as an opportunity to improve the product at any time

in the development process, always focusing on delivering value [5]. In this sense, software analytics can support agile teams to make more appropriate changes based on actual data, rather than only on their personal experiences or intuitions. Additionally, the adoption of data-driven continuous improvement can help agile teams to save resources and decrease the cost of building and maintaining the software [6]. Process improvement is one of the main reasons for measurement in agile software development [7]. However, the measurement tends to be immediate and straightforward, since agile principles emphasize measuring progress in terms of working software over measuring intermediate work products [5].

Currently, various tools provide structure on top which data-driven improvement processes can be implemented. However, due the perceived complexity and effort required to set up such tools and to establish a measurement program, agreed with the urgency of the product delivery, lack of time, and others reasons, many agile teams end up not systematically using metrics to track product and process performance [8]. There is a lack tools to ease the adoption of software analytics, but also a lack of approaches to effectively change the habits within agile teams towards data-driven decision making.

Seeking a practical method to introduce *software analytics* into agile teams, we have outlined an artifact to support software analytics activities in agile environments named Software Analytics Canvas (SA Canvas). It was designed based on a set of patterns that we have identified from experience reports of researchers and practitioners in the software analytics area [9], [10]. In this paper, we present the canvas and report two studies designed to (i) evaluate the usefulness and ease-of-use perceived by the users, and (ii) refine the design of the proposed artifact. The goal of these studies is to answer the following research questions (RQs):

- RQ1: What are the users’ perceptions about the usefulness and ease-of-use of the SA Canvas?
- RQ2: What characteristics can be improved in the design of the SA Canvas?

To answer RQ1, we recruited six software practitioners for planning and managing activities from a software analytics project using the canvas. As input to the project, we provide information from a web-based system in the Space Weather area. After three iterations with the canvas, the participants were able to evaluate the usefulness and ease of use of the artifact. To answer RQ2, we call the same subjects for a participatory design session to provide ideas for possible artifact enhancements.

II. BACKGROUND

A. Software Analytics

Software analytics allows software practitioners (developers, testers, designers, and managers, to name a few) to leverage insightful information (accurate and in-depth) and actionable (with real practical value) for completing various tasks around software systems, software users, and software development processes [11]. The SA process comprehends monitoring, analysis, and understanding of software data to support the decision-making process throughout the different phases of the software lifecycle [3].

Within the SA context, we refer to the software data as any data generated from different sources such as code, bug reports and test executions recorded in software repositories (e.g., version control systems and issue-tracking systems), and information about data of usage typically stored in the log files [12]. Furthermore, SA has been used to address different type of concerns, such as issues related to the source code (e.g., code quality, bug proneness, number of defects, and amount of effort to fix bugs) [13]; development process (e.g., productivity and ROI) [4]; product business (e.g., usage of features, data quality, and user satisfaction) [14]; and software runtime properties (e.g., performance, number of transactions and error log) [15].

B. Software Analytics Patterns

Considering software analytics as an essential practice for leveraging value delivery in agile contexts, we have identified in previous studies a set of eight patterns focusing on how to incorporate SA activities into agile practices on a continuous basis to inform the decision-making process of software practitioners, including project managers, analysts and software developers from small, large, or multiple teams. Below, we present the eight SA patterns and a brief description of the proposed solutions in each of them. For a more detailed description of these patterns, see [9] and [10].

- 1) **What You Want to Know:** refers to defining the key issues that the development team wants to focus on, in order to guide their selection of the appropriate means for measurement, assessment and monitoring these issues throughout the project.
- 2) **Choose the Means:** refers to defining the data sources and most appropriate means, such as tools, techniques and other approaches for selecting and collecting data that will be useful for future decisions.

- 3) **Software Analytics Planning:** refers to adding tasks related to the *software analytics* on the to-do list to be prioritized with the regular project tasks according to the team's demand for information.
- 4) **Analytics in Small Steps:** it means that the tasks related to the *software analytics* can be distributed throughout the project, adding information to the team about the system at small portions by adjusting the granularity of the analytic activities.
- 5) **Reachable Improvement Goals:** refers to defining reachable improvement goals from the *software analytics* findings and break the activities down into smaller tasks to fit together with the other tasks.
- 6) **Learning from Experiments:** refers to create an alternative solution and perform an experiment collecting data that allow the comparison with the current solution.
- 7) **Define Quality Standards:** refers to define quality standards and establish minimal or maximum thresholds for any software aspect that the team intends to monitor.
- 8) **Suspend Measurement:** refers to suspend measurement of the issues with a low possibility of recurrence, or measurement of the issues that need to be continually monitored, but the team has defined that, for some reason (e.g., effort, cost or other project constraints), the monitoring of these issues cannot be implemented immediately.

III. RESEARCH APPROACH

In order to develop an artifact to support agile teams throughout the software analytics activities, our research approach follows the guidelines of Design Science Research (DSR), as proposed by Hevner et al. [16]. DSR is a problem-solving paradigm, where “knowledge and understanding of a problem domain and its solution are achieved in the building and application of the designed artifact”.

In this paper, we describe the design process of the SA Canvas artifact, which includes the building and evaluation cycles. A first version of the canvas emerged from patterns previously identified from experiences reports in the SA field (Section II-B). Aiming at evaluating the artifact and improving its characteristics, we have carried out a formative evaluation in two rounds (Section V).

For the first round, we selected six subjects (in pairs) to plan and manage software analysis activities using the SA Canvas. After the hands-on experience of handling the artifact, we gathered the users' perceptions of usefulness and ease of use of the proposed artifact, using the Technology Acceptance Model (TAM) [17]. According to Davis [17], *perceived usefulness* (PU) refers to “the degree to which a person believes that using a particular system would enhance his or her job performance”; and *perceived ease of use* (PEU) refers to “the degree to which a person believes that using a particular system would be free of effort”. We measured both variables within the TAM through a multiple-item questionnaire using a 6-point Likert scale – from “Completely Disagree” to “Completely Agree”.

For the second round, we organized a redesign session using principles of participatory design (PD) [18] to collect information for artifact improvement, involving the same participants of the first round. During the PD session, the participants were encouraged to draw sketches as an idea for the canvas redesign.

IV. SOFTWARE ANALYTICS CANVAS DESIGN

This section presents the SA Canvas template we have designed as an artifact to support the software analytics activities into agile development environments. Canvas artifacts are visual maps – structured and preformatted – used to support the collaborative teamwork in their communication processes. Canvas is considered a hands-on tool that fosters understanding, discussion, creativity, and analysis on a given matter [19]. Nowadays, there is a range of applications using canvas – e.g., development of new businesses, conception, and planning of projects, strategic alignment of projects, value proposition, among others.

The SA patterns presented in Section II-B were the basis for the creation of our canvas. As shown in Figure 1, it is composed of seven blocks with names based on the patterns. The seven names are Key Issues, Data Sources, Data Gathering, Analytics Implementation, Insights, Incremental Goals, and Quality Thresholds. Note that, we added in each block a guiding question to help beginner users.

SOFTWARE ANALYTICS CANVAS		PROJECT: PROJECT NAME		VERSION: 1.0	
KEY ISSUES What do we want to know about the software, process and/or usage patterns?	DATA SOURCES What are the data sources that can provide information on the issues raised?	DATA GATHERING How to collect and analyze software data related to this issue?	INSIGHTS What have we found out from the analysis?	QUALITY THRESHOLDS What parameters we can establish to evaluate the quality of our decisions?	
ANALYTICS IMPLEMENTATION How to implement software analytics tasks along with other tasks?		INCREMENTAL GOALS What incremental goals can we establish based on the insights from data analysis?			
To Do Done		To Do Done			

Fig. 1. Software Analytics Canvas [1st Version]

The explanation of each canvas block is presented below, including its description, the related patterns, and its corresponding guiding question.

- **Key Issues.** As a first step, the team can raise issues that need to be verified, analyzed and improved. As mentioned in Section , the issues can be, for example, related to the internal quality of the system (e.g., code quality), external quality of the system (e.g., performance, bug density, the effort required to fix defects), productivity (e.g., effort estimation), and/or usage patterns (e.g., usability, user satisfaction). This element is related to the pattern called *What You Want to Know*. The guiding question is: *What*

do we want to know about the software, process and/or usage patterns?

- **Data Sources.** After defining the key issues, the team identifies what kind of data is needed to know more about the issue raised, and from which sources the data should be extracted, for example, a dump of the database system on recent transactions, source code, behaviors' user, historical data about bugs incidence, etc. For specific issues, the team may recognize the need to collect data from multiple sources for cross-referencing. The two patterns related to this element is *Choose the Means* and *Learning from Experiments*. The guiding question is: *What are the data sources that can provide information on the issues raised?*
- **Data Gathering.** After identifying the data sources, the team should decide which metrics and tools will be used to gather the data. The team can, for example, enable the collection of specific code metrics in the development environment, export from SGBD data referring to a given period, verify the need to create a specific script to extract data from the software repository, etc. Furthermore, the team needs to decide which methods and tools will be used to analyze the data collected. The team can employ from simple statistical methods (e.g., descriptive and inferential statistics) to more sophisticated methods (e.g., data mining, natural language processing, machine learning, etc.), according to the type and amount of data. Also, the team also needs to decide on the tools to support their analysis. For example, the team can opt for *software analytics platforms* which can be configured according to the team's needs. This element also is related to both *Choose the Means* and *Learning from Experiments*. The guiding question is: *How to collect and analyze software data related to this issue?*
- **Insights.** The team analyzes the results obtained from the collected data and discusses possible solutions and insights to making-decision. For example, the team find that "tests have low coverage in module X", "customers prefer this approach" and so on. Then, Insights are raised from the search for solutions. Notice that, sometimes, the data analysis did not reveal significant information about the issue raised. So, the team will decide whether to continue the investigation by collecting new data or if the issue is disregarded, once no action is necessary. This element is a trigger for *Reachable Improvement Goals* pattern. The guiding question is: *What have we found out from the analysis?*
- **Quality Thresholds.** When implementing the improvements via informed decision-making, the team can evaluate the impact of the changes by collecting feedback from stakeholders. From collecting feedback, the team will have enough information to decide whether to consider the issue resolved, or whether the issue should be monitored for longer. Concerning unresolved issues, the team will decide whether they will be re-analyzed from new data, or discarded. Ideally, the team should establish

the quality thresholds values for any issue that the team decides to evaluate or to keep in monitoring. For example, in issues related to coverage testing, the response time cannot exceed 2 seconds, or the test coverage must be at least 80%. *Define Quality Standards* is the patterns related to this element. The question is: *What parameters we can establish to evaluate the quality of our decisions?*

- **Analytics Implementation.** The team should plan how to conduct analysis activities to seek meaningful information from collected data. These activities should be included on the to-do list and prioritized along with the other development tasks. In order to avoid overloading the team, such activities – that also includes the preparation of the analytical infrastructure – can be distributed throughout the project and executed by steps resulting in something deliverable. This block is divided into two regions, the first for the works to be done, and the other to control the work done. *Software Analytics Planning* and *Analytics in Small Steps* are the patterns related to this element. The guiding question is: *How to implement software analytics tasks along with other tasks?*
- **Incremental Goals.** From their insights, the team discusses and define reachable goals to put their solutions into practice, considering that these improvements can be made incrementally. Therefore, the most important in this step is to define where the team wants to reach and what goals they want to achieve. *Reachable Improvement Goals* is the related pattern to this element. However, if the current goals have been fulfilled, the pattern is *Suspend Measurement*. The main question is: *What incremental goals can we define based on the insights from data analysis?*

V. ARTIFACT EVALUATION

This section describes the two studies conducted to evaluate the SA Canvas built to aid agile teams during the planning and managing of software analytics activities.

A. Perceived Usefulness and Ease-of-use (RQ1)

We have conducted the first study in order to investigate the users' perceptions of the usefulness and ease-of-use of the SA Canvas (RQ1). This study was conducted in the Laboratory of Computation and Applied Mathematics at the National Institute for Space Research in Brazil, where we selected six subjects from the course of Agile Projects. Participants had at least three years of experience in software development, and only one of them had no experience with agile methods. We divided the participants into three pairs, seeking to balance them based on the experience of each participant. Table I shows the participants' background and their experience time in developing software (in years).

During the study, participants were invited to plan and manage a software analytics project based on a real case using SA Canvas. For this purpose, we prepared for each team a SA Canvas using a whiteboard and a document describing the case study which should be used as input for the planning

TABLE I
PARTICIPANTS CHARACTERIZATION

Pairs	Subjects	Background	Professional Experience
G1	P1	web development	6 to 10
	P2	software architecture	16 to 20
G2	P3	systems analysis	3 to 5
	P4	systems analysis	11 to 15
G3	P5	computer programming	3 to 5
	P6	systems analysis	16 to 20

and management of the software analytics project. As for the case study, we describe a real case of EMBRACE, one of the research centers in the area of space weather at INPE. In the document, we described the context of study related to a web system to make available some of the products developed by the researchers working in the EMBRACE. In addition to the information about the products developed, we included in the document some concerns related to the web portal that the researchers of the space weather had the intention to investigate and solve. Considering the possible demands described in the document for a software analytics project, we prepared a list of possible data sources to give participants some examples. Moreover, then, we created a tutorial printed on A4 with the illustration of the canvas, the description of its components, and the guiding questions (in Portuguese).

We conducted a pilot study with two researchers from the computer lab to evaluate their iteration with the SA Canvas on the whiteboard and the other materials – case study description, list of possible data sources, and canvas tutorial. From the pilot study, (i) we established that peers should have to raise at least two issues of software analytics; and that (ii) we should carry out a warm-up exercise together with all participants before they begin planning their projects. After that, we held four weekly meetings with participants, as showed in Figure 2.

Fig. 2. Meetings over time.

1st Meeting. At the first meeting, we introduced concepts about software analytics, provided an overview of SA patterns, and presented SA Canvas using the practical example related to code coverage improvement. For more information, we asked the participants to read the two articles on software analytics patterns [9] [10] before the next meeting. After the meeting, participants read and signed an informed consent form to participate in this study.

2nd Meeting. At the second meeting, we invited the participants to a practical exercise to understand how they should use the canvas. One of the participants provided us with a real example of his own work. From this example, we helped them to plan software analytics activities on the board using sticky notes. This activity took approximately one hour.

After warming up, a pair of participants at a time should fill out four blocks of the Canvas (Key Issues, Data Sources, Data Gathering, and Analytics Implementation) based on information written in the document on the EMBRACE case study and the support material (list of possible data sources and the canvas tutorial). Additionally, we asked teams to use different color sticks for different key issues. Each pair took from 25 to 40 minutes to fill the four blocks with at least two key issues. The sessions were recorded for future analyzes, and one of the researchers observed the activities in silence, taking notes on the interaction of participants with the artifact.

After the first iteration, we prepared a report with (i) feedback about how they had used the canvas (including corrective actions), and (ii) fictional information on the evolution of the activities planned by them and executed by the developers. Also, we have introduced some insights mixed into the text to be extracted by them. Because each team raised different key issues, we then prepared three different documents for each of them.

3rd Meeting. The report's information was used as input for the second iteration when the team should adjust some fill-in mistakes pointed out by researchers, update the canvas with the tasks done, proceed in the planning their activities for the next iteration, and fill in the remaining canvas blocks from the insights. As in the first iteration, the sessions were recorded and observed by one of the researchers. The sessions took from 40 to 60 minutes. From the results of this iteration, we prepared a new report for each team with the feedback on the use of the canvas, other fictitious information about the evolution of the project, and new insights mixed into the text.

4th Meeting. As in the previous iteration, from the researchers' report, the teams should adjust some fill-in mistakes pointed out by researchers, update the canvas with the tasks done, proceed in the planning their activities for the next iteration, and fill in the remaining canvas blocks from the insights. The sessions took on average 40 minutes, and just like the previous ones, they were recorded and observed by one of the researchers. At the end of the iteration, we asked the participants individually to answer a questionnaire with questions of the TAM [17], based on their experiences during the software analytics project when they used SA Canvas to plan and manage its activities.

Findings. The questions answered by the participants can be found in the following link: <https://goo.gl/ZbEcC3>. Figure 3 shows the responses from the questionnaire, where to some degree all participants agree that the SA Canvas is useful. However, there was some disagreement concerning the ease of use. Some participants do not agree that it was easy to learn and understand what should be done at certain times (PEU1

and PEU2). The learning curve certainly will have an impact on the user ability to handle the artifact (PEU5). Furthermore, users tend to be more critical as to the usefulness of the artifact when its use is not effortless.

Fig. 3. Perceived usefulness and use of use.

B. Participatory Redesign (RQ2)

To identify what and how we could improve in the SA Canvas (RQ2), we conducted a participatory design session with the same participants from the previous study. The method used to conduct the redesign section was divided into three steps. In the first step, each participant received a document with the description of all the components of the canvas and a form to inform their particular suggestions to improve SA Canvas. After that, each participant should sketch a redesign proposal. In the second step, they consolidated their opinions with their peers by drawing a new sketch for canvas redesign. Lastly, in the third step, all participants discussed their redesign proposals and proposed a single sketch to the canvas. Two of the researchers participated in the session as observers making notes of relevant information. On average, each step lasted 30 minutes.

Findings. From the participants' suggestions, we can identify the need to better clarify at least three blocks:

- In "Insights", three participants suggested making it clear that insights should be described from the results of the analysis.
- The name of the "Quality Thresholds" block seems not to be suitable. Participants suggested making it clear that the values may be minimum or maximum.
- Understanding what should be considered in "Incremental Goals" was difficult for them. Some have suggested a more appropriate name since the main idea is to implement the improvements.

As a final result, the participants sketched the canvas with the following characteristics:

- At the top of the canvas, there are five blocks reserved for planning (inputs and outputs): "Key Issues", "Data Sources", "Data Gathering", "Incremental Goals", and "Quality Threshold".
- The "Quality Threshold" block has been subdivided into two parts to include a minimum acceptable value (minimum) and the goal to achieve (goal).
- At the bottom of the canvas, there is a block called "Analytics Tasks" block instead of "Analytics Implemen-

tation". This block has been subdivided into four parts to accommodate the tasks to do, in progress, done, and the impediments.

VI. DISCUSSION, CONCLUSION AND FUTURE WORK

Although feedback, continuous improvement, inspection, and adaptation are always present in the agile speech, there is little evidence on measurement in practice. Often this measurements and adaptation are adopted on an ad hoc basis. Software analytics is an approach that aims at data-driven continuous improvement, but it is not very widespread in practice.

To bridge this gap, we previously identified patterns on how software analysis could be introduced into the software development process continuously. By looking for a more efficient and practical way to apply the SA patterns into agile development context, we proposed a canvas addressed to the software analytics activities taking into account how teams communicate and collaborate. SA Canvas can be considered a goal-focused approach, similar to the well-known Goal Question Metric (GQM) approach proposed by Basili et al. [20]. The goal-focused approaches are good ways to ensure that measurement goals are articulated with the metrics being collected, and also, to avoid having useless measurements.

We argue that the SA Canvas is a suitable artifact to agile teams' informative workspaces where various techniques and tools for software visualization are commonly applied as information radiators – e.g., count of velocity automated tests, continuous integration status, incident reports, and so forth [21].

In our viewpoint, our canvas has two interesting characteristics. First, it can work as a hub in terms of information flow related to software analytics projects. Information hubs can be considered spaces where information flows meet and decisions are made. Second, the proposed artifact is a situation awareness channel, which considers how people are kept informed about what is happening [22]. For Agile teams, the support of different visualization techniques and tools throughout the software development process is crucial to foster awareness and communication. Additionally, this factor can have a positive impact on the sense of purpose [8] when the professionals follow the evolution of their actions within a cycle of continuous improvement.

As a contribution of this paper, we present the methods used for formative evaluation of the artifact. As a result, we found that the SA Canvas is a useful artifact, but some participants reported difficulties in learning and understanding how to use it. To investigate what could be improved, we carried out a participatory design session, where the same subjects pointed out the components of the canvas that needed to be redefined and provided a sketch with a new layout of the canvas' blocks. These results will help us to refine the proposed artifact. In future work, we will empirically investigate the use of SA Canvas in an industrial setting and experienced agile teams in order to get more relevant research results concerning its effectiveness and impact on the software analytics process.

Sprint Performance Forecasts in Agile Software Development

The Effect of Futurespectives on Team-Driven Dynamics

Abstract—In agile software development, the sprint performances and dynamics of teams often imply tendencies for the success of a project. Post mortem strategies, e.g., retrospectives help the team to report and share individually gained experiences (positives and negatives) from previous sprints, and enable them to use these experiences for future sprint planning. The interpretation of effects on sprint performance is often subjective, especially with concern to social-driven factors in teams. Involving strategies from predictive analytics in sprint retrospectives could reduce potential interpretation gaps of dynamics, and enhance the pre-knowledge, also awareness situation when preparing for the next sprint. In a case study involving 15 software projects with a total of 130 involved undergraduate students, we investigated the post-effects on team performances and behavioral-driven factors when providing predictive analytics in retrospectives. Besides measures for productivity, we consider human factors, e.g., team structures, communication, meetings and mood affects in teams as well as project success metrics. We developed a unique JIRA plugin called *ProDynamics* that collects performance information from projects and derives trend-insights for next sprints. The *ProDynamics* plugin enables the use of a times series and neural network model within a JIRA system to interpret factorial dependencies and behavioral pattern, thus to show the next sprint course of a team.

Index Terms—team dynamics, human factors, data analytics, futurespectives, sprint performances, agile

I. INTRODUCTION

In agile software development, accurate sprint estimations and development performances by teams are essential and can cause the difference whether project goals will be sufficiently completed in time, or neglected [1] [2]. However, studies with the focus on software process improvement are often motivated by increasing the overall success of projects, with the help of using modern methods or technologies that enable additional feedback [3] [4]. For organizations, sprint feedback is important and valuable because it allows the teams to receive both subjective and objective information from different perspectives, e.g., productivity monitoring systems like JIRA, customer responses, and team perceptions also experiences. The feedback mentioned above strongly relies on human factors [5]. While tool-oriented technologies and development frameworks are continuously improved, do the social-driven factors of the team present particular difficulty

in the development process chain. Accordingly, the need for understanding the effects of human factors has continuously grown in relevance for the software engineering discipline, in particular for the improvement of the development process [6] [7]. Towards this, team feedback with focus on past sprints conditions can provide a substantial insight towards earlier experiences, dysfunctional habits or positive performance influences. For example, feedback through retrospective sprint characterization and visualizations benefits of post-mortem summaries, similarly to sprint reports [8]. However, dependency implications or trend highlighting concerning team behavior or performances changes over time are barely considered or hard to grasp. This leads to possible knowledge and interpretation gaps when preparing follow-up sprints because previous effects may not be fully identified or adequately encountered. It is highly desirable to give teams a more sustainable feedback opportunity that involves sprint feedback involving both, retrospective and future characterization. Subsequently, we derive the following two research questions from the above-reported context.

RQ₁: Do agile teams show affects for their self-organization based on previous sprint highlighting and customer satisfaction feedback?

RQ₂: Can sprint performance forecasts based on retrospective data help teams to improve development performances in follow-up sprints?

We addressed and investigated *RQ1* and *RQ2* within a case study involving 130 undergraduate students working in 15 software projects, all founded from industrial, government or public institutional partners. The teams followed a Scrum-oriented development process with support through the project management software JIRA. The case study involves weekly self-assessments resolved in JIRA. The question set covers team behavioral driven features, to gain the situational dynamics in a project with effect for the performances in sprints — satisfactory reflections of customer became additionally elicited at the end of every sprint. Productivity information, e.g., velocity during sprints, estimation gaps or sprint interventions become tracked and accessed directly by

JIRA. Half of the projects (seven) were granted to obtain a JIRA plugin called *ProDynamics* [8]. The plugin is based on earlier studies, enabling teams to give and receive additional retrospective feedback for a better knowledge transfer at the end of sprints [8] [9]. In this study, we extended the primarily retrospective feedback in *ProDynamics* with two predictive analytics features. Teams with access to *ProDynamics* can additionally perform time series analyzes for short-term forecasts, also sprint performance tendencies with the help of a neural network encoder-decoder model [10].

This paper is structured as follows. In Section II, we discuss related work on team behavioral effects, feedback and data analytics adaption. Section III provides a brief overview of the study context. In Section IV, we address the methodology about self-assessments in sprints, also time series and neural network forecasts. In Section V, we describe and interpret results. Section VI concludes our research and future work.

II. RELATED WORK

This study builds on previous results and related work with the focus on human-centered software engineering, and the relevance of fast feedback in an agile context.

Human-centered software engineering takes an import role in modern software development [5]. The focus on team communication, self-organization, and well-working relationships within teams reflect the need for better understanding of behavior-driven factors [9]. When planning sprints in agile software development, pre-knowledge on people having different personalities, skills, and ambitions within the organizational structure is crucial [7]. By means, understanding such human interdependencies enrich project improvements throughout better team performances due to a reduction of estimation gaps [11]. Besides, e.g., the meeting and communication manner or atmosphere changes over time can grant valuable project directions towards potential follow-up conflicts or misleading habits that endanger the sprint performances [12] [13]. Nevertheless, human-centered software engineering strongly depends on the contribution and self-reflection of teams, in sharing experiences from previous sprints [14].

Whenever targeting sprint performance improvements in agile development, team feedback, and change adaption should be sincerely considered [15] [4]. In the early 2000s, research results by Rising et al. [16] subsequently revealed that team feedback during iterative development phases helps the teams most when also involving customer feedback and reflections. The customer perception forms a substantial base in the improvement process by associating group subjective sprint perceptions with the team and development expectation of stakeholder. Vetrò et al. [3] also focused on the effect of fast feedback cycles in software development. The authors observed the impact of different feedback mechanism when gathering information from software development teams directed affects for the quality and transferability of experiences and knowledge with changes in following sprints.

Retrospectives are commonly applied in Scrum and most other agile processes to share and interpret team experi-

ences on performance effectiveness collected during the last sprint [5] [11]. Knowledge gained this way is then taken into account to estimate the next sprints more effectively according to previous outcomes. However, the interpretation of team-behavioral pattern often remains subjectively. However, computer-supported interpretation of sprint performance becomes increasingly important and visible - study results, e.g., reported by Vetrò et al. [15] show the improvement potentials in combining data analytics with traditional team feedback appraisals to improve future sprint estimations [17] [15]. The authors applied multiple-regression analyzes to characterize behavioral pattern on, e.g., meeting and development manner, to grant teams better insights on factorial influences over time, especially for efficiency hazards occurred during sprints. Our case study combines feedback mechanisms and predictive analytics about human-centered sprint performance factors.

III. CONTEXT OF COMPARATIVE CASE STUDY

This approach focuses on the effects of feedback on development performance by teams when providing additional feedback that involves forecasts and sprint tendencies. The futurespectives considered in this study base on computer-supported analyzes that relates to team and customer reflections. Predictive analytics is also integrated to characterize interdependencies of behavior pattern. We analyzed *RQ1* and *RQ2* using a comparative study design [18] by observing 130 undergraduate students working in fifteen project teams (eight to nine student per team). Each project was pre-estimated with an approximated development complexity of 2,000 working hours, equally distributed over 15 weeks. Seven of the fifteen teams used the *ProDynamics* JIRA plugin, enabling them to characterize the previous team and development performances, and to esteem next sprints with the support of times series forecasts and neural network prediction models.

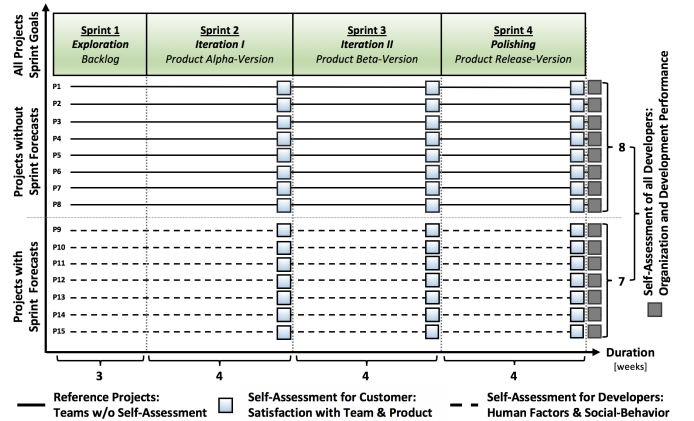

Fig. 1. Comparative Study: Projects, Sprints and Self-Assessments

Figure 1 shows a process overview of the comparative case study design. Participating in the software projects is eligible for students in the fifth semester of their computer science undergraduate studies. The main focus is to collect practical team experience following an iterative development process

including agile methods and practices, such as weekly scrums and storyboards. Students do not receive gradings for participating or performances during the projects. Nevertheless, the course is compulsory within the syllabus. As mentioned before, Scrum was mandatory in each project. All teams had to self-organize inner structures, meetings, and communication, and to manage sprint tasks on a Scrum-board using the project management software JIRA.

For a primary information flow and status exchange, each team was requested to meet face-to-face for at least once a week. For product progress updates, a subsequent meeting with the customer was regularly scheduled once a week. During the sprints, change request could occur, which led to adjusted or discarded issues. At the end of each sprint, teams used retrospectives to highlight and reflect on positive and negative sprint situations. This has mostly been experiences that help the team to better estimate the next sprint tasks and organizational structures. During the projects, additional customer-reflections and satisfaction feedback were assessed to monitor group and development performances also from customer perspectives.

IV. METHODOLOGY

This methodology section starts with (A) the ideology of our JIRA plugin for advanced sprint retrospective and future trend support. The chapter covers the role and realization of (B) the self-assessments on teams and customer satisfaction that were collected as part of the case study. Furthermore, we show how the elicited team and sprint information is later used within (C) the time series and neural network prediction models. In the last subsection, we describe (D) the monitoring process for the sprint performances with a focus on *RQ1* and *RQ2*.

A. ProDynamics –Retrospectives & Futurespective Support:

The project management system JIRA is worldwide known for its team-oriented sprint planning and issue tracking support, commonly used in agile software development. Its usage is scalable from large industrial projects to small entrepreneur solutions. The standard features of JIRA provide substantial help for teams to monitor not yet completed sprints and to derive performance reports for past sprints (development velocity). Lessons learned or experiences gained during a sprint are often reflected by the teams through post-mortem retrospectives [19]. This way, dysfunctional or beneficial sprint characteristics, as well as other individually gained insights, become shared and discussed within the team, enabling them to plan the next sprint in addition to pre-experienced situations or manners. However, reasons for performance affects are not always easy to explain, in particular since the standard JIRA system only characterizes productivity statistics without further implication. We addressed this problem in enabling teams to access fast feedback through a JIRA plugin called *ProDynamics* [8]. In Fig. 2, we give an overview on the sprint analysis features currently provided in *ProDynamics*.

The red box highlights the two newly integrated sprint forecasting features of this study. The plugin addresses the ideology to support and increase the team's understanding and awareness for factorial effects on team-driven sprint behavior and development performance. Previous study results have shown that after suitable preparation of retrospective data, teams can be supported by retrospective computer-aided feedback [8] [15]. However, we believe that the support for such teams in their sprint estimations can further enrich the organizational and development performances with the help of integrated data analytics solutions.

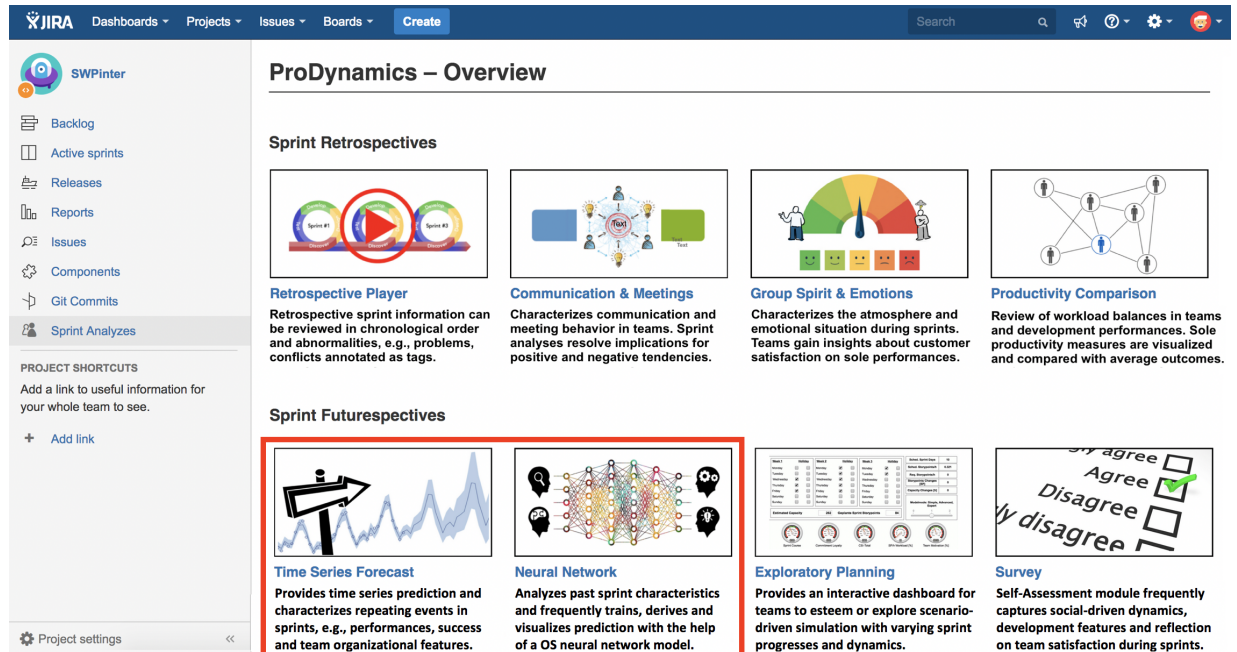

Fig. 2. Behavior-Driven Feedback Support on Sprint Futurespectives in JIRA

B. Self-Assessments for Teams, and Customer-Satisfaction:

Interpretations of previous sprint dynamics or estimations of follow-up sprints concerning the social nature of agile teams can be challenging [7]. Various human factors, such as mood, communication or meeting manner have a direct effect for the ongoing project, while dysfunctional behavior often remains undetected or hard to grasp until problems enlarge [9] [20].

Our approach is designed for teams with an open mentality for self-reflection in exchange for sustainable feedback that enables opportunities for change-driven improvements of organizational and development structures [14] [4]. Using the *ProDynamics* plugin, we enable an integrated self-assessment solution for a systematic elicitation of team dynamics in ongoing sprints. During our comparative case study with $n = 15$ projects, three different assessments were applied to grasp the maximal descriptive team characteristics over time. The assessment designs and question features are based on previous studies, also related work [21] [9], and continuously refined to reach the currently applied versions. The question set is self-adapting, e.g., the information elicitation about communication or meeting behavior only occur for members with active information exchange. With this, the interviewees' effort to complete a survey could be minimized to a length of 1-2 minutes. All assessments are realized through 5-points Likert scales, determining his or her level of agreement on a symmetric agree-disagree scale with predefined sprint or team behavioral statements. In the following, we explain the three assessment types in detail. A summary of the variants, in particular, the intervals, self-assessment sprint information by categories, and interviewees are shown in Fig. 3.

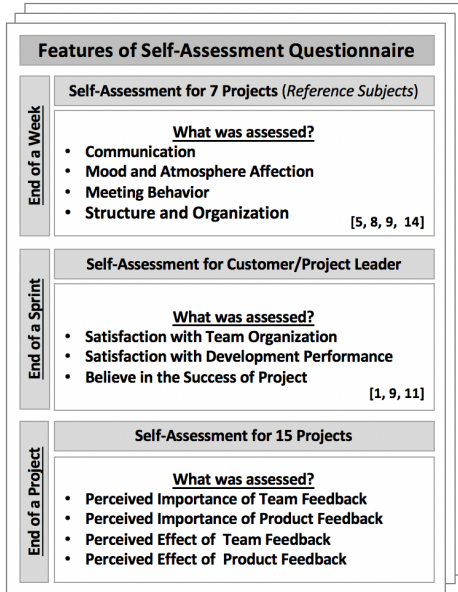

Fig. 3. Self-Assessment Intervals, Interviewees and Features

1) *Self-Assessment at the End of each Week:* During the 15 weeks of this case study, seven out of the fifteen student developer teams voluntarily participated in the study.

Besides the access to the *ProDynamics* retrospective and futurespective sprint features, the participation included a weekly self-assessment for each team member. The assessments capture social- and organization features, such as:

- who-to-whom communication and media channel use
- meeting quantity and average duration
- the atmosphere in the group, personal mood
- satisfaction about the last weeks' performances

We derived other team and sprint metrics, e.g., meeting participation, maverick trends, and centralized communication structures from each team member's response. A summary of all assessment information is shown in Fig. 3. Subsequently, all category features that are currently considered by the time series and neural network model, including productivity measures from JIRA, become listed in Fig. 5.

2) *Self-Assessment at the End of each Sprint:* The second self-assessment question set on the satisfaction with the team and development performances for all 15 software projects was also answered by the customer, and the scrum master at the end of each sprint (except the first). We activated the performance assessments with the second sprint, because the first three weeks of the project were mainly for exploration, to create and fill the backlog, form team structures, get to know the customer and reach a steady state before the next sprint.

However, the survey covers in total ten questions, four about the team organization, four on the development performance as well as two items focusing on the overall satisfaction with the team and product. The question structure became realized through 5-points Likert scales, determining the customers and scrum master's level of agreement on a symmetric agree-disagree scale, similar to the other two self-assessments. The question set was used as one reference indicator between team-driven dynamics during the sprints and potential effects for the customers' satisfaction. The scrum masters' responses become utilized to determine possible offsets between external views and the team inside knowledge. For the comparison of satisfaction changes between the teams with access to *ProDynamics* and those that did not, the customer and scrum master of all fifteen projects were invited to complete this self-assessment form.

3) *Self-Assessment at the End of each Project:* The third self-assessment took place only once at the end of each project and became applied to all 130-student developer. The survey includes questions on the personal perception of the developers, e.g., whether there were moments with a need for additional feedback during the sprints, and if there were recognizable effects (positive or negative) within the own team in case of provided feedback. The following four assessment features became only ones elicit at the end of each project for the validation of every student's perception of their team and development performances during the 15 weeks:

- importance of organizational feedback for the team
- importance of product feedback for the development
- perceived effect in the team because of team feedback
- perceived effect in the team because of product feedback

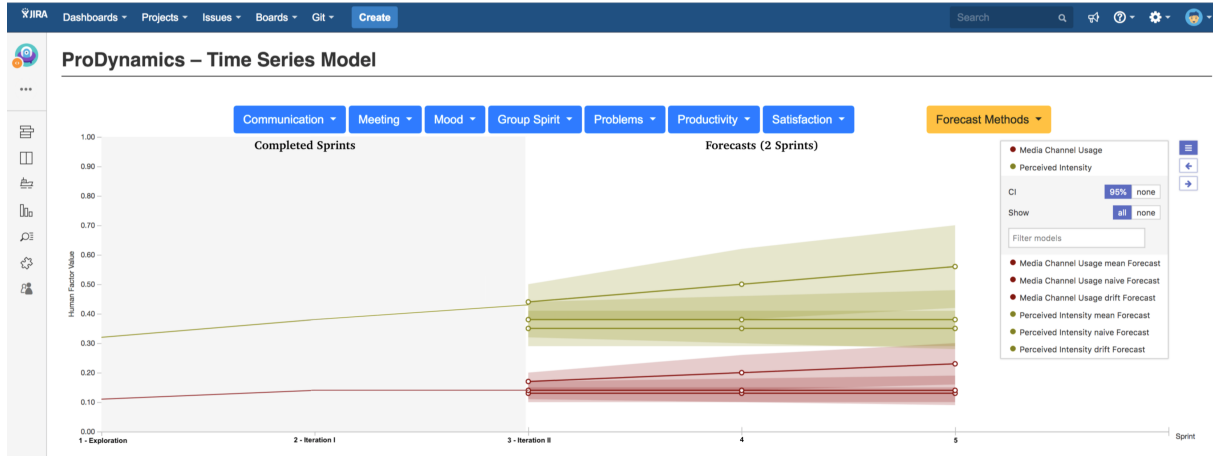

Fig. 4. Time Series Sprint Forecasts derived in *ProDynamics*

The responses were compared with the customer and scrum master satisfaction after each sprint. This survey also involves questions about the need and usefulness, e.g., of a centralized feedback solution in JIRA. Also, whether JIRA was an adequate solution to manage and organize sprints during the case study project. Those are by-product information, in particular with no relevance to answer *RQ1* and *RQ2*.

C. Sprint-Trends through Time Series and Neural Networks

With this case study, we investigated whether teams can gain a more sustainable use of feedback when considering both, past retrospective records and future sprint performance predictions. Besides this, we incorporated retrospective sprint characteristics (e.g., organization structures, communication- and meeting behavior, productivities, motivation) with two predictive models to grant teams an additional trend characterization on behavior-driven factors when esteeming the next sprints. We chose both predictive methods based on their functional properties in supporting inference-statistical analysis, e.g., sprint series. The analysis helps to estimate sprint and team measurements in the future based on past team-behavior in sprint sequences.

The times series forecast used for the sprint-trend esteems based on an open source java library published by Workday¹. The library provides time series analyzes, involving ARIMA-, Mean-, Naïve- and Drift-forecasts. The forecasting model in this study become fitted by the measurements listed in Fig. 4.

The ARIMA-model characterizes seasonal inferences from past and forecasts future points in the series [10]. The Mean-method derives the arithmetic mean from the sequence of sprint data to esteem follow-up values within fitted parameter ranges. The seasonal Naïve-method uses sprint metrics from the second sprint week on to predict the third sprint parameters. The prediction of the fourth sprint metrics is derived with the values from the third sprint, and so on. The Drift-method obtains a straight line between the first and last data point to characterize the sprint metrics tendency drift. Seasonal patterns

are not taken into account with this Drift-method. Figure 4 shows a time series forecast for the communication metrics Media Channel Usage and Perceived Intensity.

The time series viewer enables the teams to choose from one to four supported forecasting methods. The interactive chart allows a user to select different past sprints and the underlying metrics. With this, the chosen sprint metric(s) become analyzed and forecast with the help of the four forecasting methods. The prediction interval can reach a maximal length smaller than the number of yet completed sprints. The colored lines within the gray background area shown in Fig. 4 present the real data points for two selected communication parameters. The colored areas on the right half of the chart mark the 95% confidence interval of the prediction of each forecast. For example, the maximally available forecast horizon in Fig. 4 is two sprints, because the time series model derives its prediction based on three yet completed sprints. Sprint forecasts are labeled on the time axis through a counter and completed sprints name tags.

The *ProDynamics* – Neural Network viewer focuses on the second prediction approach for estimating social-driven team measurements based on retrospective sprint and team records. The neural network is implemented in using the open source library Deeplearning4j. The Deeplearning4j-library covers cross-platform algorithms on machine learning and artificial intelligence is implemented in Java and runs in a JVM such as used by the JIRA system. Similar to our time series forecast solution the neural network viewer provides past sprint metric plots based on the user selections.

Also, the neural network model allows the team to review past sprint conditions covering organizational structures, social-driven team behavior, customer satisfaction, productivity measures as well as problem and conflict appearances. An overview of all covered factors is listed in Fig. 5, which is a result of the assessed team and customer responses as well of development performances that is natively tracked in JIRA. The model is trained with the listed data features considering the availability of already completed sprint records.

¹ <https://github.com/Workday/timeseries-forecast>

Fig. 5. Neural Network Sprint Predictions derived in *ProDynamics*

Training the model requires enlarged computation effort for the data encoding process. Therefore, model updates are performed automatically, but only once during the weekend. The neural network viewer enables the teams to choose individual real data plots of past sprints, or with an active future horizon. The maximal size of future-horizon is limited to the number of yet completed sprints minus one, similar to the time series model. The interactive chart allows a user to select between the sprint metrics and plot trends for the considered team-driven factors. The colored lines in front of the dash border line present the real data points for the two chosen communication parameter Media Channel Usage and Perceived Intensity. The colored lines on the left side of the dashed border present the computed prediction according to the feature records encoding of three yet completed sprints.

D. Sprint Performance Monitoring

In this study, the sprint performances of teams' base on the development (velocity of tasks) as well on the organizational performances during each sprint. The velocities in all teams are comparable productivity measures tracked within JIRA, thus did not require to be separately assessed. This enabled us a direct performance comparison was between a particular group and the average of all other teams during a sprint. Besides the sole productivity measures of teams, we used the customer and scrum master satisfaction feedback after each sprint to determine whether the development outcome also fulfilled product expectations according to quality and functional requirements.

However, the team performances over time with concern on social-driven changes due to futurespective feedback became solely traced through the customer, and scrum master feedback elicited at the end of every sprint. We are reasoning this processing with the fact, that only half of all teams could

access the *ProDynamics* futurespectives, and also frequently completed the self-assessments on social-driven behaviors. In considering the customer and scrum master perceived team performances during each sprint, we could compare the organization performance changes of all teams. Subsequently, the effects and trends could become characterized due to the comparative study subjects with different sprint estimation and planning support. Of course, at this appraisal level, sole factorial influences become not closer taken into account. However, it allowed us first interpretations about whether teams adopt the *ProDynamics* usage, also whether groups with access get used to derive better sprint estimations with constant or even positively improving customer satisfaction outcome, on organizational and product aspects.

V. INTERPRETATION AND VALIDITY OF RESULTS

In the following two subsections, we statistically interpret and discuss the effects of *ProDynamics* futurespectives on the sprint performances, also emphasize related threats to validity.

A. Interpretation of statistical measures

In Section IV, we described the sprint performances as a result of sprint productivity (velocity), also the customer and scrum master satisfaction responses on the team and product performances after every sprint. With the help of Pearson correlation analysis and 2-paired t-Tests, we determined sprint performance differences between the seven groups that actively used the *ProDynamics* prediction features and the other eight teams without access. We found out that the teams with access to the provided sprint forecasts showed fewer estimation errors, therefore with more optimal velocity distribution at 98% as the comparison of the orange boxes (1) in Fig. 6 and Fig. 7 reveal. The overall sprint estimation error for those teams was $\pm 9\%$. In particular, do the groups

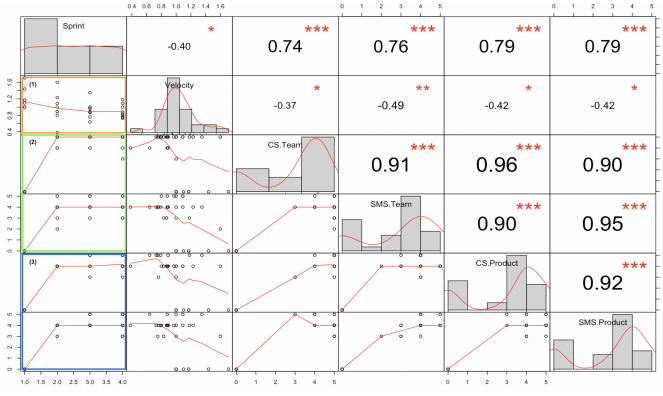

Fig. 6. Team Projects without *ProDynamics*-Futurespective access

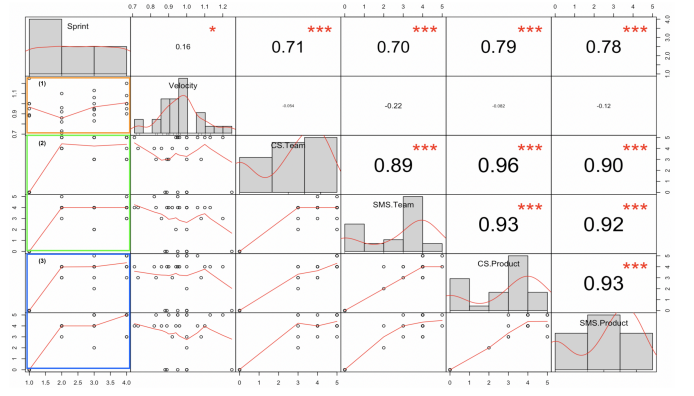

Fig. 7. Team Projects with *ProDynamics*-Futurespective access

without access to *ProDynamics* showed strong tendencies for over-estimating their sprint tasks during the first two sprints, followed by underestimations that caused strong deviations between the number of scheduled tasks and completed ones. Due to this, an overall sprint estimation error of $\pm 19\%$ was identified. However, in comparing the yellow markings (2) in both figures, the team's organizational performances revealed no benefits given due to the additionally provided sprint forecasts. Moreover, the outcome is on a constant level, while both, customer and scrum master reflected a sustainable organization and communication structure in most teams.

The third factor of the sprint performances involves the software product, in particular, the quality, and requirements fulfillment after each sprint. The futurespective in *ProDynamics* enabled a few teams to preview customer satisfaction according to previous performances. However, the forecasts only highlight chances for adjustment, while the teams decide whether to use the available information to improve the previous situation. By comparing the blue boxes (3) in Fig. 6 and Fig. 7, an affect for teams with *ProDynamics* usages becomes reflected throughout an increasing product satisfaction by the customer and scrum master. The satisfaction increase can be of course also because of excitement about the product majority.

Nevertheless, a significant rise in teams with customer feedback knowledge could be measured, while comparable projects remained on a constant level. For redundancy, we also considered the product satisfaction of scrum master, which significantly correlates with our interpretation. Beside results of this case study showed strong accordance between customer and scrum master perceived team and development performances. While the scrum master usually tends to have more team internal information and critical knowledge about accomplishments, does the deviation with external customer ratings present a low perception gap.

B. Threats to validity

Construct validity: We looked at the social-driven team affects only through statistical and artificial methods. The sprint information features obtained in *ProDynamics* are chosen based on previous studies [18] [13]. However, the ac-

curacy of the predictions strongly depends on the quality and completeness of the self-assessed data. The effects on performances depend on whether the teams considered the sprint forecasts in follow-up esteems. Customer satisfaction responses as one success indicator might have involved offsets, because of unjustified expectation or lack of experience.

Internal validity: The interpretations and results of this study rely on the self-assessed team and customer feedback. Only voluntary groups completed surveys, in exchange for accessing additional prediction support in JIRA. Therefore, team responses can be assumed to be accurate and unbiased [16]. Participating teams accepted the privacy limitation, e.g., communications and performances were viewable, but exclusively by the assigned team.

External validity: Since we examine student teams, the results should not be overgeneralized. However, the software projects are founded by a real customer from industry, public institutions or governments. Hence, data collected from other company or university projects could lead to different results. Due to further limitations like the involvement of social-driven factors and unknown domain influences, our interpretations may not embrace all possibly existing project scenarios.

Conclusion validity: All interpretations are plausible and statistically valid. However, there may be different self-assessment responses when repeating the project with the same participants: team-behavioral factors, emotions, skills or unknown influences could have changed in the meantime. Subsequently, the accuracy of predictions could vary due to differently completed surveys, and project progresses. However, the methodology can be generalized and applied to various agile projects that allow assessments on team and sprint information.

VI. CONCLUSION

This study focuses on the effects of social-driven dynamics in agile software developments when providing teams additional feedback on sprint tendencies. To determine the impact of futurespective feedback, we realized a JIRA plugin named *ProDynamics* that simplifies the elicitation of team-driven factors as well as performance measures within JIRA.

The feedback becomes resolved through sprint series forecasts and neural network predictions in an integrated JIRA plugin solution. The computer-based sprint analyzes use team and customer reflections that were frequently assessed, analyzed and characterized for factorial interdependencies on development performances and team-driven behavioral pattern.

With the help of a comparative case study involving fifteen software projects with 130 students, throughout 15 weeks, we gathered weekly information about communication, meeting and emotional metrics from half of the projects. The elicited data became frequently used to train time series and neural network models, enabled the 7 out of 15 groups to gain additional insights about previous sprint and team performances, also derive trend-forecasts for follow-up sprints. Measuring the performance differences between the groups with pro-active feedback and those without involved customer and scrum master feedback from all 15 projects, that became repeatedly elicited at the end of every sprint. The feedback covered past sprint perceiving on both, team and development performances.

Pearson correlation statistics helped us to interpret the effects on sprint performance, in particular, the team and development performance in each project. We found statistical evidence towards that the groups with access to the additionally provided *ProDynamics* forecasts showed a definite decrease for sprint estimation gaps by 10%, while the groups without *ProDynamics* access tend to have more volatile velocity performances. We could show, that the additional use of forecasting methods supports the groups to interpret customer satisfaction better, thus improve the product outcome at the end of sprint. The study also revealed, that teams not necessarily adjust internal organization structures due to predictive information. Most of the groups showed an almost steady level in their weekly communication and meeting behavior, towards no significant affects could be determined.

We can conclude that the *ProDynamics* futurespectives enabled a sustainable team organizational and development performance improvement for the groups with access to the plugin. The team performances dynamics during the sprint sequences showed strong stabilizing characteristics, due to more accurate sprint estimates compared with the comparison groups that only used general sprint information in JIRA, e.g., burndown- and velocity charts. Besides, the *ProDynamics* plugin realized a simplified data elicitation for social-driven team factors, while some group had could reach a positive effect for follow-up sprint executions.

We are currently working on a newer version for the *ProDynamics* plugin, that does extend the retrospective, and futurespective sprint analyzes, by a planning-oriented simulation feature. With this, we believe that teams can potentially improve sprint estimations because of training effects. Various scenarios could be explored before an official sprint start, by incorporating past performances with a generalized simulation model for agile development processes, e.g., system dynamics. A simulation-based approach could grant the team a better insight about appearing behavioral dynamics over time, also help to discover new characteristics, that would remain

undetermined otherwise. Generally spoken, simulations could gain further knowledge and train the sprint estimation skills of teams and project manager.

Abstract—The importance and complexity of software in embedded devices are increasing. It becomes an active research topic on how to carry out the full and efficient testing of military high confidence embedded software such as weaponry, aerospace and so on. The combinatorial test is an effective test case generation technique. But the complexity of the constructor of the combinatorial test suites is NP-complete. The effectiveness and complexity of combinatorial test methods have attracted researchers in the field of combined mathematics and software engineering to study it deeply. For the characteristics of military embedded software, a multi-constraint combinatorial test method is proposed. This method takes into consideration the constraint relationship among parameters, and uses it to guarantee the covering of the seed combination and the simplification of the use case set. And it implements the test case generation tool based on this method. The results show that this tool generates a few use cases and can guarantee the covering of key combinations.

Key Words: *High Confidence; Embedded Software; Multi-constraint; Combinatorial Test*

I. INTRODUCTION

With the development of information technology, the importance and complexity of embedded system are higher and higher. The software caused by the embedded system fails covers about 70%[1-2];Software becomes an important factor restricting the quality of embedded system. Software testing is an important means to ensure software quality. It becomes an active research topic on how to carry out the verification and verification (V&V) of high - efficient and high - quality weapon equipment, aerospace and other high confidence embedded software[3-6]. A lot of practice shows that combinatorial testing is an effective software testing method. It generates a small amount of high-quality test data and systematically tests the combination of parameters. Testing case set generation is a hot topic in combinatorial testing research. People have presented many mathematical methods, heuristic search methods and various greedy algorithms. But these methods have their own limitations and can only have certain advantages when solving some certain problems. For example, TConfig[6] is a mathematical method to construct the recursive structure by using the orthogonal tables and other basic components. This method has a fast generating speed. But the downside is that it need to rely on existing algebra or combined objects. For the heuristic search, we can use tabu search [7], simulated annealing (SA)[8] and other methods to generate small test

case sets. But these methods generally take a long time. In contrast, heuristic greedy algorithms are not only flexible but also fast. At present, a variety of heuristic greedy algorithms have been presented such as AETG[9-11], etc.TCG[12], DDA[13-14] and IPO[15]. Each of these methods has its own advantages. They are all universal methods which are not ideal for solving some specific problems.

In this paper, according to the characteristics of military high confidence embedded software such as weapon equipment, aerospace and so on, a multi-constraint combination test method which can configure seed combinations, covering strength and parameter constraints is proposed. This method takes into consideration the importance of different parameters and the constraint relation between the parameters, taking advantage of them to ensure the covering of the seed combinations and the simplification of the use case set. And it implements the test case generation tool based on this method. The test result shows that this tool generates a few use cases and can guarantee the covering of key combinations.

The second section introduces the basic concepts and models of combinatorial test. The third section presents the multi-constraint combinatorial test methods. And the fourth section describes the experimental design and the results, finally the summary and outlooks.

II. THE BASIC MODEL OF COMBINATORIAL TEST

Assume n parameters are affecting the system software SUT(software under testing), recorded as $F = \{f_1, f_2, \dots, f_n\}$. These parameters can be SUT configure parameter internal events external input, etc. The parameter f_i has a_i possible values by equivalence partitioning, boundary value method and other pre-parametric decomposition, forming the value set $V_i = \{a_1, a_2, \dots, a_i\}, 1 \leq i \leq n$.

Definition 1. Regard n -tuple (v_1, v_2, \dots, v_n) as a test case for SUT, and $v_1 \in V_1, v_2 \in V_2, \dots, v_n \in V_n$.

Correspondingly, regard a collection of n tuples as a test case set for SUT. In the combinatorial test, the test case set is often referred to as a combination covering table (Covering Array for short).

Definition 2. The t -dimension overlay table of the system SUT $CA(N; t, n, (v_1, v_2, \dots, v_n))$ is an $N \times n$ array. The i column corresponds to the i parameter, which is recorded as v_i . The subarray of $N \times t$ that is formed by any t parameter contains all

DOI reference number: 10.18293/SEKE2019-016

of the t tuples of the t parameter, in which t is the strength of the combinatorial test.

According to the definition of the covering array CA(covering array) which is given by Cohen et al. to describe the set of test cases in a combinatorial test case, generally, an array of overrides that can cover any two parameters of any parameter is called a two-dimensional combination (2-way) or Pairwise combination. t -way is the combination of values that can cover the t parameters. When t is equal to the number of parameters n , the override array can override all of the combined conditions of the parameter system, which is 100% full coverage. Therefore, the mathematical model of the combinatorial test case set is often non-continuous, multi-objective and nonlinear constraint solving the problem.

III. MULTI-CONSTRAINT HCESCT COMBINATORIAL TEST METHOD

The most important difference between military embedded software and general software is that the security and reliability requirements of military embedded software are extremely high, and it is best to have 100% test case coverage. But some special system software that has a combination explosion or an important level of software can't reach 100% complete coverage because of many considerations for military software testing, the complexity of operating environment, time and cost. Reasonable use of combinatorial test technology for the military embedded system software to select effective test case set can make up the randomness of artificial design cases and randomness of test cases.

HCESCT (High Confidence Embedded Software Test Generation Method for Combinatorial Testing) is the combinatorial test case generation method presented by this paper with military embedded software as the test target. In combination with the characteristics of high reliability and security requirements, HCESCT method is mainly concerned with adopting reasonable strategies to solve the problem of explosion of cases in the test process. At the same time, ensure that important values are not missed. The combinatorial test method process in this paper is shown in Fig. 1.

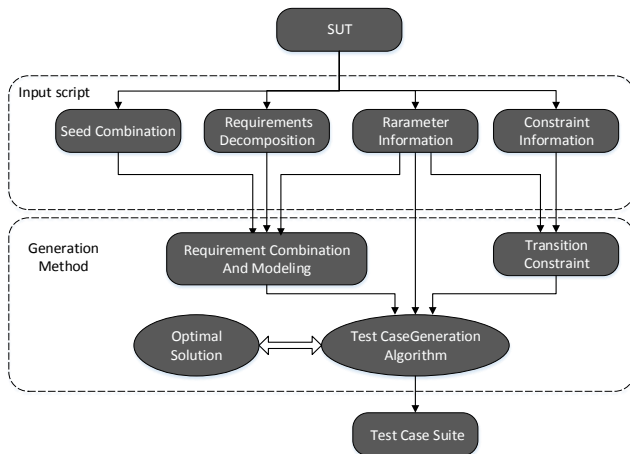

Fig. 1. The Combinatorial Test Method Flow Chart

According to the characteristics of high confidence embedded software, some key parameters must be covered. Depending on the importance of parameters, some require only 2-dimensional coverage, but some combination of parameters need to be covered in higher dimensions. In real software, there is always a certain dependence relation between the parameters of software, which leads to some constraint relationship among some values in these parameters. In order to support the various flexible strategies of the military embedded software combinatorial test method, important combinations must be guaranteed not missing. Here are a few effective generation strategies.

A. Seed Combinations

In high confidence embedded software with high-reliability requirements, it is particularly important to have some parameter combinations. If these parameter combinations go wrong, they can have disastrous consequences. Therefore, the Seed combination (Seed) strategy is added. At the stage of software portfolio testing modeling, add the combination of parameters that must be combined in the software application scenario as a seed combination to ensure that the use case set generated at the end of the HCESCT algorithm is sure to screen out these important combinations. The modeling approach is as follows:

[SEED]

P1:v1,P2:v2,P3:v3;

This constraint statement (P1,P2,P3)=(v1,v2,v3) must be present in the test case

B. Variable Intensity Coverage

Also in order to ensure the coverage of the tested software, the coverage of about 70% of the matched pairs is obviously poor. In multi-parameter systems such as influencing factors, software input and pattern categories, it is necessary to adopt a flexible and variable strategy to ensure the high-dimensional combination of important parameters and the secondary parameter matching combination. For example, on a loaded software, functional requirements specify that the most important parameters affecting software output include the launch mode parameters Mod, temperature Tem, wind power WindF and the wind condition WindD. In parametric system modeling, the variable intensity coverage strategy should be used to cover the four parameters in a 3-way or 4-way combination. At the same time, other parameters with little effect on the launch function such as humidity, launch time and altitude use a matching combination. Enter in the modeling script:

[STRENGTHS]

default : 2; // The global coverage intensity is matched.

Mod, Tim, WindF, WindD : 3; // Variable intensity, important parameter high dimensional combination

With some scripts as input, this algorithm combines the parameters of different important levels with varying intensity.

C. Parameter Constraint

In military software, there're always situations that signal A is received, but parameter b-e fails or signal B is received, but parameter M-N fails. This situation is called a

conflict among parameters. To solve this problem, the parameter constraint description is added to the script during the parameter modeling phase. Adding the parameter constraint strategy, while searching in the generation algorithm, for any parameter:

- Collect all the conditions that block this parameter;
- The parameter is blocked when any condition is satisfied;
- This parameter must be valid when all conditions are not satisfied.

In accordance with the above judgment logic, the algorithm is able to automatically block the combination of invalid parameters that have been identified, and prevent the algorithm from generating too many invalid test cases. The parametric constraint modeling method is as follows:

[CONSTRAINTS]

$P1 == v1 \rightarrow P2 != v2;$

$P3 == v3 \rightarrow P4 == v4 \& P5 > v5。$

D. HCESCT Algorithm Introduction

As mentioned above, HCESCT uses the greedy algorithm that incorporates a flexible and practical combined strategy. Adopt the classic line-by-line search and a one-time-one-line generation strategy:

1) *Initialize covering requirements (Target combination: a combination that needs to be covered)*

- Intensity—combination of all two parameters

2) *Generate test cases per article*

- Try to cover many of the uncovered target combinations.
- The new test case must satisfy all constraints.
- Combinatorial optimization problem

3) *When a new target combination cannot be overridden, stop.*

- The remaining uncovered target combination violates the constraint and cannot be overridden.

The methods of constraint in the algorithm are as follows:

- Convert to a forbidden combination
- The constraint solving technique is adopted to ensure the correctness of the results.

The algorithm framework is shown below:

TABLE I. ALGORITHM KERNEL ALGORITHM OF HCESCT

Algorithm Kernel algorithm of HCESCT
1: init(combination_set);
2: while true do
3: gen_opt_problem();
4: if solve() == OK then
5: new_test_case= translate_solver_output();
6: test_suite.add(new_test_case);
7: update(combination_set, new_test_case);
8: else
9: break ;
10: end if

11: **end while**

The traditional greedy algorithm produces a new test case that determines and overrides the uncovered combination in the while. This is an optimization problem for both search methods and heuristic methods. There are some algorithms for handling parameter constraints. Distribution parameter values in the algorithm, for example, they call external solver or other methods to determine whether the test cases to satisfy the constraints, or to determine which parameter values can be assigned to the parameters in recycling. In contrast, our algorithm integrates generation optimization and constraint solving together. In each while, every time a new test case is generated, only the optimization problem is considered to ensure that the new test case covers at least one uncovered combination. The judgment and retry process that generates the use case satisfies the constraints are done in the external solution function, not in the upper algorithm while. Because the constraint solving function solve the parameter constraint judgment problem very well, this will save a lot of resources in the overall cost of the algorithm. HCESCT algorithm diagram is shown in Fig. 2.

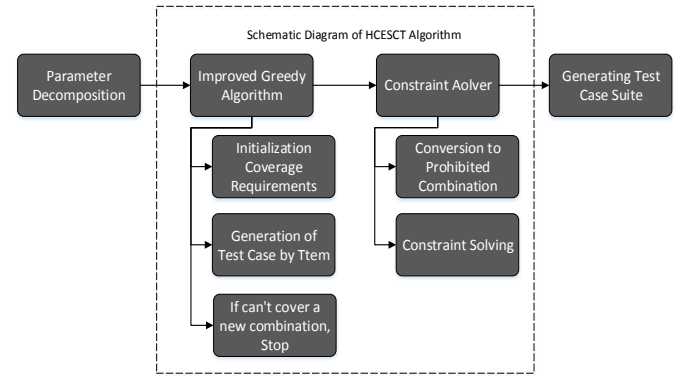

Fig. 2. HCESCT Algorithm Diagram

IV. THE COMBINATORIAL TEST EXPERIMENT AND THE GENERATION EFFECT CONTRAST

To illustrate the method of combinatorial test strategy in this paper and contrast the generation effects of existing main tools, some high confidence embedded data processing software are taken as an example. The software is in the demand analysis phase. And the type of input is shown in the table below:

TABLE II. INPUT DATA TYPE

	A Group P Data	A Group M Data	B Group M Data	B Group M Data
Data Source 1	0	0	0	0
Data Source2	0	0	0	0
Data Source3	0	0	0	0

Data processing software has three different types of data sources, and each data source is independent of each other. The software can accept data from three sources at a time. The data format of each data source is one of the four types of A group P data, A group M data, B group P data and B group M data. Among them, the A group P data of data source 1 and the B group P data of data source 3 is an important combination of data sources and the most frequently processed data of software. Similarly, data source 1 and data source 2 will not send B group P data to the data

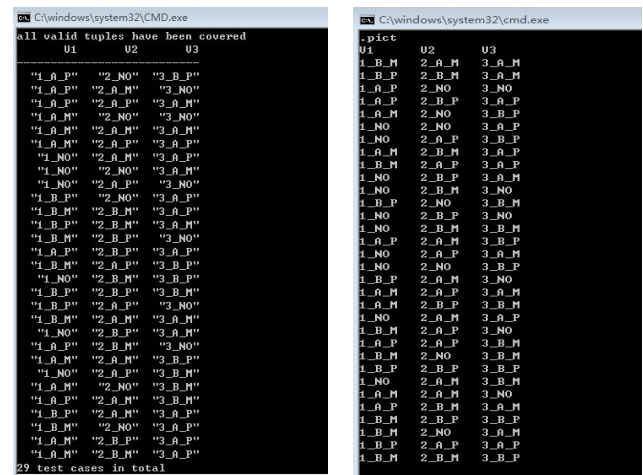

As is shown in HCESCT combinatorial test method flow chart, after this data is decomposed into embedded software requirements, a requirement combination is required. That means taking A group P data of data source 1 as a parameter value. The parametric model after modeling is shown in table 3.

	A Group P Data	A Group M Data	B Group M Data	B Group M Data	No Data
Parameter V1	1_A_P	1_A_M	1_B_P	1_B_M	1_NO
Parameter V2	2_A_P	2_A_M	2_B_P	2_B_M	2_NO
Parameter V3	3_A_P	3_A_M	3_B_P	3_B_M	3_NO

The HCESCT combinatorial test method was used to analyze the demand of the measured parts and integrate and model the requirements. The seed combinations are: V1=1_A_P , V2=2_NO , V3=3_B_P. When the parameter constraint is V3=3_B_M, V2!=2_B_M; When the parameter constraint is V3=3_B_P, V2!=2_B_P , V3!=3_B_P. Use the script as shown in the following diagram to generate input for the combinatorial test case generation algorithm.

```
TestModel-INPUT
[PARAMETERS]
string V1: "1_A_P", "1_A_M", "1_B_P", "1_B_M", "1_No"
string V2: "2_A_P", "2_A_M", "2_B_P", "2_B_M", "2_No"
string V3: "3_A_P", "3_A_M", "3_B_P", "3_B_M", "3_No"
[STRENGTHS]
default:2;
[SEEDS]
V1: "1_A_P", V2: "2_No", V3: "3_B_P";
[CONSTRAINTS]
V3=="3_B_M" -> V2!="2_B_M";
V3=="3_B_M" -> V1!="1_B_M";
V3=="3_B_P" -> V2!="2_B_P";
V3=="3_B_P" -> V1!="1_B_P";
```

The results generated by the combinatorial test case generation program and the PICT[16] execution results are shown in Fig. 4. There are 29 use cases generated by this method, and PICT generates 31 test cases. Furthermore, the syntax of this article is more concise, which avoids tools like PICT using complex syntax such as judgment statements to express parameter constraints.

Abstract—We propose a concurrent program testing technique that is a specification-based one and uses simulation relations from concurrent programs to formal specifications. For a formal specification S , a concurrent program P and a simulation relation r from P to S , the proposed technique is outlined as follows: (1) state sequences s_0, s_1, \dots, s_n are generated from P , (2) state sequences s'_0, s'_1, \dots, s'_m for S are obtained by converting s_0, s_1, \dots, s_n with r and (3) it is checked that S can accept s'_0, s'_1, \dots, s'_m . (1) is very crucial, but we first tackle (2) and (3) and then the present paper focuses on (2) and (3).

Keywords—concurrent program testing; Maude; meta-programming; simulation-based testing; simulation relations

I. INTRODUCTION

Major concepts of programming languages that can be used to write concurrent programs emerged in the 1980s and since nearly then studies on testing concurrent programs have been conducted. Arora, et al. have comprehensively surveyed testing concurrent programs [1]. They categorize it into eight classes: (a) reachability testing, (b) structural testing, (c) model-based testing, (d) mutation-based testing, (e) slicing-based testing, (f) formal method-based testing, (g) random testing, and (h) search-based testing. Model checking concurrent programs has been intensively studied, which may be classified into (c) and/or (f). Java Pathfinder (JPF) [2], [3] is such a model checker. Model checking is superior to the other testing techniques in that the former exhaustively checks all possible execution paths (or computations). However, model checking concurrent programs often encounters the notorious state explosion, which has not yet been conquered reasonably well.

We need a concurrent program testing technique that can scale reasonably well because most important software systems are in the form of concurrent programs, which are large-scale. We then propose a concurrent program testing technique in this paper toward this aim. The technique is a specification-based one. We suppose that programmers write concurrent programs based on formal specifications. The FeliCa team has demonstrated that use of formal specifications is useful as well as feasible in a practical setting [4].

This work was partially supported by JSPS KAKENHI Grant Number JP26240008 & JP19H04082.

DOI reference number: 10.18293/SEKE2019-027

Therefore, our assumption must be reasonable. Programmers need to comprehend formal specifications and must know their concurrent programs well and then they must be able to find some good relations between formal specifications and concurrent programs. Such relations should be simulation relations from the latter to the former. Then, we use such simulation relations to test concurrent programs.

Given a formal specification S , a concurrent program P and a simulation relation r from P to S , the proposed technique is outlined as follows: (1) state sequences s_0, s_1, \dots, s_n are generated from P , (2) state sequences s'_0, s'_1, \dots, s'_m for S are obtained by converting s_0, s_1, \dots, s_n with r and (3) it is checked that S can accept s'_0, s'_1, \dots, s'_m . (1) is very crucial, but we first tackle (2) and (3) and then the present paper focuses on (2) and (3).

Our approach uses formal specifications to test concurrent programs. Testing programs based on formal specifications has been studied [5]. Among such techniques are a CSP-based one [6] and an Event-B model-based on [7]. One difference between existing such techniques and our approach is that test cases are generated from formal specifications in the former, while the counterparts are generated from concurrent programs.

The rest of the paper is organized as follows: § II Preliminaries, § III Toward Concurrent Program Testing, § IV Specification Testing with Simulation Relations, § V Experiments, and § VI Conclusion.

II. PRELIMINARIES

A state machine $M \triangleq \langle S, I, T \rangle$ consists of a set S of states, the set $I \subseteq S$ of initial states and a binary relation $T \subseteq S \times S$ over states. $(s, s') \in T$ is called a state transition and may be written as $s \rightarrow_M s'$. Let \rightarrow_M^* be the reflexive and transitive closure of \rightarrow_M . The set $R_M \subseteq S$ of reachable states w.r.t. M is inductively defined as follows: (1) for each $s \in I$, $s \in R$ and (2) if $s \in R$ and $(s, s') \in T$, then $s' \in R$. A state predicate p is called invariant w.r.t. M iff $p(s)$ holds for all $s \in R_M$. A finite sequence $s_0, \dots, s_i, s_{i+1}, \dots, s_n$ of states is called a finite semi-computation of M if $s_0 \in I$ and $s_i \rightarrow_M^* s_{i+1}$ for each $i = 0, \dots, n-1$. If that is the case, it is called that M can accept $s_0, \dots, s_i, s_{i+1}, \dots, s_n$.

Given two state machines M_C and M_A , a relation r over R_C and R_A is called a simulation relation from M_C to

Figure 1. A simulation relation from M_C to M_A

M_A if r satisfies the following two conditions: (1) for each $s_C \in I_C$, there exists $s_A \in I_A$ such that $r(s_C, s_A)$ and (2) for each $s_C, s'_C \in R_C$ and $s_A \in R_A$ such that $r(s_C, s_A)$ and $s_C \rightarrow_{M_C} s'_C$, there exists $s'_A \in R_A$ such that $r(s_A, s'_A)$ and $s_A \rightarrow_{M_A}^* s'_A$ [8] (see Fig. 1). If that is the case, we may write that M_A simulates M_C with r . There is a theorem on simulation relations from M_C to M_A and invariants w.r.t M_C and M_A : for any state machines M_C and M_A such that there exists a simulation relation r from M_C to M_A , any state predicates p_C for M_C and p_A for M_A such that $p_A(s_A) \Rightarrow p_C(s_C)$ for any reachable states $s_A \in R_{M_A}$ and $s_C \in R_{M_C}$ with $r(s_C, s_A)$, if $p_A(s_A)$ holds for all $s_A \in R_{M_A}$, then $p_C(s_C)$ holds for all $s_C \in R_{M_C}$ [8]. The theorem makes it possible to verify that p_C is invariant w.r.t. M_C by proving that p_A is invariant w.r.t. M_A , M_A simulates M_C with r and $p_A(s_A)$ implies $p_C(s_C)$ for all $s_A \in R_{M_A}$ and $s_C \in R_{M_C}$ with $r(s_C, s_A)$.

States are expressed as braced soups of observable components, where soups are associative-commutative collections and observable components are name-value pairs in this paper. The state that consists of observable components oc_1 , oc_2 and oc_3 is expressed as $\{oc_1 \ oc_2 \ oc_3\}$, which equals $\{oc_3 \ oc_1 \ oc_2\}$ and some others because of associativity and commutativity. We use Maude [9], a rewriting logic-based computer language, as a specification language because Maude makes it possible to use associative-commutative collections.

Simple Communication Protocol (SCP), a communication protocol, is used as one running example in this paper. SCP consists of a sender, a receiver and two channels between them. One channel called dc (data channel) is a cell that is used to transfer pairs $\langle d, b \rangle$, where d is a data value and b is a Boolean value, to the receiver from the sender, and the other channel called ac (ack channel) is a cell that is used to deliver Boolean values (as ack) to the sender from the receiver. Both cells are unreliable in that the contents may drop. The sender maintains two pieces of information that are sb (sender bit) and data. sb is a Boolean value and data is the data to be delivered next to the receiver. The receiver maintains two pieces of information that are rb (receiver bit) and buf. rb is Boolean value and buf is the list of data received so far. Initially, sb is true, data is $d(0)$, rb is true,

Figure 2. A state of SCP

buf is empty, dc is empty and cc is empty. The sender has two actions to do that are d-snd and d-rec. d-snd does the following: the pair $\langle \text{data}, \text{sb} \rangle$ is put into dc. d-rec does the following: if ac has a Boolean value b , then b is extracted and if $b \neq \text{sb}$, then data is set to the next data and sb is negated and otherwise nothing changes. The receiver has two actions to do that are a-snd and a-rec. a-snd does the following: rb is put into ac. a-rec does the following: if dc has $\langle d, b \rangle$, then $\langle d, b \rangle$ is extracted and if $b = \text{rb}$, then d is added to buf at the end and rb is negated and otherwise nothing changes. There are two more actions that are d-drp and a-drp. d-drp does the following: if dc is not empty, dc becomes empty. a-drp does the following: if ac is not empty, ac becomes empty. Fig. 2 shows a state of SCP.

A state of SCP is expressed as follows:

```
{(scp-sb: b1) (scp-data: d(n)) (scp-rb: b2)
 (scp-buf: dl) (scp-dc: cell1) (scp-ac: cell2)}
```

Each of the six actions in SCP is formalized as state transitions, which are described in Maude (conditional) rewrite rules (or rules) as follows:

```
rl [d-snd] : {(scp-sb: B) (scp-data: D)
 (scp-dc: DC) OCs}
=> {(scp-sb: B) (scp-data: D)
 (scp-dc: (< D, B >)) OCs} .
```

```
cr1 [a-rec1] : {(scp-sb: B) (scp-data: d(N))
 (scp-ac: B') OCs}
=> {(scp-sb: (not B)) (scp-data: d(N + 1))
 (scp-ac: empc) OCs} if B /= B' .
```

```
cr1 [a-rec2] : {(scp-sb: B) (scp-data: D)
 (scp-ac: B') OCs}
=> {(scp-sb: B) (scp-data: D) (scp-ac: empc)
 OCs} if B = B' .
```

```
rl [a-snd] : {(scp-rb: B) (scp-ac: AC) OCs}
=> {(scp-rb: B) (scp-ac: B) OCs} .
```

```
cr1 [d-rec1] : {(scp-rb: B) (scp-buf: Ds)
 (scp-dc: (< D, B' >)) OCs}
=> {(scp-rb: (not B)) (scp-buf: (Ds | D))
 (scp-dc: empc) OCs} if B = B' .
```

```
cr1 [d-rec2] : {(scp-rb: B) (scp-buf: Ds)
 (scp-dc: (< D, B' >)) OCs}
=> {(scp-rb: B) (scp-buf: Ds)
 (scp-dc: empc) OCs} if B /= B' .
```

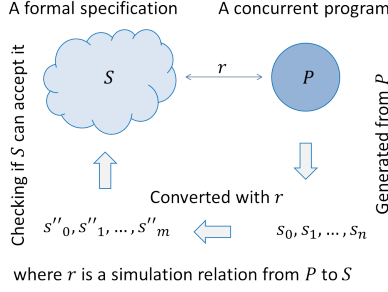

Figure 3. Specification-based concurrent program testing with a simulation relation

```

rl [d-drp] : {(scp-dc: P) OCs}
=> {(scp-dc: empc) OCs} .

rl [a-drp] : {(scp-ac: B) OCs}
=> {(scp-ac: empc) OCs} .

```

The search command given by Maude can conduct reachability analysis of state machines specified in Maude. Let s_1 and s_2 be the following states:

```

{(scp-sb: true)(scp-data: d(0))
(scp-rb: false)(scp-buf: d(0))
(scp-dc: < d(0), true >)(scp-ac: false)}

{(scp-sb: false)(scp-data: d(1))
(scp-rb: false)(scp-buf: d(0))
(scp-dc: < d(0), true >)(scp-ac: false)}

```

The search command “search [1,2] in SCP : $s_1 \Rightarrow^* s_2$.” checks if s_2 is reachable from s_1 in depth 2, where SCP is the module in which SCP is specified. If so, the command finds one transition sequence from s_1 to s_2 . Because there is such a transition sequence, the commands finds it. If [1, 1] is used instead of [1, 2], then because there is no transition sequence from s_1 to s_2 in depth 1, the command does not find any such transition sequences.

Maude has meta-programming (or reflexive programming) facilities with which we can develop software tools, such as Real-Time Maude. The first search command can be expressed in the term: `metaSearch(upModule('SCP, false), upTerm(s_1), upTerm(s_2), nil, '*', 2, 0)`, where `upModule` converts a module to its meta-representation, the term representing the module, and `upTerm` converts a term to its meta-representation. By reducing the term, we can essentially get the same result as the one obtained by the first search command.

III. TOWARD CONCURRENT PROGRAM TESTING

Testing concurrent programs is inherently different from testing sequential programs. All we need to test the latter is basically to check the output for each input, although there is some room to generate better test cases. Even though there is no decidable test oracle, we could use the metamorphic

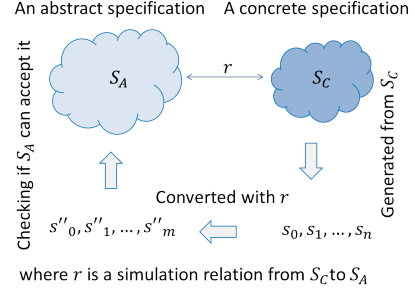

Figure 4. Specification-based specification testing with a simulation relation

testing technique. Concurrent programs have multiple active entities, such as threads, and therefore can lead to lots of execution scenarios. What execution scenario will be taken depends a scheduler, such as Java VM thread scheduler. It is usually impossible to control such a scheduler with an ordinal program. There may be some nondeterminism in concurrent programs. Hence, it does not suffice to have concurrent programs run on real machines to test such programs because we cannot check all possible execution scenarios.

One possible remedy is to use software model checkers, such as Java Pathfinder (JPF) [3]. JPF has its own VM running on a native Java VM and controls its own VM to cover all possible execution scenarios of concurrent programs. Many case studies with JPF have been reported and several techniques for JPF that may mitigate the notorious state explosion have been proposed. Even so, non-JPF experts can often encounter the state explosion that cannot be mitigated at all. We have written an ABP simulator in Java and tried to model check with JPF running on a computer that carries a 32GB memory the simulator in which each channel capacity is 3 and 3 messages are delivered to the receiver from the sender [10]. We have spent several days but the information we have obtained was out of memory. Thus, we do not think that it would suffice to use software model checkers, such as JPF, to test concurrent programs.

We propose a concurrent program testing technique that is a specification-based testing one (see Fig. 3). Let S be a formal specification of a state machine and P be a concurrent program. A state machine could be extracted from P , for example, as what is done by JPF. What we would like to do is to test if P is an implementation of S , or S simulates P . To this end, we use a simulation relation candidate r from P to S . For a formal specification S , a concurrent program P and a simulation relation r from P to S , the proposed technique does the following: (1) finite state sequences s_1, s_2, \dots, s_n are generate from P , (2) each s_i of P is converted to a state s'_i of S with r , (3) one of each two consecutive states s'_i and s'_{i+1} such that $s'_i = s'_{i+1}$ is deleted, (4) finite state sequences $s''_1, s''_2, \dots, s''_m$ are then obtained

and (5) it is checked that $s''_1, s''_2, \dots, s''_m$ can be accepted by S . We suppose that programmers write concurrent programs based on formal specifications, although it may be possible to generate concurrent programs (semi-)automatically from formal specifications in some cases. The FeliCa team has demonstrated that programmers can write programs based on formal specifications and moreover use of formal specifications can make programs high-quality. Therefore, our assumption is meaningful as well as feasible. If so, programmers must have profound enough understandings of both formal specifications and concurrent programs so that they can come up with simulation relation candidates from the latter to the former.

In our approach, state sequences generated from P are test cases. Therefore, it is really crucial that what state sequences are generated from P and how they are generated. The former and the latter have something to do with the quality of test cases and the scalability of our approach, respectively. Some may say that our approach has the same problems as software model checkers. Our approach never checks any properties while generating state sequences from P . It would take non-trivial time to check properties. Thus, we anticipate that our approach can scale better than software model checkers.

IV. SPECIFICATION TESTING WITH SIMULATION RELATIONS

This paper mainly focuses on the left part of the diagram shown in Fig.3. However, we need something, which is substituted for P , from which state sequences are generated. We use an abstract specification S_A as S and a concrete specification S_C as P in this paper (see Fig.4).

It is often the case that any state sequences generated from S_C cannot be accepted by S_A . A simulation relation r from S_C to S_A is not necessarily a function from S_C states to S_A states or from S_A states to S_C states in general. Because states in S_C are often designed by refining those in S_A , however, we conjecture that r is a function from S_C states to S_A states in practice.

Given a finite sequence s_0, s_1, \dots, s_n of states generated from S_C , each state is converted into a state in S_A with r , generating s'_0, s'_1, \dots, s'_n , where $s'_i = r(s_i)$ for each i and r is used as a function from S_C states to S_A states. There may be two consecutive states s'_i and s'_{i+1} such that $s'_i = s'_{i+1}$. If so, one of them is deleted. We then generate a sequence $s''_0, s''_1, \dots, s''_m$ of states in S_A such that there does not exist i such that $s''_i = s''_{i+1}$ (see the bottom part of Fig.4). We finally check if $s''_0, s''_1, \dots, s''_m$ is a finite semi-computation of S_A (see the left part of Fig.4).

Let sim be a function from S_C states to S_A . The function simList that converts s_0, s_1, \dots, s_n to $s''_0, s''_1, \dots, s''_m$ is defined as follows:

```
eq simList(C | L, S)
= if S == {empty}
```

Figure 5. A state of ABP

```
then sim(C) | simList(L, sim(C))
else (
  if compareTo(sim(C), S)
  then simList(L, S)
  else sim(C) | simList(L, sim(C)) fi ) fi .
```

where $_|_$ is used as the constructor of state sequences. $\text{compareTo}(\text{sim}(C), S)$ checks if there are two consecutive states such that they are equal.

Given a module mQid in which a state machine is specified, two states $S1$ & $S2$ and the depth B , the function checkSttTrans checks if $S2$ is reachable from $S1$ in B w.r.t. the state machine, which is defined as follows:

```
ceq checkSttTrans(mQid, S1, S2, B)
= if sttTrans? :: ResultTriple
  then true else false fi
if sttTrans? :=
  metaSearch(upModule(mQid, false),
    upTerm(S1), upTerm(S2), nil, '*', B, 0) .
```

metaSearch is used to check if $S2$ is reachable from $S1$ in B w.r.t. the state machine specified as mQid .

Given a module mQid in which a state machine is specified, a sequence of the state machine states and a depth B , the function checkConform checks if the state sequence is a finite semi-computation of the state machine, which is defined as follows:

```
eq checkConform(mQid, S1 | S2 | L, B)
= $checkConform(mQid, S2 | L, S1, 0, B) .
eq $checkConform(mQid, nil, S, N, B)
= success .
eq $checkConform(mQid, S2 | L, S1, N, B)
= if checkSttTrans(mQid, S1, S2, B)
  then $checkConform(mQid, L, S2, N + 1, B)
  else {msg: "Failure", from: S1, to: S2,
    index: N, bound: B} fi .
```

$\text{checkSttTrans}(\text{mQid}, S1, S2, B)$ checks if $S1 \rightarrow^*_{\text{mQid}} S2$ in the depth B .

V. EXPERIMENTS

We use a specification of Alternating Bit Protocol (ABP) as S_C . ABP is a communication protocol as SCP. A state in ABP is shown in Fig.5. The difference between ABP and SCP is as follows: instead of the two cells used in SCP, ABP uses as two channels two queues that are unreliable in that

an element in the queues may drop and/or be duplicated. Therefore, there are two actions for each queue: d-drp and d-dup for dc and a-drp and a-dup for ac. There are totally eight actions in ABP.

A state of ABP is expressed as follows:

```
{ (abp-sb: b1) (abp-data: d(n)) (abp-rb: b2)
  (abp-buf: dl) (abp-dc: q1) (abp-ac: q2) }
```

Each of the eight actions in ABP is formalized as state transitions, which are described in Maude rules as follows:

```
rl [d-snd] : {(abp-sb: B) (abp-data: D)
  (abp-dc: Ps) OCs}
=> {(abp-sb: B) (abp-data: D)
  (abp-dc: (Ps | < D, B >)) OCs} .

crl [a-rec1] : {(abp-sb: B) (abp-data: d(N))
  (abp-ac: (B' | Bs)) OCs}
=> {(abp-sb: (not B)) (abp-data: d(N + 1))
  (abp-ac: Bs) OCs} if B /= B' .

crl [a-rec2] : {(abp-sb: B) (abp-data: D)
  (abp-ac: (B' | Bs)) OCs}
=> {(abp-sb: B) (abp-data: D)
  (abp-ac: Bs) OCs} if B = B' .

rl [a-snd] : {(abp-rb: B) (abp-ac: Bs) OCs}
=> {(abp-rb: B) (abp-ac: (Bs | B)) OCs} .

crl [d-rec1] : {(abp-rb: B) (abp-buf: Ds)
  (abp-dc: (< D, B' > | Ps)) OCs}
=> {(abp-rb: (not B)) (abp-buf: (Ds | D))
  (abp-dc: Ps) OCs} if B = B' .

crl [d-rec2] : {(abp-rb: B) (abp-buf: Ds)
  (abp-dc: (< D, B' > | Ps)) OCs}
=> {(abp-rb: B) (abp-buf: Ds) (abp-dc: Ps)
  OCs} if B /= B' .

rl [d-drp] : {(abp-dc: (Ps1 | P | Ps2)) OCs}
=> {(abp-dc: (Ps1 | Ps2)) OCs} .

rl [d-dup] : {(abp-dc: (Ps1 | P | Ps2)) OCs}
=> {(abp-dc: (Ps1 | P | P | Ps2)) OCs} .

rl [a-drp] : {(abp-ac: (Bs1 | B | Bs2)) OCs}
=> {(abp-ac: (Bs1 | Bs2)) OCs} .

rl [a-dup] : {(abp-ac: (Bs1 | B | Bs2)) OCs}
=> {(abp-ac: (Bs1 | B | B | Bs2)) OCs} .
```

Let `sim` be a simulation function that converts an ABP state

```
(abp-sb: S) (abp-data: D) (abp-rb: R)
  (abp-buf: BUFF) (abp-dc: DC2) (abp-ac: AC2)
```

to a SCP state

```
{(scp-sb: S) (scp-data: D) (scp-rb: R)
  (scp-buf: BUFF) (scp-dc: norm(hd(DC2)))
  (scp-ac: norm(hd(AC2))) }
```

where `hd` returns the top element if a given queue is not empty and an error element otherwise and `norm` returns the

Figure 6. Time taken when the length of each state sequence is fixed (100) and the number of state sequences is changed (100, 1000, 10000, 50000, 100000, 500000 & 1000000)

cell in which the element is stored if the argument is an element and the empty cell if it is an error element.

Let `seqABP100` be a sequence of states randomly generated from the ABP specification such that its length is 100. Let `seqSCP` be the sequence of states obtained by `simList(seqABP100, {empty})`. We can check if `seqSCP` is a finite semi-computation of the SCP specification in the depth 2 by `checkConform('SCP', seqSCP, 2)`. The result is success. If we use 1 as the depth instead of 2, we get the following result:

```
{msg: "Failure", from: {scp-sb: true scp-data:
  d(0) scp-rb: false scp-buf: d(0) scp-dc:
  < d(0), true > scp-ac: false}, to: {scp-sb:
  false scp-data: d(1) scp-rb: false scp-buf:
  d(0) scp-dc: < d(0), true > scp-ac: false},
  index: 20, bound: 1}
```

This is because two state transitions need to be taken to move the state following `from:` to the state following `to:` in SCP as described in Sect. II.

It is also important to know how many state transitions need to be taken to move one state to the next state in the state sequence of S_A obtained by converting a state sequence of S_C with a simulation function. We also conjecture that programmers who have written a concurrent program based on a formal specification can guess such information because they need to understand the formal specification well and know a simulation relation from the concurrent program to the formal specification.

We used the SCP and ABP specifications in Maude to measure time taken to generate state sequences from the ABP specification, transform them with the simulation relation from ABP to SCP to other state sequences, and check if the state sequences obtained can be accepted by the SCP specification. We used one node of SGI UV3000

Figure 7. Time taken when the number of state sequences is fixed (1) and the length of the state sequence is changed (100, 1000, 10000, 50000, 100000, 250000 & 500000)

that carries 2.90GH microprocessor and 256GB memory for the experiments. Two sets of experiments were conducted. One set is to fix the length of each state sequence, which is 100, and modify the number of state sequences generated, which is one of 100, 1000, 10000, 50000, 100000, 500000 and 1000000. The other set is to fix the number of state sequences generated, which is one, and modify the length of the state sequence, which is one of 100, 1000, 10000, 50000, 100000, 250000 and 500000. For both sets of experiments, 2 was used as the depth of state transitions. Fig.6 shows the experimental results for the first set. The time taken increases almost linearly as the number of state sequences generated increases. Fig.7 shows the experimental results for the second set. The time taken increases a bit greater than linearly as the length of the state sequence generated increases.

VI. CONCLUSION

We have proposed a concurrent program testing technique that is a specification-based one and uses simulation relations from concurrent programs to formal specifications. For a formal specification S , a concurrent program P and a simulation relation from P to S , the proposed technique is outlined as follows: (1) state sequences s_0, s_1, \dots, s_n are generated from P , (2) state sequences $s''_0, s''_1, \dots, s''_m$ for S are obtained by converting s_0, s_1, \dots, s_n with r and (3) it is checked that S can accept $s''_0, s''_1, \dots, s''_m$. The present paper has focused on (2) and (3).

The first set of experiments (shown in Fig.6) indicates that it would be feasible to (almost) exhaustively check if state sequences whose length is small and that are generated from a concurrent program can be accepted by a formal specification with a simulation relation (candidate) from the program to the specification. This must be useful because of the small world hypothesis [11], which means that most flaws of programs lurk in a shallow depth and could be found

with such exhaustive testing in a shallow depth. The second set of experiments (shown in Fig.7) indicates that it would not be feasible to exhaustively test state sequences whose length is large and that are generated from a concurrent program with a formal specification and a simulation relation (candidate) from the program to the specification. There may be flaws lurking in programs in a non-shallow depth [12]. Therefore, it is worth testing state sequences whose length is large. It seems feasible to do so selectively. What and how long state sequences are selected is one piece of our future work.

The present paper does not mention anything about how to generate state sequences from concurrent programs. We plan to use Java as a programming language to write concurrent programs and to use JPF to generate state sequences from concurrent programs.

Abstract— Traditional access control models aim to prevent data leakage via direct accesses. A direct access occurs when a requester poses his query directly on the desired object. However, these models fail to protect sensitive data from being accessed with inference channels. An inference channel is produced by the combination of the legitimate response which a user receives from the system and metadata. Detecting and removing inference in database systems guarantee a high-quality design in terms of data secrecy and privacy. Parting from the fact that data distribution exacerbates inference problem, we give in this paper a survey of the current and emerging research on the inference problem in both centralized and distributed database systems and highlighting research directions in this field.

Keywords- Access Control, Inference Control, External Knowledge, Data Distribution, Secrecy and Privacy

I. INTRODUCTION

Access control models protect sensitive data from direct disclosure via direct accesses, however they fail to prevent indirect accesses [10]. Indirect accesses via inference channels occur when a malicious user combines the legitimate response that he received from the system with metadata. According to [11], external information to be combined with data in order to produce an inference channel could be database schema, system's semantics, statistical information, exceptions, error messages, user-defined functions and data dependencies. Detecting and removing inference in database systems guarantee a high-quality design in terms of data secrecy and privacy since this latter is considered as a new vision of the inference problem. Absolutely, this diversity of techniques to bypass access control mechanisms with inference channels has attracted considerable attention in recent years. A growing body of literature has examined the inference problem but no one of the proposed solutions seems to be the universal one. In reality, for each of the underlying techniques a specific solution has been proposed for handling each particular attack. There is consensus among security community that data distribution exacerbates inference problem. This is why several attempts have been done in the last two decades to

address this problem. This paper investigates current and emerging research on the inference control in centralized database systems, then it highlights inference in distributed environment. The reminder of this paper is organized as follows: Section 2 provides a brief description of research efforts on controlling inference in centralized database systems, section 3 review works on the inference control in distributed environment. Research directions are given in section 4. Finally, we conclude in section 5.

II. INFERENCE CONTROL IN CENTRALIZED DATABASE SYSTEMS

Traditional access control models aim to prevent data leakage via direct accesses. A direct access occurs when a requester poses his query directly on the desired object. However, these models fail to protect sensitive data from being accessed via indirect accesses [10]. An inference problem (also called inference aggregation problem) occurs when a user deduces sensitive information from a sequence of innocuous information in the database. It has been widely investigated in the literature since 1987 with the emergence of multilevel database systems. The first works in this field are presented in [16, 20, 22].

A. Inference Attacks and Prevention Methods

According to [10], there are three types of inference attack: Statistical attacks, semantic attacks and inference due to data mining. For each of the mentioned techniques, researchers have devoted a lot of efforts to deal with inference problem. For statistical attacks, techniques like Anonymization and Data-perturbation have been developed to protect data from indirect access. For security threats based on data mining, techniques like privacy-preserving data mining and Privacy-preserving data publishing was carried out. Furthermore, a lot of works have investigated the semantic attacks [3, 15, 20].

There exist in the literature more than one criteria to classify approaches that deal with inference. One proposed criteria is to classify these approaches according to data level and schema level [28]. In such classification, inference constraints are classified into schema constraints level and data constraints level. Other criteria could be according to

the time when the inference control techniques are performed. According to this criteria, the proposed approaches are classified in two categories: design time [7, 13, 14, 15, 20, 26] and query run time [1, 3, 11, 21, 22].

B. Discussion of the Inference Prevention Methods

The purpose of inference control at design time is to detect inference channels from earliest stage and eliminate them. These approaches provide a better performance for the system since no monitoring module is needed when the users query the database, by consequence improving query execution time. Nevertheless, design time approaches are too restrictive and may lead to over classification of the data. Besides, it requires that the designer has a good concept of how the system will be utilized. On the other hand, run time approaches provide data availability since they monitor the suspicious queries at run time. However, run time approaches lead to performance degradation of the database server since every query needs to be checked by the inference engine. Furthermore, the inference engine needs to manage a huge number of log files and users. As a result, this could induce slowing down query processing. In addition, run time approaches could induce a non deterministic access control behavior (users with the same privileges may not get the same response).

To summarise, the main evaluation criteria of these techniques is a trade-off between availability and system performance. We assert that the distribution of the data exacerbates the inference and privacy problems. In the next section we investigate the inference problem in distributed environment.

III. INFERENCE CONTROL IN DISTRIBUTED ENVIRONMENT

Inference control in distributed environment have been investigated from early 2000 until now. This field of study has received intention from researchers in database security, due to the fact that distribution aggravates inference problems and privacy concerns. In this section, we start by investigating research efforts on inference prevention in distributed database systems, then we review inference in data integration systems and discuss different works for mitigating this later. We survey inference problem in data integration systems through the *Mediator/Wrapper* architecture for the reason that this is the most suitable design to access distributed, heterogeneous and autonomous data sources. Additionally, we highlight inference prevention methods in data outsourcing scenario.

A. Inference Control in Distributed Database Systems

In [4], the authors have considered the inference problem where the data is combined from distributed database and released to the final users. In this situation of data dissemination, problem arises when non-sensitive attributes compromise sensitive attributes. According to presented work, one technique to mitigate inference is by modifying the non-sensitive data in the database.

Nevertheless, even with this modification, sensitive attributes still deducible when data from other databases is incorporated. The main idea behind this work is to not release certain non-sensitive information that can lead to probabilistic inference about the sensitive information while minimizing the loss of functionality. Consequently, the outputs are records that have been modified in order to anonymize sensitive attributes.

The authors of [24] have built on [4] to develop a work turning around inference prevention in distributed database systems. They proposed an inference prevention approach that enables each of the database in a distributed system to keep track of probabilistic dependencies with other databases and by consequence use that information to help preserve the confidentiality of sensitive data. The methodology is called "Agent-based" because every node in the distributed system is augmented with an agent to keep track of other nodes so that single point of failure and communication bottleneck are avoided. However, this approach has some limits. It treats the case where the distributed databases are overlapped (similar or have common attributes). Moreover, it assumes that the records in the distributed databases share the same keys constraints.

Inference problem have been also investigated in Peer-to-Peer environment through the work in [6]. The authors pinpoint the inference that occurs in homogeneous peer agent through distributed data mining and call this process peer-to-peer agent-based data mining systems. They assert that performing Distributed Data Mining (DDM) in such extremely open distributed systems exacerbates data privacy and security issues. As a matter of fact, inference occurs in DDM when one or more peer sites learn any confidential information about the dataset owned by other peers during a data mining session. The authors firstly classified inference attacks in DDM in two categories: inside attack scenario and outside attack scenario. After identifying DDM inference attacks, the authors propose an algorithm to control potential attacks (inside and outside attacks) to particular schema for homogeneous distributed clustering, known as *KDEC*. However, the algorithm proposed by the authors need to be improved from an accuracy point to expose further possible weakness of the *KDEC* schema.

B. Inference Control in Data Integration Systems

Inference control in data integration systems have been investigated in the last decade through the works in [12, 17, 18]. In such systems, a mediator is defined as a unique entry point to the distributed data sources. It provides to the user a unique view of the distributed data. From a security point of view, access control is a major challenge in this situation since the global policy must comply with the source policies. Complying with source policies means that a prohibited access at the source level should be also prohibited at the global level. [12, 17, 18] have demonstrated that despite the generation of a global policy at the mediator level that synthesizes and enforces the back-end data sources policies,

security breaches still possible via inference channel produced by semantic constraints. The problem is that the designer of the system cannot anticipate the inference channels that arise due to the dependencies that appear at the mediator level.

The first work attempting to control inference in data integration systems was introduced in [12]. The authors propose an incremental approach to prevent inference with functional dependencies. The proposed methodology includes three steps: synthesizing global policies, detection phase and Reconfiguration phase. In this work, authors have discussed only semantic constraints due to functional dependencies. Neither inclusion nor multivalued dependencies was investigated. Besides, other mapping approaches need to be discussed such as LAV and GLAV approaches.

The authors of [18] have inspired from [12] to propose an approach aiming to control inference in data integration systems. The proposed methodology resort to formal concept analysis as a formal framework to reason about authorization rules and functional dependencies as a source of inference. The authors adopt an access control model with authorization views and propose an incremental approach with three steps: generation of the global policy, global schema and global FD, Identifying disclosure transactions and Reconfiguration phase.

In [17] the authors have examined inference that arise in the web through RDF store. They propose a fine-grained framework for RDF data, then they exploit close graph to verify the consistency propriety of an access control policy when inference rules and authorization rules interact. Without accessing the data (at policy design-time), the authors propose an algorithm to verify if an information leakage will arise given a policy P and a set of inference rules R . Furthermore, the authors demonstrate the applicability of the access control model using a conflict resolution strategy (most specific takes precedence).

C. Inference and Data Outsourcing

Inference problem was not only investigated in previous distribution scenarios but also in data outsourcing. In this case, data owners place their data among cloud service providers in order to increase flexibility, optimize storage, enhance data manipulation and decrease processing time. Nonetheless, data security is widely recognized as a major barrier to cloud computing and other data outsourcing or Database-As-a-Service arrangements. Users are reluctant to place their sensitive data in the cloud due to concerns about data disclosure to potentially untrusted cloud providers and other malicious part [27]. It is from this perspective that inference problem was investigated in [2, 8].

In [2] authors resort to a controlled query evaluation strategy (CQE) to detect inference based on the knowledge of non-confidential information contained in the outsourced

fragments and priori knowledge that a malicious user might have. Regarding that CQE relies on logic-oriented view on database systems, the main idea of this approach is to model fragmentation logic-oriented too allowing for inference proofness to be proved formally even the semantic database constraints that an attacker may hold. Besides, vertical database fragmentation technique was considered by authors in [8] to ensure data confidentiality in presence of data dependencies among attributes. Those dependencies allow unauthorized users to deduce information about sensitive attributes. To tackle this issue, authors reformulate the problem graphically through an hypergraph representation and then compute the closure of a fragmentation by deducing all information derivable from its fragments via dependencies to identify indirect access. Nevertheless, the major limit of this approach is that it explores the problem only in single relational database.

IV. RESEARCH DIRECTIONS

Since the discussed works are recent, there are a number of concepts associated to security policies, privacy, data distribution and semantic constraints which could be considered to ensure better security and prevent inference from occurring in distributed environment. Hence, there are many research directions to pursue:

- Absence of modularity in data integration systems: in the case where a new source joins the system it is necessary to revise the global schema and the global policy. This is not suitable for distributed environment where the source joins and leaves the system continuously (e.g. Mobile environment).
- Authors deal only with semantic constraints represented by functional dependencies and probabilistic dependencies as a source of inference. However, other semantic constraints, example inclusion dependencies, join dependencies and multivalued dependencies should be considered as sources of inference.
- In data integration scenario, all approaches aim to handle inference at query run time by keeping track of the history of user queries and the current query. In the case where the system deals with a large volume of data and users number, run time approaches will lead to performance degradation by slowing down query processing, consequently, this may push the server (mediator) to bottleneck. Hence, design time approach should be adopted to overcome these problems since it is performed offline.
- Another weakness in these approaches is the negligence of collaborative inference. In fact, authors propose to block a sequence of violating transaction from being achieved to prevent the inference channel, but, what if this violating transactions results from a

combination of a set of queries from more than one user?

- Functional dependencies should be considered as a source of inference in data outsourcing scenario. although data dependencies may resemble functional dependencies, they model a different concept. In future work, we will present a study aiming to prevent inference from occurring in distributed cloud database. Our approach is graph-based that firstly detects inference channels caused by functional dependencies and secondly breaks those channels by exploiting vertical database fragmentation while minimizing dependencies loss.

V. CONCLUSION

This paper has surveyed the inference problem from two perspectives: centralized and distributed design. We first gave a review of current and emerging research about the inference control in centralized database systems, we have introduced different inference attacks and their prevention methods and discussed the trade-off between them. Furthermore, an insightful discussion about inference control in distributed environment was provided. We also pinpoint potential issues that are still unresolved. These issues are expected to be addressed in future work.

Abstract—Software testing is widely perceived to be the main activity in the software development process that provides confidence in the quality of a product prior to release. However, the term *software testing* itself provokes a multitude of different definitions and opinions as to the nature of the profession, the role of software testers and the utility of different processes and tools that come with the territory [1][2]. We argue that in order for researchers to effectively study the field and contribute to its progress, a consensus first needs to be reached about the entity being studied. In this paper we present an empirical study based on the modified Delphi card sort method involving four cohorts of testers in Malta and London. The result of this study is a consolidated consensus-based mental model outlining how software testers perceive their profession. This mental model can be used to align any future research efforts and tool development with testers’ own perception of their context.

Index Terms—Software testing, human factors and ergonomics, mental models

I. INTRODUCTION

“Ergonomics [or human factors] is the scientific discipline concerned with the understanding of interactions among humans and other elements of a system, and the profession that applies theory, principles, data and methods to design in order to optimise human well-being and overall system performance.” [3]

Testing is a human-intensive activity, requiring constantly changing information, in different formats, from various sources with different levels of access and over a variety of channels and tools. The level of experience and training background adds up to the complex nature of the domain, all of which contribute to high levels of cognitive workload. To date, and to the best of our knowledge, testing as a discipline in its various forms and shapes has never been treated scientifically from an ergonomics and human factors perspective. The terms ‘ergonomics’ and ‘human factors’ are interchangeable, however their use implies either the immediate physical environment (e.g. the workbench), or to the wider context in which work is carried out (e.g. the process), respectively [4].

In the past, we have attempted to treat this domain from both an ergonomics perspective (e.g. augmented reality in workbenches, just-in-time information and cognitive workload as well as from a human-factors perspective (e.g. the impact of training on tester performance [5], human-centred test

frameworks). Throughout this period we also immersed ourselves in practice within industry teams, as much as possible, to be able to experience and discuss issues with industry professionals.

It transpires that there is a more pressing need that needs to be tackled first before we are able to further this line of investigation. Due to the complexity of the domain, different people will have different and often wide-ranging perceptions and expectations of testing in practice and theory. Therefore, to be able to reason in terms of human factors and ergonomics in testing, we first need to build a clear picture of how testers reason about testing in general. This paper aims to achieve this. We therefore present a mental-model built following an empirical exercise with software testing professionals in Malta and London using the modified Delphi card sorting method. This mental-model aims at providing a common vocabulary through which we can study problems and propose solutions which would ultimately benefit software testers and their well-being.

A mental model or a conceptual model, represents the “cognitive shorthand” [6] of how a person, or a group of people, understand a complex product or domain. Looking at this from the perspective of a website, this conceptual model is enough to help users navigate and interact with the site, however if the implementation varies widely from the users’ mental model, users will find it close to impossible to reach their goals without having to think hard about their actions and how the site is reacting.

Although we understand that testing is complex in nature, we present a mental model based on a consensus-driven empirical exercise which elicits testers’ beliefs about the domain and its various aspects. This aims to inform human factors and ergonomics researchers and designers in their effort to contribute towards this domain. Through an understanding of how testing professionals perceive this domain, contributions could be better aligned and communicated to resonate with the nature of their work. A designer’s primary goal is to build user interfaces that map as closely as possible with the users’ mental models, abstracting away the internal complexities [7]. This same principle applies for research efforts, whereby we first need to understand the primary stakeholders’ beliefs and perceptions driving everyday work before being able to improve working conditions. Closing the gap between testers’ mental models and researchers’ perceptions or beliefs about the domain increases the chances of (a) improving the tester’s

well-being by solving the right problems at the right level, and (b) adoption of research outcomes in industry. As in design, research efforts need to be aligned with the user's mental model. For this to happen, researchers need to use their expertise in research and frame their efforts as closely to the testers' mental model as possible, building a model which bridges their knowledge and efforts with testers' perceptions. Cooper defines this as the "represented model" which is "one of the designer's most important goals". Cooper states that "it is critical that designers understand in detail how their target users think about the work they do with the software" [6].

II. SOFTWARE TESTING

Software testing is an activity predominantly associated with ensuring that a product meets a certain level of quality before it is released to customers. Despite its widespread use and numerous practitioners worldwide, software testing is arguably the least understood part of the development process [2]. In the two decades that we have studied and practised in the field, the lack of consensus on the nature of the field, its processes, tools and practitioners' role has been an ever palpable characteristic. Many conversations that we have had about software testing decisions in the industry have involved phrases like "*I do not believe in automated testing*", "*that is not what I think your role as a tester should be*" or "*we need to release tomorrow, can you test this quickly please?*".

Even definitions by respected authorities differ, albeit with some overlap. The British Standards Index refers to software testing as the activity of exercising software with the intent of finding errors and verifying that it satisfies specified requirements [8]. The IEEE has a similar definition but includes the notion that a system can be tested without being exercised (inspection). The ISTQB syllabus [9] (the de facto standard for tester certification) makes reference to testing being a measurement of software quality.

Within the field itself, there are a multiplicity of roles, taxonomies, strategies, techniques, processes and tools. The correct time, place and usage of each of these elements is the subject of frequent debate, which has also given rise to different schools of thought within the industry. Engineering-driven schools treat testing as a standards-driven industry which practitioners can consequently be trained and certified in. On the other end of the scale, the "Context-Driven" school of thought claims that the value of any practice depends on its context and the concept of a one-size-fits-all definition of the field and its practices is misguided [10].

In a widely cited paper charting the progress and future direction of the field, Bertolino [1] makes reference to the multiplicity of meanings that arise from the term "software testing", as well as the particular research challenges that this fact generates. Bertolino goes on to set out the field's achievements to date, ongoing challenges and future dreams. The first dream she outlines is that of the development of a unified theory of testing.

This lack of clarity is a contributing motivation behind this work. Before one can design research, tools and processes that

cater for the human tester more effectively, one first needs to understand the role and subsequent needs of the human tester. To this end, we undertook a consensus-based investigative approach as discussed in the following section.

III. METHODOLOGY

Motivated by the objective of establishing a consensus-based mental model amongst practitioners in the field about the nature of software testing, we selected a methodology centred around the Modified Delphi Card Sort method. The Delphi technique is a widely used and accepted method for gathering data from respondents within their domain of expertise [11]. Originally developed in the 1950s by Dalkey and Hemler [12], it has been widely used and adapted in various disciplines as a means of seeking out information that can generate consensus amongst participants.

Whereas initial versions of the technique involved using questionnaires with participants, we have chosen to use a card-sort variant whereby participants are asked to group concepts from their domain under categories using index cards. This can be done in one of two ways. The first is to utilise an open card-sort approach, whereby participants start with an empty slate and build a representation from there. The second way involves providing the first participant with a so-called *seeded deck*, that is, an initial model of the domain which she may choose to agree or disagree with in whole or in part. The participant can make any changes she sees fit by changing categories, adding terms and removing others. The result of the first participant's card sort are used as the seeded deck for the next participant, and so on. This technique has been shown to converge to a consensus with as little as 8-10 participants [13].

As depicted in Figure 1, two card sort exercises were carried out: one during a meeting of professional testers in Malta and another at a similar meeting organised by the British Computer Society in London.

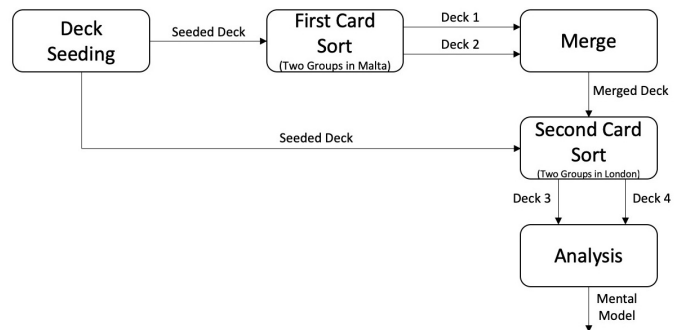

Fig. 1. An overview of the process used during the study.

Following an initial deck seeding exercise (Section III-A), two parallel card sort exercises were carried out (Section III-B) by two cohorts of participants, which resulted in two sorted decks that were subsequently merged (Section III-C). A second card sort (Section III-D) then took place, again with two parallel cohorts, one using the original seeded deck

and the other using the merged deck from the first card sort. This resulted in two final decks of cards which were fed into an analysis process (Section III-E) in order to produce the consolidated mental model. Each of these stages are discussed in turn below.

A. Deck Seeding

The seeded deck was compiled from a subset of terms found in a glossary published by the International Software Testing Qualifications Board (ISTQB) [14]. Given that the glossary contains over 600 terms, our initial processing of the glossary involved the removal of outlier terms and synonyms. Whilst outlier terms consisted of terms which we felt would not be helpful as part of the seeded deck (e.g. *Agile Manifesto* and *Myers-Briggs Type Indicator*), it is worth noting that should we be mistaken, it was entirely permissible for the terms to be reintroduced by participants during the card sort. At this point, we carried out a manual categorisation of the remaining terms into five broad categories: (1) *Testware* refers to entities that exist in the most part to enable and/or support the planning and execution of testing activities on a project; (2) *Artefact* refers to entities that are created, used and manipulated by testers or other stakeholders at some point during the testing process; (3) *Runtime*: refers to terms which represent entities that come into play in the period that a system is being executed as part of a test; (4) *Tools*: refers to devices, typically embodied as software systems that help support testers in a variety of tasks; and finally (5) *Test Strategy*, a category containing terms that identify different types of plans of action that testers can use to achieve their goal during software testing.

Once these categories were identified, we manually reduced the amounts of terms in each category based on our knowledge of the testing domain. Therefore, whereas a category called *Test Strategy* initially contained eighty terms, we manually reduced this to seven by keeping the most common strategies (e.g. *Acceptance Testing*) and removing the more obscure ones (e.g. *Monkey Testing*).

The resulting seeded deck consisted of five categories and twenty-five terms as shown in Table I.

TABLE I
THE CONTENTS OF THE INITIAL SEEDED DECK.

Category	Seeded Terms
Testware	Test Outcome, Test Data, Reports, Documentation, Test Suite, Test Script
Artefact	Features, Bugs, Code
Runtime	Configuration, System Under Test, Environment, Tester
Tools	Static Analysis Tools, Coverage Tools, Performance Testing Tools, Bug Tracking Tools, Automated Testing Tools
Test Strategy	Acceptance Testing, Ad Hoc Testing, Branch Testing, Exploratory Testing, Integration Testing, Performance Testing, Regression Testing

The materialisation of this seeded deck enabled us to move on to the next stage of the study.

B. First Card Sort - Malta

Armed with two copies of the seeded deck, we attended a gathering of software testing professionals in Malta and recruited sixteen participants, who we split evenly into two cohorts. Each participant was asked to reflect on their mental model of software testing and subsequently spend as much time as needed to modify the deck so that it accurately fit his/her mental model. This was done by any combination of (1) *adding* new terms or groups; (2) *moving* cards between groups; and (3) *removing* terms or groups which they considered not to be a fit for purpose. When a participant was finished, the next participant was asked to come in and continue the exercise.

At the end of the exercise, the two decks were analysed and merged into a single deck as discussed in the following section.

C. Merging of Decks

The two decks resulting from the parallel card sorts carried out in Malta were merged using a five-step process as follows. The first step involved *discarding replicated terms* such that terms which were added multiple times in the same deck were earmarked for discarding so that only one instance of each term remained. In cases where the terms appeared in different categories, reference to the ISTQB Glossary [14] was made in an effort to choose the category that best fit the emerging mental model. The next step involved *renaming of synonyms* to make sure that any instances whereby testers were referring to the same concept using different labels, one term was selected and used in place of all the synonyms. We then turned our attention to categories and automatically *retained any categories that were common in both decks* for the merged deck. Similarly we also *retained terms that appeared in both decks*. If the terms appeared in different groups, a judgement was made as to which group was the best fit for that term. Finally, we *discarded any empty categories*. Any categories that contained no terms following the preceding steps in the merge were discarded.

The two card sort exercises in Malta both retained the original five categories from the seeded deck and added four groups between them. However, the merging process resulted in the four new categories having no terms and were consequently removed. This resulted a merged deck with the characteristics described in Table II.

TABLE II
THE NUMBER OF INITIAL (I), RETAINED (R), ADDED (A), DELETED (D) AND FINAL (F) TERMS FOLLOWING THE FIRST CARD SORT AND MERGE.

Category	I	R	A	D	F
Testware	6	5 (83%)	2 (33%)	1 (17%)	7 (+17%)
Artefact	3	2 (67%)	5 (166%)	1 (33%)	7 (+133%)
Runtime	4	3 (75%)	2 (50%)	1 (25%)	5 (+25%)
Tools	5	4 (80%)	8 (160%)	1 (20%)	12 (+140%)
Test Strategy	7	5 (71%)	7 (100%)	2 (29%)	12 (+71%)
Totals:	25	19 (76%)	24 (96%)	6 (24%)	43 (+72%)

The figures in Table II indicate that there was an overall increase of 72% in the size of the mental model with about

24% of our initial seeded deck being rejected by participants. The highest relative increases were in the *Tools* category (+140%) and the *Artefact* category (+133%).

D. Second Card Sort - London

In order to further refine the emerging mental model, two cohorts of seven volunteers attending a one-day software testing conference organised by the British Computer Society in London were tasked with carrying out a further card sort. One cohort started with the original seeded deck whilst the other one started with the merged deck. The exact same protocol that was used in the first card sort was utilised in the second card sort with the results being fed into the final stage of the study.

E. Analysis

The card sort exercises generated 83 terms in total and each was either seeded, added, removed or moved at one or more points during this study. In order to make sense of this data, a scoring system was devised whereby every time participants interacted with a term, the term would gain or lose a certain amount of points. Therefore, when a term was seeded by a researcher, added by a participant or removed by a participant, it gained 1 point, 2 points and lost one point respectively. Whilst these values may seem arbitrary, they were designed to (1) characterise each term's journey through the study into a single score; and (2) assign more importance to terms which were added by participants without any prior mention.

The result was a ranked list of 83 terms in five categories which was then analysed by researchers with a view of establishing a cutoff point in each category that would indicate which terms should be included in the consolidated mental model. The cutoff decision was made based on (1) identifying points in the list where a significant scoring gap occurred between one term and the next; and (2) manually removing terms which objectively did not fit the category or were synonyms for other terms that were already included. The result was a mental model with the same categories as those designed in the original seeded deck.

IV. DISCUSSION

The mental model resulting from the research is represented in the form of a mind map in Figure 2. In this section, we discuss characteristics of this mental model and comment on its convergence, evolution and its implications on testers' perception of their field.

A. Convergence

Consistent with other studies that used the Modified Delphi Card Sort method, participants appear to converge towards a consensus relatively quickly. As shown in Table III, whereas the first card sort resulted in an increase in deck size from 25 to 43 terms (72%), there was only a net decrease of 2 terms (-5%) in deck size following the second card sort. Also, as shown in Table IV, more terms were retained, and less were added or removed as research progressed from the first to the second card sort.

TABLE III
COMPARING MENTAL MODEL SIZE FROM THE SEEDED DECK (Δ_s) THROUGH TO THE MERGED DECK (Δ_m) AND THE FINAL MENTAL MODEL.

Category	Seeded #	Merged #	Δ_s	Final #	Δ_s	Δ_m
Testware	6	7	+17%	5	-17%	-29%

TABLE IV
TERMS RETAINED, ADDED AND DELETED BETWEEN SUCCESSIVE DECKS.

	Seeded \rightarrow Merged	Merged \rightarrow Final
Retained	19 (76%)	37 (86%)
Added	24 (+96%)	4 (+9%)
Deleted	6 (-24%)	6 (-14%)
Net Churn:	18 (+72%)	-2 (-5%)

B. How the seeded model evolved

The contents of the Testware category remained mostly unchanged with no terms being added and one term (*Documentation*) being moved to the Artefacts category. The Artefacts category itself grew threefold in size from three terms to nine with practitioners strongly backing terms that the original seeded model had left out. Interestingly, the term *Features* was consistently removed by participants but was replaced by multiple other terms such as *Specification* and *Acceptance Criteria*.

The Runtime category retained all but one of its seeded terms (*Tester*) and doubled in size from three to six terms with the testers introducing the terms *Mocking*, *User* and *Bugs*.

Finally, practitioners retained most of the terms from the Tools and Test Strategies categories, removing two terms from each category but also supplemented each category considerably. Six new types of tools were added, as well as six new testing strategies. All terms added received consistent backing from participants in successive card sorts.

C. Interesting Observations

The process of obtaining information about the mental model of software testers from practitioners themselves provided some interesting insights.

Firstly, testers do not see themselves as part of their own mental model. The term *Tester* was presented to three cohorts as a result of being part of the seeded deck. However, it was removed every single time. This indicates to us that contrary to our view that the tester should be at the centre of any discussion related to the testing process, the testers take themselves out of the equation. This flies contrary to many discussions we witnessed in the industry whereby testers would express frustration at not being included enough in the software development process.

Secondly, testers need to somehow effectively use as many as eleven different testing strategies in their day-to-day job. This is complemented by nine different types of testing tools,

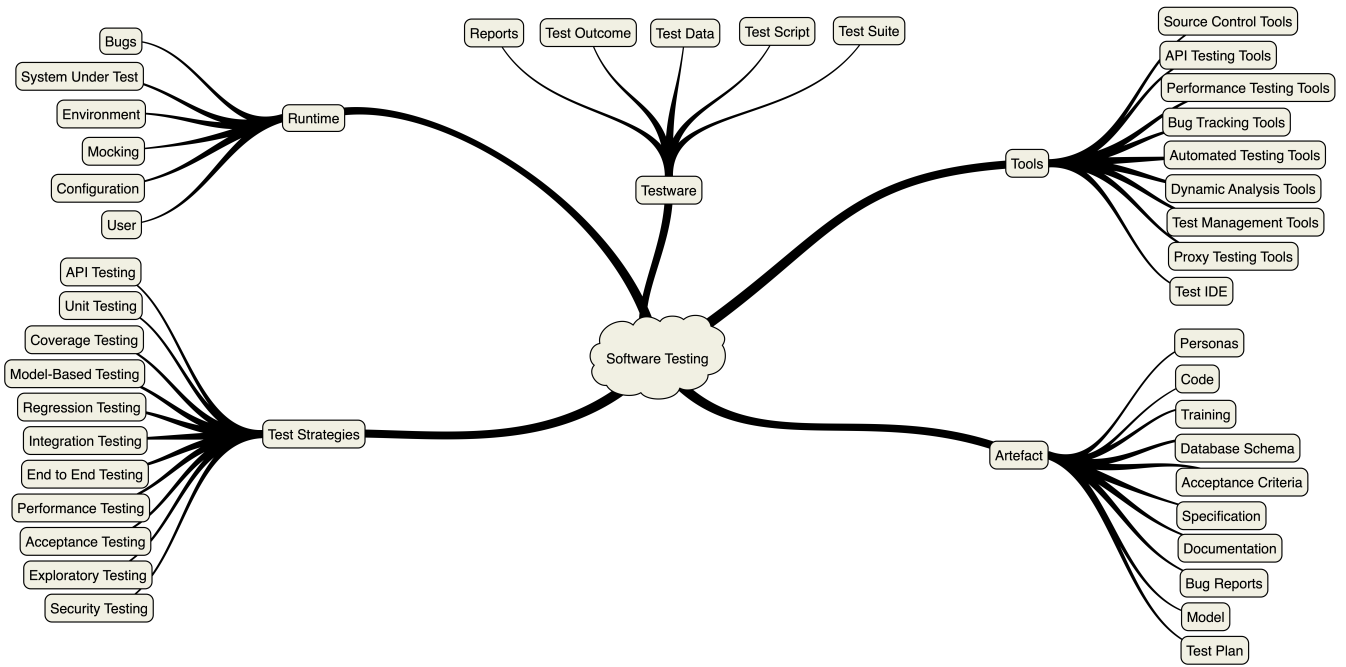

Fig. 2. The tester’s mental model that resulted from the card sorts.

which hopefully make the testers’ lives easier. This indicative of the highly complex nature of the testing profession.

In the multiple opportunities that presented themselves throughout this study (from seeding through multiple card sorts), the term *Usability Testing* was only mentioned once and did not make it into the consolidated mental model. This is interesting because it indicates that testers do not perceive usability testing as a core part of their job. Rather, they are concerned with ensuring that the product meets the stated specifications, even if the specifications do not necessarily provide the customer with the experience they desire. Given the ease with which customers can move to competitors in today’s dynamic online markets, this type of thinking could be counterproductive and end up producing high quality software that customers do not want [15].

V. RELATED WORK

In this section, we compare and contrast our work with similar research efforts. Different works in the literature concerned with understanding the software testing domain exist for one of three reasons: (1) understanding the application of testing in a specific domain; (2) knowledge management; or (3) forming a more coherent understanding for pedagogical purposes.

With regards to domain-specific work, Nasser et al. [16] present an ontology based on state machine based testing whilst Sapna and Mohanty’s [17] work focuses on scenario-based testing. Yu et al. [18] focus on understanding software testing as a service (TAAS). Whilst such studies have value at forming an in-depth understanding of testing within individual domains, our work is more focused on forming a wider practitioner-oriented understanding of the field. Nevertheless,

it is interesting to note how the organisation of different models differs based on their focus. For example, Yu et al. [18] proposed categories such as *Test Type*, *Target Under Test*, *Test Environment* and *Test Schedule*. Whilst these categories bare resemblance to those in our work and the work of others, the emphasis can be seen to focus on scenarios whereby testing is perceived (and even sold) as an outsourced service.

Focusing on increasing testcase reuse through knowledge management, Guo et al. [19] develop an ontology centred solely around the *test case*. They develop and propose the use of their unified standard format for test cases and argue that this can promote reuse. Focusing on web services, Bai et al. [20] propose a so-called Test Ontology Model that models testing artefacts and relationships between them. Barbosa et al. [21] propose *OntoTest* a collection of six sub-ontologies of testing named as *Testing Process*, *Testing Phase*, *Testing Artifact*, *Testing Step*, *Testing Resource*, and *Testing Procedure*.

Perhaps the work that is most closely related to this paper is that by Arnicans and Straujums [22] who propose a hierarchical model of the testing domain constructed from the 800 entries in the ISTQB Glossary [14], the same source used for creating the seeded deck in our study. Using a technique whereby each term in the glossary was assigned a weight and subsequently related to other words, they converted the ISTQB Glossary into a browsable hierarchical concept map. They found that the ‘weightiest’ nine terms were *testing*, *test*, *tool*, *software*, *process*, *analysis*, *capability*, *technique* and *coverage*. These top-level terms contain 425 (70%) of the glossary’s entries between them. There are some similarities between Arnicans and Straujums’ top terms and the categories in our mental model but the mapping is not direct. For example, the

term *tool* maps to our *tools* category whilst *software* maps to *artefact* and *technique* maps to *test strategies*. However, the terms contained in each of these mapped categories are not the same. One example is that some techniques that we refer to as strategies, are referred to as being part of the *process* category in Arnicans and Straujum's work. One should note that the scope behind the work differs from ours in that whilst Arniscans and Straujum are concerned with making the ISTQB Glossary more understandable, we are interested in understanding the mental model held by practitioners in the field.

VI. CONCLUSIONS AND FUTURE WORK

We motivated this study by arguing that since testing is a human-intensive activity, the human tester needs to be at the centre of research contributions to the field. This implies that testing, as a discipline, would benefit from being treated scientifically from an ergonomics and human-factors perspective. However, our initial work in this area uncovered a lack of clarity as to what exactly constitutes software testing from the tester's perspective.

As a result of the study presented in this paper, we propose a mental model elicited from practitioners using a consensus building approach. Having this mental model available provides researchers with an insight into how testing practitioners perceive their professional context and can thus form as a basis for aligning research efforts with practitioners' views. The

A. Future Work

With regards to future work, we would like to pursue two main paths of research. Firstly, we would like to continue to validate the model through further card sorts in order to reduce external threats to validity whilst also gaining a deeper understanding about whether cohorts of testers with specific characteristics (e.g. experience testers or testers working in a specific domain) would diverge from the model. Our initial discussions with peers about the results presented here resulted in questions regarding issues such as how the background of participants might have affected the results or why certain terms do not appear. It would be interesting to investigate these questions and also repeat these exercises on a regular basis to understand if and how practitioner perceptions evolve. Secondly, we would like to revisit our work on treating software testing from an ergonomics and human factors perspective (e.g. augmented reality workbenches, just-in-time information and cognitive workload) in light of the mental model and its implications. This will help us refocus such efforts so as to increase the chances of (a) improving the tester's well-being by solving the right problems at the right level, and (b) adoption of research outcomes by industry stakeholders.

mental model by no means covers the whole testing domain but we argue that aligning research efforts to this model is more likely to provide value to the practitioners who created it.

Semantic Analysis for Deep Q-Network in Android GUI Testing

Tuyet Vuong*, Shingo Takada*

*Dept. of Information and Computer Science, Keio University, Yokohama, Japan

{tuyet, michigan}@doi.ics.keio.ac.jp

Abstract—Since the big boom of smartphone and consequently of mobile applications, developers nowadays have many tools to help them create applications easier and faster. However, efficient automated testing tools are still missing, especially for GUI testing. We propose an automated GUI testing tool for Android applications using Deep Q-Network and semantic analysis of the GUI. We identify the semantic meanings of GUI elements and use them as an input to a neural network, which through training, approximates the behavioral model of the application under test. The neural network is trained using the Q-Learning algorithm of Reinforcement Learning. It guides the testing tool to explore more often functionalities that can only be accessed through a specific sequence of actions. The tool does not require access to the source code of the application under test. It obtains higher code coverage and is better at fault detection in comparison to state-of-the-art testing tools.

Keywords: *Automated Android Testing; GUI Testing; Reinforcement Learning, Deep Q-network*

I. INTRODUCTION

In 2017, the number of monthly active Android devices reached a new milestone of 2 billion [1], accompanied by about 3 million applications in the Google Play Store [2]. The mobile application market is on-demand and so competitive that a small bug in the software can cause users to uninstall the product and opt for another. Assuring application quality is hence very important. Even though a lot of effort has been made to develop automated testing techniques, we still heavily rely on manual testing in practice, with only 3% of developers fully engaging in automation [3]. Developers also admitted in recent surveys that Graphical User Interface (GUI) testing is especially labor-intensive, time-consuming, and challenging to automate because GUI tests must be constantly rewritten when changes, even small, are made [3].

Android application's GUIs contain various types of *components* such as button, text input, slide bar, switch, etc. Moreover, users can interact with each type of component in multiple ways through *events*: click, long click, swipe, scroll, etc. This complexity makes GUI testing techniques like random testing inefficient because it attributes a uniform probability distribution to all combinations of components and events, while an efficient testing strategy should select and follow the specific paths that reveal application's functionalities.

In our previous work [4], we presented an automated testing tool implementing the classic Q-Learning algorithm of reinforcement learning, which demonstrated positive improvements in code coverage. In this paper, we continue to follow the reinforcement learning approach and propose two main contributions:

- Improve the learning of the application's behavioral model by analyzing the semantic representations of GUI components.
- Use Deep Q-Network [5] to approximate the behavioral model of the application under test.

The remainder of this paper is organized as follows: Section II reviews related work in Android automated testing and the application of reinforcement learning in software testing. Section III provides a brief introduction to Deep Q-Network. Section IV elaborates our proposed approach and implementation details. Section V analyzes the evaluation results and finally section VI concludes the paper along with suggestions for future works.

II. RELATED WORK

In recent years, researchers have tried different approaches to test Android applications, among the most popular trends are random testing, model-based testing, and heuristic-based testing. Tools such as Puma [6] and A3E [7] build a model of the application under test then systematically explore the application based on this model. On the other hand, Evodroid [8] and Acteve [9] use special algorithms such as symbolic execution and evolutionary algorithms to test the application. As our paper proposes a black-box GUI testing method, we investigate further in black-box GUI testing tools.

Monkey [10] is a random event generator which is embedded in the Android Development Toolkit. It is therefore commonly used thanks to its simplicity and availability. It performs tests by sending thousands of events per second to the application and usually obtains high code coverage in comparison to other testing tools [11]. Despite the high code coverage, faults discovered by Monkey are hard to locate because tests are hard to reproduce and closer to stress tests than functionality tests. Dynodroid [12] improves random testing strategy by analyzing the context of the application then executes the most relevant event at each step (RandomBiasedStrategy). Developers can provide inputs such as authentication information beforehand to the tool to

unblock some steps. Dynodroid is also capable of generating system events by analyzing the listeners of the application.

Reinforcement Learning was used in software testing in the past and has shown its ability to improve random exploration strategy. Mariani et al. proposed a tool called AutoBlackTest [13], a black-box GUI testing tool for Java desktop software. The tool uses Q-Learning algorithm to build a behavioral model of the software, represented as a multi-directional graph. Using this behavioral model, the tool can plan its exploration route in order to get to hard-to-reach GUIs (which can only be reached through a specific sequence of actions). TESTAR [14] also uses Q-Learning to generate test sequences based on GUI. The Q-Learning algorithm was proven to be beneficial, provided that we choose an adequate set of parameters.

There are currently two main approaches when applying reinforcement learning to Android testing. The first approach is proposed by Koroglu, et al. [15], where they train a single matrix across multiple apps using random exploration then use it to test other applications. The Q-value distribution matrix is trained for two objectives: increasing activity coverage and crash detection. Overall, their tool obtained higher activity coverage and number of distinct crashes compared to other state-of-the-art testing tools. The second approach is presented in our previous work [4] and the work of D. Adamo et. al [16], where a unique set of Q-value is calculated for each application.

III. DEEP Q-NETWORK

Reinforcement Learning (RL) is a field in Artificial Intelligence where an agent learns to behave optimally in its environment through trial-and-error interactions [17], step by step. At each time step t , it observes the state s_t of the environment and takes an action a_t based on its policy π . The environment then transitions to a new state s_{t+1} based on s_t and a_t . It also outputs a scalar reward r_{t+1} as feedback that the agent then uses to update its knowledge. The goal of the agent is to learn a policy π^* that maximizes the expected cumulative reward of a sequence of actions in the environment.

The reinforcement learning problem can be formulated as a Markov decision process [17], defined by:

- A set of possible states: S
- A set of possible actions: A
- A reward function for the next state given a (state, action) pair: $R(s_t, a_t, s_{t+1})$
- A transition probability i.e distribution over the next state given a (state, action) pair: $T(s_{t+1}|s_t, a_t)$
- A discount factor $\gamma \in [0, 1]$, where lower γ emphasizes more on immediate rewards.

There are two major directions in solving RL problems: algorithms based on value functions and algorithms based on policy search [18]. Q-Learning falls into the first category. For each policy π , we define an action-value function or quality function (Q-function). The value $Q^\pi(s_t, a_t)$ is the expected cumulative reward that can be achieved by executing a sequence of actions that starts with an action a_t

from a state s_t and then follows the policy π . The optimal Q-function Q^* is the maximum expected cumulative reward achievable for a given (state, action) pair, over all possible policies.

$$Q^*(s_t, a_t) = \max_{\pi} \sum_{t \geq 0} (\gamma^t r_t | s = s_t, a = a_t, \pi) \quad (1)$$

Intuitively, if the optimal quality function Q^* is known, at each step s_t , the optimal strategy is to take the action that maximizes the sum: $r + \gamma Q^*(s_{t+1}, a_{t+1})$ where r is the immediate reward of the current step. This is known as the Bellman equation in dynamic programming [19]:

$$Q^*(s_t, a_t) = R(s_t, a_t) + \gamma \max_{a_{t+1}} Q(s_{t+1}, a_{t+1}) \quad (2)$$

The Q-learning algorithm uses equation (2) to estimate the value of Q^* iteratively. The Q-function is initialized with a default value. Every time the agent executes an action a_t from state s_t to reach state s_{t+1} and receives a reward r_{t+1} , the Q-function is updated as:

$$Q(s_t, a_t) \leftarrow Q(s_t, a_t) + \alpha(r_{t+1} + \gamma \max_a Q(s_{t+1}, a) - Q(s_t, a_t)) \quad (3)$$

In this formula, $\alpha \in [0, 1]$ is the learning rate and regulates the impact of a new observation on the estimated values. The Q-learning algorithm is guaranteed to converge to Q^* if applied to a Markovian environment, with a bounded immediate reward and with state-action pairs continually updated [20].

The main motivation for the birth of Deep Reinforcement Learning (DRL) is to scale the classic RL problems to more complex state and action spaces [5] [18]. In brief, DRL trains a neural network to approximate the optimal policy and/or optimal value functions. In the case of Q-Learning, the state-value function Q is estimated by a Deep Q-Network (DQN) with weight w :

$$Q(s_t, a_t, w) \approx Q^\pi(s_t, a_t) \quad (4)$$

The weight of the DQN is updated based on a loss function defined as:

$$L(w) = (r_t + \gamma \max_a Q(s_{t+1}, a, w) - Q(s_t, a_t, w))^2 \quad (5)$$

which leads to the following Q-Learning gradient:

$$(r_t + \gamma \max_a Q(s_{t+1}, a, w) - Q(s_t, a_t, w)) \frac{\partial Q(s_t, a_t, w)}{\partial w} \quad (6)$$

The stochastic gradient descent method can then be used to minimize the loss $L(w)$ and the Q-Network will gradually converge toward the optimal Q-function Q^* . In the next section, we explain how we use Deep Q-Network to incorporate the semantic representations of GUI states to the reinforcement learning algorithm.

IV. PROPOSED APPROACH: SEMANTIC ANALYSIS OF GUI AS AN INPUT FOR DEEP Q-NETWORK IN ANDROID GUI TESTING.

In our previous work [4] we used Q-Learning algorithm as an exploration strategy to test Android applications. We

dynamically built a behavioral model of the application under test while interacting with it. With classic Q-Learning, we calculated and constantly updated a dictionary holding the Q-value of each pair of (state, event). Even though the experiment demonstrated positive results, we noticed two main weaknesses in our model:

- The purpose of the reinforcement learning algorithm is to guide the exploration toward revealing and testing the application's hard-to-reach functionalities. However, a path that reveals the application's functionalities should consider the semantic meaning of the components upon which we take action. Take the example of an alarm clock application: the sequence of actions that reveals the functionality *Change timezone* should be described as *click on a menu component - scroll down the list - click on setting - click on change timezone button*, instead of simply *click - scroll - click - click*. The latter sequence of events would have very different outcomes when being executed on different sets of components.
- The algorithm cannot scale well when the number of states, GUI components in each state, and events increase. Mobile applications are becoming more and more complex and the Android OS can now support more and more gestures (events). Our testing tool should be able to handle large and complex GUIs.

The first point is addressed by a semantic analysis of GUI components that we elaborate in the following section. As for the second point, we propose using Deep Q-network to potentially solve the complexity problem of reinforcement learning.

A. Semantic classification of Android GUI components

GUI testing tools usually interact with the application under test by sending events to UI components but few of them have considered the meaning of the components they interact with. QBE [15] took some initiatives by separating the actions on hard buttons of the phone from the on-screen events (click, long-click, etc). However, they didn't consider any semantic meaning of the GUI components on the screen. In our approach, we use the semantic information of GUI components as an input to guide the exploration.

Recent works of T.F. Liu et. al presented a guideline to identify the semantic meaning of mobile app GUI [21]. They established a lexical database of 25 types of UI components, 197 text button concepts and 135 icon classes. We're interested in the classification of UI components in particular, where components are separated into groups such as Input, List Item, Toolbar, Background Image, etc. They employed a code-based heuristics approach: using a lexical database, they classified a component by examining its Android class and the classes of its parent components.

In our testing tool, we use the same method to classify components. However, instead of classifying all visible components, we only classify actionable components, which are either clickable, long-clickable, scrollable or checkable. If a parent component is actionable, then all of its children nodes are also actionable of the same type. We reduce the number

TABLE I
CLASSIFICATION OF UI COMPONENTS

Group	Class name
Input	EditText, SearchBox, AutoCompleteTextView, AutoSuggestView, Field, Input, CheckBox, DatePicker, RadioButton, CheckedTextView, Switch, SeekBar
Navigation	ToolBar, TitleBar, ActionBar, Menu, Navigation, SideBar, Drawer, AppBar, TabWidget
List	ListItem, ListView, RecyclerView, ListPopUpWindow, GridView, GroupView
Button	Button, GlyphView, TextView, ImageView

of component types down to four main groups: Navigation, Input, Button, and List, as these group can cover the majority of actionable components [21]. The reference for classifying each group is presented in Table I, inspired by the one provided by T.F. Liu et. al.

We identify UI components in Navigation and List group by their parent nodes. In other words, once we identify a List or Navigation component by its class name, all of its children fall under the same group respectively. The Input group should be understood in a large sense, including all components that receive information from the user. Finally, only actionable TextView and actionable ImageView are classified as Button (Text Button and Image Button respectively).

B. Deep Q-Network as an Android Testing Tool

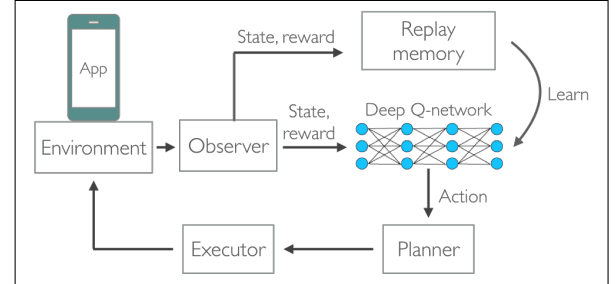

Fig. 1. The overall architecture

Our testing tool QDroid, whose architecture is presented in Figure 1, consists of 5 main modules: Environment, Observer, Deep Q-Network (including a replay memory), Planner, and Executor. QDroid interacts with the application under test step by step in order to estimate a behavioral model of the application, represented by the Deep Q-network. The goal of the testing tool is to generate test cases that test application's hard-to-reach states, cover the most code possible, and reveal faults, all in a limited amount of time.

A test case is created when the testing tool executes a sequence of actions in the application under test, this sequence is also known as an *episode* in reinforcement learning. In our implementation, an episode ends when one of the following conditions is met:

- It reaches the maximum number of 20 steps (transitions). After an empirical study where we vary the episode's length from 10 to 50, the value 20 was chosen because it gave the best average coverage across apps.
- Its last action leads to exiting the application.

- The screen is frozen (no changes in GUI) for the last 10 steps.

After an episode, the environment is reset, and the testing tool jumps to a random activity of the application. We reset the environment by killing all running processes in the emulator, then uninstalling and reinstalling the application. Each step of an episode proceeds as follows:

- 1) The *Observer* observes the application under test and builds the abstract representation of the GUI (the current *state*).
- 2) The *Observer* converts the current state into an input that we then use to feed to the Deep Q-Network.
- 3) The *Deep Q-Network* outputs a probability distribution over the next component that we should act on and passes it to the *Planner*.
- 4) The *Planner* chooses the next component to execute based on an $\epsilon - greedy$ policy.
- 5) The *Executor* executes an event on the chosen component.
- 6) The *Environment* transitions to a new state and returns the reward of the transition.
- 7) The transition, consisting of the old state, the new state, the executed component, and the reward, is added to the *Replay Memory*.
- 8) The *Deep Q-network* updates its weight by learning from a sampled batch of transitions from the *Replay Memory*.

This workflow is similar to the one in our previous work because both of them follow the Q-Learning algorithm. Nevertheless, the main difference with this architecture is concerned with the Deep Q-Network and the Observer, which also leads to changes in the Executor and the Planner. The implementation details of each module are given below:

1) *Environment*: The Environment is an interface that allows us to interact with the Android emulator and the application under test. Besides communicating with the Observer and the Executor, its most important role is to hold a function that calculates the reward value for each transition. We consider that a transition is better than another if it triggers more UI changes [13] [4]. Given two states s_1 and s_2 , the reward function calculates the degree of change from s_1 to s_2 by counting the number of GUI events in s_2 but not in s_1 , described as $|s_2 \setminus s_1|$. The relative change is then defined by the ratio $|s_2 \setminus s_1| / |s_2|$ where $|s_2|$ is the number of GUI events in $|s_2|$.

2) *Observer*: During run time, the Observer extracts the current screen's GUI hierarchy using Android UI Automator [22], obtaining the GUI tree. It then analyzes the GUI tree and classifies all actionable UI components into semantic categories as presented in Table I. It creates an abstract representation of the screen, also known as a *state*. A state consists of the activity's name and a set of GUI components. Each component is represented by a tuple containing the following information: semantic group, coordinates, class name, resource id, and four booleans indicating if the component is clickable, long-clickable, scrollable, checkable. The Observer

only acknowledges components that belong strictly to the application under test in order to assure the accuracy of the model. However, it also takes into account two hard buttons of the phone: the menu button and the back button, which are important and necessary to navigate in the application. The two hard buttons are classified in the Navigation semantic group.

The Observer creates a vector of length 4 where the elements hold the number of components belonging to the semantic groups given in Table I. The vector is then passed as an input of the DQN.

3) *Deep Q-Network and replay memory*: Following Mnih, et. al's guidelines [8], we integrate a Deep Q-Network into our testing tool while simplifying its structure, because the dimension of our input is much smaller than in the case of learning from raw images. Our Deep Q-Network has two fully connected layers, each one is followed by ReLu activation and the loss function is defined as in section III. We implement a Replay Memory with a capacity of 500 transitions and a target Q-network which is updated every 20 learning steps. We train the Deep Q-Network every 5 transitions with a batch of 32 transitions sampled randomly from the Replay Memory.

4) *Planner*: The Planner is the principal actor that guides the testing tool to explore the application. It receives a probability distribution over the four GUI component groups and decides which component to act on next based on a $\epsilon - greedy$ policy. The policy selects a random component with the probability ϵ and follows the prediction of the Deep Q-Network with the probability $1 - \epsilon$. At the beginning of the testing process, we want to encourage exploration behavior so that we can rapidly populate the state space. After a certain number of episodes when the Deep Q-network has collected enough transitions and has gained a certain knowledge about the application under test, we encourage the exploitation behavior: using the knowledge of the DQN to navigate in a more intelligent way. Hence, we decided to set $\epsilon = 1$ at the first episode and gradually decrease ϵ to 0.5 over the first 100 episodes (equivalent to about 2000 transitions). The value of ϵ is then maintained constant until the end of the testing process. When the Planner acts according to the Deep Q-Network prediction, it selects a component on the screen that has the highest probability value. For example, if the DQN outputs the probability distribution for (Input, Navigation, List, Button) respectively as (0.6, 0.2, 0.1, 0.1), the Planner will look for a component of group Input first. If there is not any component of group Input, it will look for a component of group Navigation and continue in the same manner until finding a component.

5) *Executor*: Unlike the executor in the testing tool of our previous work, which knows exactly which event to send to which component on screen, in this approach the executor only receives the information of which component on the screen that it needs to take action on. Based on the component's semantic group and clickable/long-clickable/checkable/scrollable information, the executor decides the type of event that it needs to send to the component.

For example, if the component is in the group Input and class EditText, the executor generates a random text to fill the input field. If the component is in the List group and scrollable, the executor executes a scrolling event. The testing tool currently supports 7 types of events: click, long click, scroll up, scroll down, swipe left, swipe right, text input.

V. EVALUATION

A. Overview

We aim to answer three research questions:

- RQ1: Does QDroid achieve higher code coverage than our previous approach and state-of-the-art testing tools?
- RQ2: Does QDroid achieve high code coverage faster than other state-of-the-art testing tools?
- RQ3: Can the tool reveal faults during test? Is it better than other tools ?

We measure code coverage (line and method coverage) and count the number of distinct faults as metrics for evaluation. We compare the results of QDroid with our previous work (ClassicQ) [4] and state-of-the-art testing tools: Dynodroid (Dyno) [12], Puma [6], A3E [7] and GuiRipper (GuiR) [23].

We use AndroTest [11], a framework for comparing different automated testing tools to set up virtual machines and run each testing tool separately. Each virtual machine runs Ubuntu 32-bit, has 6114Mb of base memory and 2 processors. Each testing session is run for 2 hours, on a fresh Android emulator with all the data from the previous session removed. AndroTest also provides a set of instrumented open-source applications. Because a lot of apps provided are either too simple (containing only one activity with few GUI changes) or fail to start before the testing begins, we selected 12 apps which are stable for most of the testing tools.

After each test session on an application, QDroid provides developers with:

- The record of each action taken during each episode, which can be used to reconstruct test cases.
- The evolution of coverage during test.
- Android execution log, which is used to detect faults.
- The number of crashes occurred during the test.

B. Results

1) *RQ1: Does QDroid achieve higher code coverage than our previous approach and state-of-the-art testing tools?*: Table II gives details of the average method coverage obtained by each testing tool on each application. It also calculates the p-value of the hypothesis that QDroid obtains higher code coverage than each of the other testing tools in average. Fig. 2 shows the distribution of line and method coverage across target applications for QDroid, ClassicQ, Dynodroid, Puma, A3E and GuiRipper.

QDroid performs better than our previous tool ClassicQ, but it was not statistically significant ($p = 0.14$). As for other tools (Dynodroid, Puma, A3E and GuiRipper), QDroid obtained higher code coverage at a statistically significant level ($p < 0.05$). Its best and worst coverage is also higher than the best and worst coverage of all the other four tools.

TABLE II
METHOD COVERAGE AFTER TWO HOURS (%) AND P-VALUE FOR QDROID PERFORMS STATISTICALLY SIGNIFICANT BETTER THAN EACH OF THE STATE-OF-THE-ART TESTING TOOLS

Application	Qdroid	ClassicQ	Dyno	Puma	A3E	GuiR
Any Memo	35.09	35.36	15.39	-	-	3.63
My Expenses	64.18	42.50	29.56	35.24	15.05	17.04
Who has my stuffs	89.01	88.09	58.93	67.48	51.15	29.92
Tippy Tipper	56.11	55.75	46.61	52.49	52.49	20.54
Munch Life	53.85	60.00	83.08	61.54	50.00	43.85
Mini Note Viewer	54.55	40.21	20.85	35.25	5.02	7.18
Mileage	35.29	34.73	26.85	34.06	2.99	16.38
Multi SMS sender	43.71	36.13	41.33	33.06	15.32	31.29
Hot Death	64.34	13.13	29.80	39.10	3.66	37.24
Random Music Player	58.73	58.73	58.73	58.73	3.17	41.27
Dalvik Explorer	83.51	83.40	23.82	70.87	41.08	5.39
Weight Chart	38.35	18.64	35.73	16.50	-	7.28
Mean	56.39	47.22	39.22	42.03	19.99	21.75
Standard deviation	16.64	22.02	18.80	20.23	20.98	13.96
p-value	-	0.14	0.02	0.047	0.0008	0.00009

One exception is with Munch Life where QDroid performs worse. In this case, we need to repeat the same action several times on the screen where the GUI skeleton doesn't change to be able to unlock a new state. Because QDroid favors the actions that trigger changes in UI and the test case is designed to end early when no GUI change is detected, QDroid isn't able to unlock the new state.

Fig. 2. Distribution of average coverage of each testing tool across apps

2) *RQ2: Does QDroid achieve high code coverage faster than state-of-the-art testing tools?*: The evolution of code coverage for QDroid, Dynodroid, Puma, A3E and GuiRipper (the average across all target applications and all runs) is presented in Fig. 3. On average, QDroid kick-starts with a high coverage and its performance improves over time. This proves that QDroid learns the behavioral model of the application gradually, and exploits this model more and more at the later phase of the testing process.

Fig. 3. Evolution of code coverage during test

TABLE III
NUMBER OF UNIQUE FAULTS DISCOVERED ACROSS ALL RUNS

App	Qdroid	Dyno	Puma	A3E	GuiR
Any Memo	11	9	0	0	0
My Expenses	0	0	0	0	0
Who has my stuffs	0	0	0	0	0
Tippy Tipper	0	0	0	0	0
Munch Life	0	0	0	0	0
Mini Note Viewer	1	1	1	0	0
Mileage	1	0	0	0	0
Multi SMS sender	0	0	0	0	0
Hot Death	2	0	0	0	0
Random Music Player	0	0	0	0	0
Dalvik Explorer	1	0	0	0	0
Weight Chart	1	1	0	0	0

3) *RQ3: Fault detection ability*: Table III gives the number of distinct faults discovered by each testing tool. The number of faults in each application before test is unknown. Distinct faults are identified by their unique error messages in the emulator's log. QDroid is able to detect faults during tests and outperforms the four other tools. The majority of the exceptions discovered belong to six main classes *java.lang*, *java.io*, *java.net*, *android.database*, *android.content* and *android.system*. Notice that even though different testing tools can have the same number of faults for one application, the faults are not necessarily identical. This is the case of Mini Note Viewer where the faults discovered by QDroid, Dynodroid and Puma are all different. For Any Memo and Weight Chart, the faults discovered by QDroid and Dynodroid have overlaps. Note that the framework we used, AndroTest, did not specifically state how many faults existed in each of the apps. Thus, we cannot determine the fault detection percentage of each tool. Nevertheless, QDroid performed the same or better compared to all other tools.

C. Threats to validity

The number of applications used in our evaluation is limited, hence raises a threat to external validity. Even though the target applications are chosen of different sizes and categories, it is unsure that the result can be generalized.

Training of a deep neural network can give very different outcome between different runs, which introduces a threat to internal validity. We ran each testing tool five times and took the average as the final result to reduce this threat.

VI. CONCLUSION

In this paper, we present a new approach using semantic analysis of GUI components and Deep Q-Network to conduct tests on Android applications. Our automated testing tool QDroid analyses the semantic information of GUI components and uses it as input to train a Deep Q-Network. The neural network, based on the principle of reinforcement learning, estimates a behavioral model of the application and exploits this model to guide the exploration inside the application. Evaluation has shown that QDroid presents an improvement in code coverage in comparison to state-of-the-art testing tools and it is effective in detecting faults.

As the integration of Deep Q-Network in the testing tool shows positive result, future work on this topic includes an

evaluation of QDroid on applications having more complex GUI. Specifically, we plan on extending the action space (by combining event and component as one action) and the state space (for example, adding more information to distinguish similar states).

Abstract— This paper presents the design and results of an experiment to evaluate the impact/effect of data uniformity in automation of acceptance tests. An experiment to specify acceptance tests, represented by the User Scenarios through User Interaction Diagrams (US-UIDs) format, with non-technical user has been set up involving two projects. In the first project, called P1, the treatment of data uniformity is held by an expert, while in the second project, called P2, no treatment of data uniformity is done. In both projects, automation of acceptance tests was developed for evaluation and comparison of the following artifacts: data uniformity, fixture name sharing, automation time, and glue code volume. The results show that there is a meaningful statistics difference of uniformity between projects P1 and P2, where P1 resulted in a better uniformity. However, although the treatment of data uniformity does not show meaningful statistics difference according to the strategy of fixture names sharing used, the time spent in fixture naming was more than two times higher in P2. In addition, the glue code volume was less than half in P1 comparing to P2.

Keywords-component: *Acceptance Test; Agile Software Development; Glue Code; Uniformity; Reuse; US-UID.*

I. INTRODUCTION

In the agile software development, acceptance tests are adopted to enable the communication and collaboration among the stakeholders [1, 2, 3]. Some agile developers, users and clients use acceptance testing as a way of specifying software requirements instead of using only common artifacts based on natural language [17, 18]. This is an attempt to improve the quality of requirements because several problems can arise when requirements are written in natural language, for example, readers and writers can use the same word for different concepts, or express the same concept in completely different ways [18]. In addition, it is estimated that 85% of software defects are originated from ambiguous, incomplete or illusory software requirements [19].

Acceptance tests can be specified using semi-structured formats like user stories (such as Behavior Driven Development - BDD) [4, 5, 6], tables (such as Fit tables [3, 7]), or diagrams (such as US-UIDs [8, 9, 10]). However, the development process of automated acceptance testing is more complex than just specifying acceptance tests in a chosen format. Independent of the acceptance test format, it is also necessary to implement the

code that binds each acceptance test to the System Under Test (SUT). This code is known as glue code [16].

In general, acceptance tests are designed to exercise different functions of the SUT. However, in order to put the SUT in a suitable state for execution, the glue code of different acceptance tests may call some common SUT functions. In this way, the reuse of the glue code is important to reduce the time and cost of the maintenance. In line with Borg and Kropp [16], the maintenance of acceptance tests is an issue that appears from the very start of a project. The tests need to be constantly maintained and the test suite should be integrated in a continuous build process [1].

In the agile development it is desirable that users participate in the specification of the acceptance tests, while the testers develop the test automation. It is assumed that a good specification of acceptance tests facilitates the communication among the stakeholders, helping the test automation by the testers. Moreover, specification that involves multiple users can increase the complexity, mainly when users adopt particular data for the tests. For example, the data of an end-of-session requirement can be called "Log out" by one user and "Sign out" by another one. Both data of end-of-session might communicate the intent to the tester, however the ambiguity can lead the tester to a misunderstanding in a way that it is implemented distinct glue code for the same requirement. In this case it is important to uniform the test data before automating the test in order to avoid unnecessary glue code implementation. In [11], Longo and Vilain proposed a metric to measure the data uniformity of acceptance tests in order to detect exaggerated variances in data that may weaken the quality of acceptance tests.

To investigate the impact of data uniformity in automated acceptance tests, in this work we performed an experiment using the User Scenarios through User Interaction Diagrams (US-UIDs) format for the acceptance tests. To execute US-UIDs as acceptance tests, it is necessary to bind them to the SUT. The binding between the US-UIDs and the SUT is done through the fixture names and the glue code [10]. Fixture names are labels created a-posteriori of the US-UIDs specifications to bind the US-UID elements to the glue code. The glue code is responsible for exchanging information between the US-UIDs and the SUT during the test execution. While the specification of the US-UIDs representing the acceptance testes is a responsibility of the clients and users, the fixture naming and glue code creation is a responsibility of the testers [10].

This paper is organized as follow. Section 2 shows details of the problem of data uniformity in the automation of acceptance tests represented by US-UIDs. Section 3 describes the experiment performed and the evaluation methodology. Section 4 presents the results. Finally, Section 5 shows the conclusions.

II. EXAMPLE OF THE PROBLEM

The User Scenarios through User Interaction Diagrams (US-UIDs) are used for software requirements specifications [8, 9, 10]. These diagrams can be used as automated acceptance tests. The US-UIDs have been suggested as a specialization of the technique UID [20], where the information is replaced with concrete values from the user scenarios. The applicability of the US-UIDs is usually made by non-technical users to create acceptance testing before the development.

In the following we talk about the problem of data uniformity in the acceptance tests represented by US-UIDs. To illustrate this problem, Figure 1 shows a pair of US-UIDs. The pair of US-UIDs shown in this example are for specifying requirements of an application similar to WhatsApp. The US-UID A refers to the requirement to respond to a message, and US-UID B refers to the requirement to check status. The example considers two US-UIDs with the objective of showing data uniformity problems only in first interaction state (represented by ellipses [8]). The uniformity is calculated comparing data from user inputs (represented by rectangle with string inside [8]) and system outputs (loose strings [8]) between the US-UIDs.

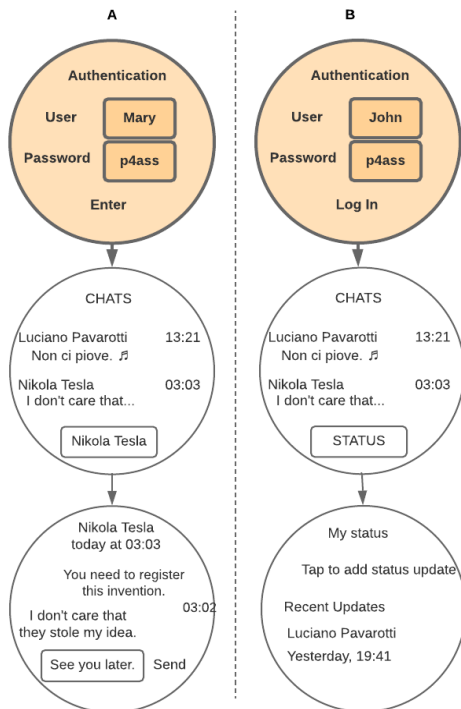

Figure 1. Two US-UIDs with problems of uniformity in data.

The example highlights two problems of data uniformity, where the first one is related to the values of the user inputs “Mary” and “John”. These two values are different from each other, but, still, have the same meaning. The meaning is clearly a username. Specially, in US-UIDs with features little known

among the stakeholders, this type of non-uniform data might cause loss of meaning leading to miss understandings.

The second problem of data uniformity is related to the system outputs “Enter” (US-UID A, Figure 1) and “Log In” (US-UID B, Figure 1). Both system outputs represent, in the SUT implementation, the text of the button for the action for system access. For communication purposes, the stakeholders are able to understand that the text in these two system outputs which, despite the difference, have the same meaning. However, using these US-UIDs as automated tests leads to an unnecessary implementation of the glue code, because the glue code must provide two distinct values (“Enter” and “Log in”) for the same requirement.

For the example of the US-UIDs from Figure 1 (considering only the first state of interaction of each US-UID and non-uniform data), three strategies for fixture naming can be developed. These strategies impact in different glue code implementations and also spreads the problems of data uniformity in different glue code structures. The Figure 2 shows three different strategies to naming fixtures and Figure 3 shows de glue code for each strategy.

A. Strategy of Shared Fixture Names (S1)

The strategy of shared fixture names causes two interaction states (Figure 2, S1) and two user inputs or two system outputs from different US-UIDs share the same fixture name. Figure 2 shows three possible shared fixture names: “AuthenticationState” for the two interaction states, “user” for two user inputs, and “enterButton” for two system outputs. The two interaction states of the US-UIDs from the example are named by “AuthenticationState”, sharing, thus, the same fixture name.

The fixture name “user” is used to name the user inputs “Mary” and “John” which represent the user names. Although this fixture name is not the same as the input names, there is no sense of conflict with these names for the example. However, the fixture name “enterButton” for the system outputs “Enter” and “Log In” might create doubts. The proper decision of the developer is to return the US-UIDs to the users or clients and solve which system output name is the most appropriate. However, if the developer keeps the names irregular, the glue code will be developed as shown in Figure 3 (S1).

During the creation of the glue code, it is necessary to implement the class for the interaction states and the methods for each user input and system output in order to bind the US-UIDs to the SUT. The interaction states are linked to the class “AuthenticationState”. The method `getEnterButton` is responsible to bind the SUT to the fixture “enterButton” and to return the result to fulfill the test exercise. In line 6 (S1, Figure 3) the SUT is represented only by the string “Enter OR Log In?”. In this case a conflict is generated (Figure 3, S1, line 6) because the method may simply return one value, but in US-UIDs there are as candidates the values “Enter” or “Log In”, in which, this way, the irregular data is detected due to the conflict on the decision of method return. Therefore, the developer will have a lag upon reviewing the US-UIDs. The reviewing process can take longer and increase the costs if help from users or clients is needed.

B. Strategy of Fixture Names with Hybrid Sharing (S2)

The strategy of fixture names with hybrid sharing occurs when two or more interaction states share the same fixture name, and two user inputs or system outputs have different fixture names. Figure 2 (S1) shows the possible fixture names that show a problem of uniformity and both interaction states from US-UIDs A and B share the same glue code class. The user inputs “Mary” and “John” have problems of data uniformity but, in practice, they are easily detected. Therefore, in the example of strategy of fixture names with hybrid sharing, the user inputs are not considered. As an example, both interaction states share the fixture “*AuthenticationState*” and the fixture names “*enterButton*” and “*loginButton*” are fixture names that are not shared for the system outputs “Enter” and “Log In”. Therefore, the system outputs with similar meaning are handled in different ways. Figure 3 (S2) shows the glue code for the fixture name of hybrid sharing for the example from Figure 2 (S2).

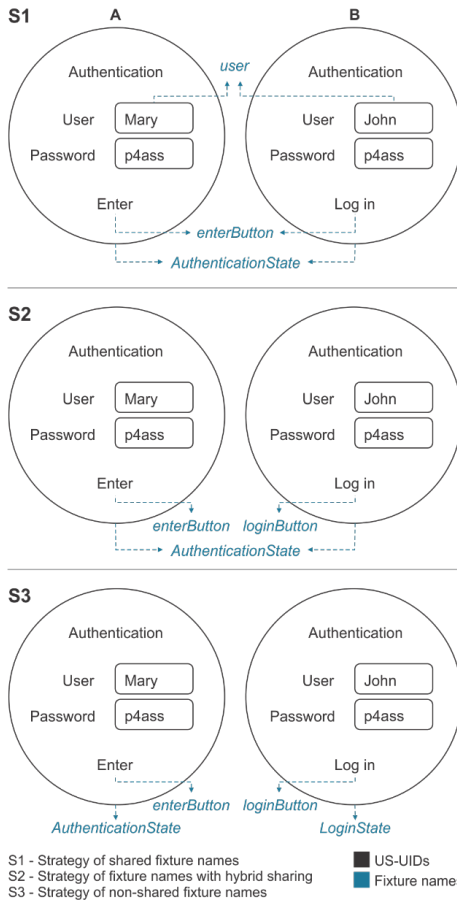

Figure 2. Example of three strategies for fixture naming can be developed.

The fixture code allows the use of a class with non-shared methods, therefore, distinct methods allow returns of different values. The method *getEnterButton* is responsible for binding the SUT to the fixture “*enterButton*” and for returning the result to fulfill the test exercise. The method *getLoginButton* is responsible for binding the SUT to the fixture “*loginButton*” and for returning the value that fulfills the test exercise. Therefore, both methods have different responsibilities and do not cause any conflicts. It is important to point out that, in this example, both methods return the values from test results just because they are not linked to the SUT yet.

C. Strategy of Non-Shared Fixture Names (S3)

The strategy of non-shared fixture names occurs when two interaction states to have different fixture names, as well as two user inputs or two system outputs to have different fixtures. Figure 2 (S3) demonstrates the possible fixture names that show a problem of uniformity.

```

----- S1 -----
1 @Fixture("AuthenticationState")
2 public class AuthenticationFixture {
3
4     public void setUser(String name) {}
5     public String getEnterButton() {
6         return "Enter OR Log In?";
7     }
8 }
/* The return value of the method is conflicting for the two US-UIDs.
When the programmer arrives at this point it is common to detect the
conflict. */

----- S2 -----
1 @Fixture("AuthenticationState")
2 public class AuthenticationFixture {
3
4     public String getEnterButton() {
5         return "Enter";
6     }
7     public String getLoginButton() {
8         return "Log In";
9     }
10 }
/* For this type of fixture sharing the problem of data uniformity can be
detected only if we analyze the two methods. */

----- S3 -----
1 @Fixture("AuthenticationState")
2 public class AuthenticationFixture {
3
4     public String getEnterButton() {
5         return "Enter";
6     }
7 }
8 @Fixture("LoginState")
9 public class LoginStateFixture {
10
11     public String getLoginButton() {
12         return "Log In";
13     }
14 }
/* In this strategy, the data uniformity problem can be detected only if
you parse the two methods, but note that they are in different classes. */

```

Figure 3. Glue code for the three examples of Figure 2.

In this example we are only considering both interaction states and system outputs “*Enter*” and “*Log In*”, so there is no fixture name sharing. This way, the interaction states and system outputs with similar meaning are treated in different ways. Figure 3 (S3) shows the glue code for the non-shared fixture names for the example from Figure 2 (S3).

In the level of fixture code, both US-UIDs use two different classes for binding the US-UIDs to the SUT, thus classes and methods are not shared. The class *AuthenticationFixture* (Figure 2, S3, line 2) contains the methods for the interaction state of US-UID A (Figure 2, S3, left). For the interaction state of US-UID B (Figure 2, S3, right) the class *LoginState* (Figure 2, S3, line 10) is used. This way, the methods for binding the system

outputs “Enter” and “Log In” to the SUT are allocated in different classes. The method *getEnterButton* is responsible for binding the SUT to the fixture “*enterButton*” and for returning the result to fulfill the test exercise. The method *getLoginButton* is responsible for binding the SUT to the fixture “*loginButton*” and for returning the result that fulfills the test exercise. Therefore, both methods have different responsibilities and do not cause any conflict. Again, in this example, both methods return the values from test results because they are not linked to the SUT yet.

III. EXPERIMENT

The experiment evaluates the treatment of data uniformity in the automation process of acceptance tests using the US-UIDs format. In the experiment, activities such as US-UIDs specification, fixtures naming, and glue code creation are elaborated. The purpose is to investigate the following research questions:

- RQ1: Does the help of an expert in the US-UIDs specification improve the data uniformity?
- RQ2: Does the treatment of uniformity affect any of the strategies of fixture name sharing?
- RQ3: How long does the fixture naming take? How much of the volume of glue code is implemented?

A. Methodology for Evaluation

For the evaluation, a specification of US-UIDs from requirements of a messaging system has been considered. Figure 4 shows an activities diagram with the three steps of the evaluation: preparation, experiment and result analysis.

1) *Preparation*. In the preparation step, the participants are trained on the language of the US-UIDs for about 15 minutes; this training is the same as the adopted by Longo and Vilain [8, 9]. During the preparation, non-technical participants are oriented to use pencil, rubber and paper for a small training. After the training with the US-UID, explanations on the messaging system are given. The participants are requested to figure out requisites for an application similar to WhatsApp, Telegram, Hangout or Messenger and, then, specify the requisites as US-UIDs.

2) *Experiment*: In order to answer the questions and to analyze the treatment of data uniformity in the specification of US-UIDs by non-technical¹ participants, the specifications are divided in two projects (P1 and P2). In the project P1, the specification is done by one participant. After the specifying, an expert² checks the data uniformity for each US-UID. If the US-UID does not show data uniformity, it is then returned to the participant so that he may improve the uniformity according to the expert guidelines. If, in the evaluation from an expert, the US-UID shows a good data uniformity, then the US-UID specification is finished. In the project P2, the specification is done by four non-technical participants without the expert's

help. After the specification step is finished, the activity of fixture naming is stated, which is carried out by only one tester. The time of this activity is timed, as it also shows the tester effort to understand the US-UIDs. For all the US-UIDs, the fixtures are named, and this information is necessary for binding the US-UIDS elements to the glue code. After the activity of fixture naming is finished, the activity of glue code creation is carried out. An algorithm has been implemented in order to generate the glue code. The algorithm has the US-UIDs as an input and generates the glue code according to the framework proposed by Longo et al. [10].

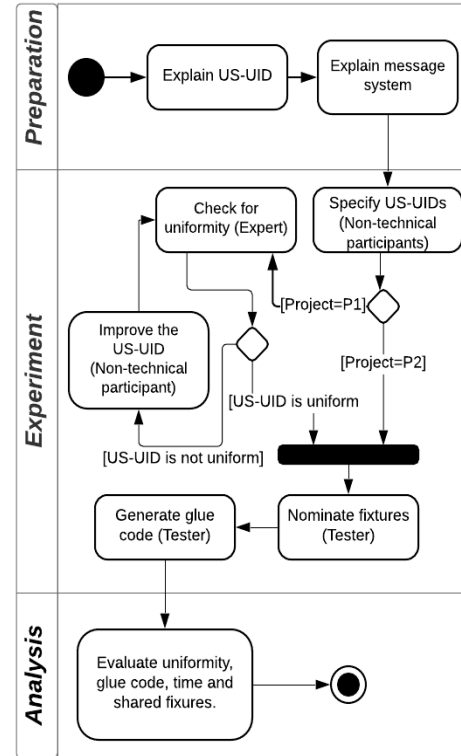

Figure 4. Activity diagram for uniformity evaluation.

IV. RESULTS

A. Descriptive Measures of the US-UIDs

In calculating the measures, all the US-UIDs specified by the participants have been added. This way, there are differences in the descriptive measures of US-UIDs that specify the same requirement, as the specification way of each participant is different. In the project P1, 6 US-UIDs, 31 interaction states, 126 system outputs, 43 user inputs and 25 transitions have been specified. Whereas in project the P2, 20 US-UIDs, 59 interaction states, 308 system outputs, 66 user inputs and 39 interaction states have been specified. There are no doubts that differences exist in the number of elements of the US-UIDs, but it highlights that the intention is specifying the same requirement in both projects.

¹ Non-technical participants are individuals without technical training in information technology.

² Expert is an experienced developer with US-UIDs.

B. Data Uniformity of the US-UIDs (RQ1)

In order to evaluate the data uniformity between both projects, a metric of data uniformity proposed by Longo and Vilain [11], is used. The metric compares pairs of US-UIDs and the results in a quantitative value. The value measured is in the interval [0%, 100%], where 0% indicates total irregularity and 100% indicates total uniformity. In order to apply the metrics, the US-UIDs resulted from experiment, and that were described on paper, are scanned to the tool Sc3n4r10³ and, then, the metric is applied computationally. Question RQ1 can be answered by the following formula with the following hypothesis:

$$H0: Uniformity_{p1} = Uniformity_{p2}$$

$$H1: Uniformity_{p1} \neq Uniformity_{p2}$$

$Uniformity_{p1}$ is the uniformity measure of the US-UIDs from project P1; $Uniformity_{p2}$ is the uniformity measure of the US-UIDs from project P2. The decision for accepting H0 or H1 is made according to the data collected from the experiment. The decision for accepting the hypothesis H0 means that the adding of the treatment of uniformity by the expert has no effect in the specification. However, when it accepts the hypothesis H1, it states that the uniformity is different between both projects, thus it is necessary to compare the uniformity averages to discover which one is the best.

The distribution of the data uniformity was analyzed through a Z-Test, at a level of significance of ($\alpha = 0.05$), obtaining a meaningful statistic difference among the uniformity of both projects ($P_{value}=2.2e^{-16}$). Therefore, then with the inclusion of the expert, there is significant difference in the uniformity of the US-UIDs data in both projects (H1).

Figure 5 shows the data uniformity in both projects. Project P1 generated 30 pairs of US-UIDs with uniformity average of 64%, median of 67% of uniformity, and uniformity interval between [32%, 100%]. Project P2 generated 380 pairs of US-UIDs with uniformity average of 12%, median of 6% of uniformity, and uniformity interval between [0%, 42%], with some discrepant values above this interval. The discrepant values occurred by US-UIDs where the participant had noticed the importance of keeping data uniformity in order to better specify the US-UIDs.

Figure 5. Uniformity of each project per pair of US-UIDs.

C. Fixture Name Sharing (RQ2)

The strategies of fixture name sharing were measured by the times that each fixture name is shared, sectioned by interaction states, system outputs and user inputs. For example, according to Figure 2 (S1), the fixture name “user” is shared two times, i.e., “user” is shared by the user inputs “Mary” and “John.” For the system outputs and interaction states the count is the same. The count was applied to each project with the aid of an algorithm implemented together with tool Sc3n4r10. Question RQ2 can be answered by a hypothesis test about the number of elements that share the same fixture name with the following hypothesis:

$$H0: FixtureNameSharing_{p1} = FixtureNameSharing_{p2}$$

$$H1: FixtureNameSharing_{p1} \neq FixtureNameSharing_{p2}$$

$FixtureNameSharing_{p1}$ is the number of times each fixture name is shared in US-UIDs from project P1; $FixtureNameSharing_{p2}$ is the number of times each fixture name is shared from project P2.

The hypothesis can be formulated for fixture name shares of user inputs, system outputs, and interaction states. The decision for accepting H0 means that the help of an expert has no effect in the strategies of fixture sharing adopted by the tester. However, by accepting the hypothesis H1, it is affirmed that the strategies of fixture sharing adopted by the tester are different between both projects. Table 1 shows the statistics analysis about the fixture name sharing for each element type. For each element type, the statistic tests shown suggest that there is no meaningful difference in the fixture sharing between projects P1 and P2. Therefore, the treatment of uniformity does not affect the strategies of fixture sharing for all element type (H0).

TABLE I. STATISTICAL ANALYSIS.

Elements	Test	P _{value}	Statistical Decision ($\alpha = 0.05$)
Interactions	U Test	0.1301	H0
Outputs	Z Test	0.4426	H0
Inputs	U Test	0.0685	H0

D. Effort (RQ3)

The effort for fixture naming by the tester is analyzed through time data. Therefore, it is necessary to compare the time spent in each project. The glue code volume also indicates indirectly the effort of the activity of fixture naming.

Figure 6 shows the glue code volume and the time spent in the activity of fixture naming by the tester. Project P1 resulted in 255 lines of code and took 240 minutes to name the fixtures. Project P2 resulted in 834 lines of code and took 552 minutes to name the fixture.

Figure 6. Measures of code volume and time.

V. CONCLUSIONS

This paper proposes the treatment of data uniformity in the activity of specifications of the US-UIDs and evaluates the effect of this data uniformity in the glue code reuse. In the evaluation, the treatment of uniformity was done by a participant who is an expert during the activities where non-technical participants specify the US-UIDs. In fact, the result of the treatment by the expert increase the uniformity, i.e., there is a meaningful statistic difference between the project with the treatment of uniformity done by the expert and a project without the same. However, in the activity of fixture naming, developed by the tester, the difference of data uniformity does not affect the fixture name sharing, i.e., the uniformity is not a factor that inclines the tester in the choosing of strategies of fixture name sharing. The developing time of the activity by the tester is very different between a project with uniformity treatment and a project without treatment. Although the treatment of uniformity does not show any influence in the strategies of fixture name sharing, the tester spends more time understanding and naming the fixture in a proper way; the time difference is twice more for a project that does not treat the data uniformity. The glue code volume is also very different. A higher code volume indicates less reuse and more effort in the activity of maintenance. Thus, it is concluded that data uniformity should be addressed at the time of US-UIDs specification, as these later saves time for the naming of fixtures and significantly reduces the amount of glue code.

As a threats of validity it is important to emphasize that this work considered only the initial requirements of a messaging system, so the results may be different for a scope of applications with lots of requirements. However, it is important to maintain uniformity in project implementation because the tests are more comprehensive, which impacts in less time to develop them (although there is interaction between developers and customers for uniformization) and less glue code to maintain during development. Yet, the software development challenges from the real world, many times, rely on projects with more stakeholders, that way we need investigate the problem in projects with different amounts of participants.

Other works address the quality improvement on specifying user stories. Lucassen et al. [13, 14] proposed a framework to evaluate fourteen quality criteria. These criteria are adopted in the Grimm Method [15] and applied in a case of study in the industry. However, the applying of the Grimm Method did not result in a meaningful difference in the software development process.

Finally, the reliability of an experiment refers to the capacity of other researchers to reply the methodology [12]. For the replication, the methodology has been detailed and algorithms for uniformity measuring and fixture sharing along with the tool Sc3n4r10 have been made available. This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – Brasil (CAPES) - Finance code 001.

Abstract—The effectiveness of Model-Based Testing (MBT) is mainly due to the potential for automation it offers. If the model is formal and machine-readable, test cases can be derived automatically. The Extended Finite State Machine (EFSM) is a formal modeling technique widely used to represent a system. However, EFSM is not a common practice in industry. On the other hand, the Unified Modeling Language (UML) has become the de-facto standard for modeling software, but due to the lack of formal semantics, its diagrams can have ambiguous interpretations and are not suitable for testing automation. In this context, we present a systematic procedure for generating tests from a UML model. More specifically, our approach proposes a mapping from the UML Sequence Diagram into Extended Finite State Machine in order to provide a precise semantics to them and uses the ModelJUnit and JUnit libraries in order to generate test cases automatically.

Index Terms—Model-Based Testing, Model-Driven Engineering, Sequence Diagram, Extended Finite State Machine, ModelJUnit, JUnit

I. INTRODUCTION

A common practice in most software development processes is the use of abstract models to aid in the construction of products. These models represent the essential parts of a system and allow software engineers to take a conceptual view of several different software perspectives. An option for software modeling is the Unified Modeling Language (UML), since it is widely used and, due to its expressiveness, it is possible to model both static and structural aspects as well as dynamic or behavioral [1]. However, due to the lack of formal semantics, the use of UML can lead to some issues, such as inconsistency, transformation problems and different interpretations [2].

An option to minimize these problems is the use of formal models, since they have a precise semantics to accurately represent system behavior. However, what is observed in practice is that formal methods are little used in industry, probably due to the lack of training and familiarity with the mathematical notation by the developers.

In the context of software testing, modeling can increase the productivity of this activity. According to Utting et al. [3], Model-Based Testing (MBT) allows the automatic generation of tests from models and other software artifacts, making it possible to create tests for the software even before coding,

thus reducing the cost of development. The central idea of MBT is generating input sequences and their expected outputs from a model or specification. The input sequences are then applied to the System Under Test (SUT) and the software outputs are compared to the outputs of the model. This implies that the model must be valid, i.e. faithfully represent the requirements. Basically, MBT are used for functional black-box testing, where software functionality is examined without any knowledge of the software's internal coding.

In MBT, it is recommended to use formal models, since they can be used as a basis for automating the testing process, making it more efficient and effective [4]. There are several formal modeling techniques based on state transition machines that can be used to specify a test model. Extended Finite State Machine (EFSM) has been widely used in the formal methods community, since they make it possible to represent the flow of control and data of complex systems. Moreover, EFSM can be implemented as a test model using the the ModelJUnit [5] library, which was designed as an extension of JUnit. Therefore, the models are written in Java, a popular programming language.

In this context, we present a systematic procedure for generation of test cases from a UML model. The idea is to use concepts of Model-Driven Engineering (MDE) to transform the UML Sequence Diagrams into EFSM and using the ModelJUnit and JUnit libraries in order to generate test cases automatically. In summary, the main contributions of this paper include:

- 1) Definition of transformation rules for mapping the elements of the UML Sequence Diagram into the Extended Finite State Machine constructions using Atlas Transformation Language (ATL) [6].
- 2) Formalization of the UML Sequence Diagram into EFSM which is a semantically accurate model.
- 3) Automatic source code generation of ModelJUnit and JUnit classes from EFSM using Acceleo [7].
- 4) Systematic procedure to generate Java tests from UML Sequence Diagram automatically.

II. BACKGROUND

A. Sequence Diagram

The dynamic behavioral aspect of an object-oriented software is defined through the interaction of objects and the

exchange of messages among them. The main diagram of the interaction model is the UML Sequence Diagram, which presents the interactions between objects in the temporal order in which they occur.

Lifelines represent participants of the interaction that communicate via messages. These messages may correspond to the operation call, signal sending or a return message. More complex interactions can be created using combined fragment. A combined fragment is used to define control flow in the interaction. It can be composed of one or more operands, zero or more interaction constraints, and an interaction operator. An operand corresponds to a sequence of messages that are executed only under specific circumstances. Interaction constraints are also known as guard conditions and represent a conditional expression.

In this paper, we use three interaction operators that model the main procedural constructs:

- **alt**: construction of the if-then-else type. Only one operand will be executed.
- **opt**: construction of the if-then type. It is very similar to the alt operator, with the difference being that only one operand is defined, which may or may not be executed.
- **loop**: a construct that represents a loop where the single operand is executed zero or more times.

Other interaction operators defined by UML 2, that can be found in OMG (Object Management Group) [1], are not in the scope of this work.

B. Model-Driven Transformation

Model transformation is a key concept within the scope of Model-Driven Engineering (MDE). The MDE aims at supporting the development of complex software that involves different technologies and application domains, focusing on models and model transformation [8].

Similarly to models, metamodels play a key role on the MDE. A metamodel makes statements about what can be expressed in valid models of a given modeling language. Modeling languages need to have formal definitions so that transformation tools can automatically transform the models built into those languages. The OMG has created a special language called Meta Object Facility (MOF) [9], which is the default metalanguage for all modeling languages. Thus, each language is defined by means of a metamodel using the MOF.

Model transformation is the generation of a target model from a source model. This generation process consists of a set of transformation rules that describes how the elements of the source model are mapped into elements of the target model. The transformations can be performed in two ways: Model-To-Model (M2M) mapping or Model-To-Text (M2T) mapping.

C. Extended Finite State Machine

An Extended Finite State Machine (EFSM) consist of states, predicates, and assignments related to variables between transitions, so that it can represent the control and data flow of complex systems.

An EFSM can be formally represented by a 6-tuple (s_0, S, V, I, O, T) [10], where:

- S is a finite set of states with the initial state s_0 ;
- V is a finite set of context variables;
- I is a set of transitions entries;
- O is a set of transitions outputs;
- T is a finite set of transitions.

Each transition $tx \in T$ can also be represented formally by a tuple $tx = (s_i, s_j, P_{tx}, A_{tx}, i_{tx}, o_{tx})$, where s_i, s_j and $i_{tx} \in I$ represents the input parameters of the beginning of the state transition tx and $o_{tx} \in O$ represents the output parameter at the end of the state transition tx . In addition, P_{tx} represents the predicate conditions (guards) with their respective context variables and A_{tx} the operators (actions) with their respective current variables.

D. Model-Based Testing

The software test aims to perform an implementation of the system under construction with test data and verify that its operating behavior conforms to its specification. This implementation being tested is named the System Under Test (SUT).

In MBT, the use of models is motivated by the observation that, traditionally, the testing process is unstructured, non-reproducible, undocumented and depends on the creativity of software engineers. The idea is that artifacts used in SUT coding can help mitigate these problems [3].

In summary, the MBT covers the processes and techniques for automatic derivation of test cases from abstract software models. To achieve success in this activity, rigor is necessary in this process.

III. OUR APPROACH

In this section we present a systematic process for test case generation by EFSM extracted from UML Sequence Diagrams. The Figure 1 illustrates our approach, which is divided into two main steps as detailed below:

Step 1 - Transformation between models. Scenarios are written in the form of the UML Sequence Diagram. This UML Sequence Diagram is transformed into an EFSM through the mapping between their respective metamodels using Atlas Transformation Language (ATL). The result of this step is a formal software model represented by an EFSM.

Step 2 - Generation of test cases. From a model of the software represented by EFSM, the test cases are generated using EFSM-based test generation methods from ModelJUnit and JUnit libraries. In this step, a Model-To-Text (M2T) transformation is performed using Acceleo, resulting in a set of test cases.

A. Metamodels

We define the UML Sequence Diagram metamodel (source) and Extended Finite State Machine metamodel (target). These metamodels were implemented in Ecore using the Eclipse Modeling Framework (EMF) [11].

Fig. 1. Our Approach.

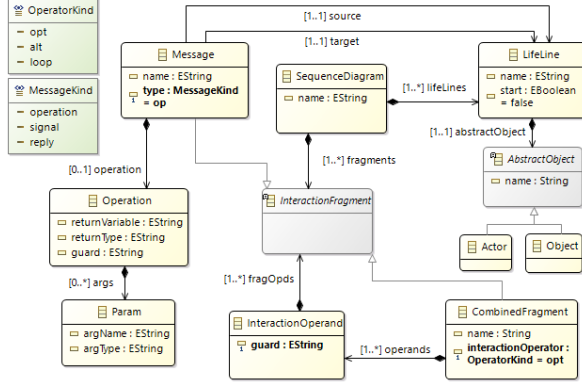

Fig. 2. Sequence Diagram Metamodel.

The complete official UML specification [1] is very complex because abstract syntax is represented in several separate diagrams, which makes it difficult to see all the connections between the important elements. In addition, the specification uses the so-called semantic variation points, meaning part of the semantics is not specified in detail to allow the use of the UML in many domains. Therefore, the official UML metamodel is heavily criticized for having many elements that are seldom used in practice [12], [13]. In this scenario, the metamodel presented in Figure 2 is simpler than the one specified by the OMG for the Sequence Diagram, and does not have constructs that are rarely used in practice. The metamodel proposed contains 13 metaclasses. The use of simplified metamodels occurs in most of the papers published in the literature [14], [15], [16].

The proposed metamodel for EFSM presented in the Figure 3 is based on the formal definition of Yang et al. [10] explained in section II.C. The metamodel is composed of six metaclasses, among which, EFSM represents an Extended Finite State Machine. The EFSM entity is composed of states, transitions and context variable.

B. Transformation Rules

In this section, we present the transformation rules between the Sequence Diagram and the Extended Finite State Machine. The following transformation rules have been defined:

- **InitFsm:** this rule creates an EFSM with the name of the sequence diagram and adds the initial state S_0 . The previous state and the current state are updated with the initial state. This rule can only be applied once.
- **Transition:** for all messages of type signal ($type = si$) or operation ($type = op$), a state is added (which is now the

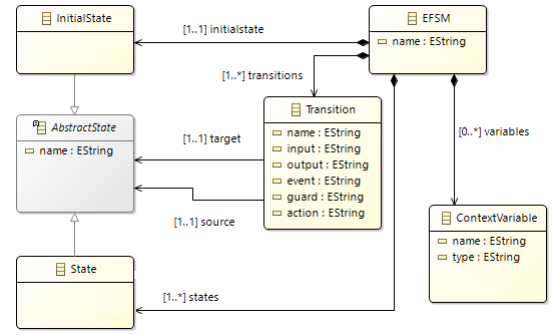

Fig. 3. Extended Finite State Machine Metamodel.

current state), and a transition that connects the previous state to the current state of the EFSM. The input for this transition will be labeled with the name of the message. If the message operation has a return, the output, guard, and action of this transition are labeled with the return of the operation. In addition, the event is labeled with the name of the operation, its return, and its arguments.

- **ContextVariable:** for all messages of type operation ($type = op$) that have a different return of *void*, a context variable is created with the name and return labeled with the name and return of the operation.
- **Alt and Opt:** when a fragment combined with the *alt* operator or *opt* operator is found in Sequence Diagram, it is added a new state for each operand and a new transition linking the current state to each of the created states. Every transition will have its input labeled with the message name and its output labeled with the guard of the respective operand.
- **Loop:** when a fragment combined with *loop* interaction operator is found in the Sequence Diagram, a reply message must be defined as the last message of the snippet. As soon as the process finds this message, a new state (which is now the current state) and a transition that connects the previous state to the current state in the EFSM are added. The input of this transition will be labeled with the name of the message and the output with the negation of the operator's guard. Another transition is created by connecting the previous state to the last state created before fragment. The input of this transition will be labeled with the name of the message and the output with the guard of the operator.

In our approach, these transformation rules were implemented using Atlas Transformation Language (ATL). ATL is one of the packages developed in the AMMA (ATLAS Model Management Architecture) model engineering platform [6]. ATL rules may be specified either in a declarative style (*Matched Rules*) or in an imperative style (*Called Rules*). *Lazy Rules* is kinds of *Matched Rules* are triggered by other rules.

In order to make feasible the transformations described above, the following *lazy rules* were implemented:

- **LrInitialState:** creates the initial state S_0 , increments the

order of the states, and changes the previous state and the current state as the initial state created. In addition, the name of the Sequence Diagram being scanned is saved in a variable.

- **LrState**: creates a new state, increments the order of states, the previous state is changed to the current state and the current state changed to the new created state.
- **LrTransition**: creates a transition that connects the previous state to the current state. The transition input and event are labeled with Sequence Diagram message information. The output, guard, and action can be null and depend on the operator and message type of the Sequence Diagram.
- **LrContextVariable**: this rule creates a context variable with the name and type labeled with the return variable of the operation and the type of the operation retract, respectively.

All of these rules implemented in ATL are available in the *Transformation/SD2EFSM/SequenceDiagram2EFSM.atl* file of the approach [repository](#)¹.

C. Test Case Generation

For test case generation our approach uses the ModelJUnit and JUnit libraries, since they are open-source and their uses are very simple for Java programmers. In addition, the ModelJUnit library enables the implementation of formal models widely used in MBT, such as EFSM. Other advantages of using ModelJUnit is that it provides a variety of useful test generation algorithms, model visualization features, model coverage statistics, and other features [17].

The process of implementing the MBT environment in the ModelJUnit and Junit libraries consists of four steps:

- 1) **The Model**: initially, we have implemented the *Fsm-Model* interface to define our model in ModelJUnit. In this Java Class we define in a enumeration variable (*enum State*) all the possible states of our EFSM and for each context variable we define a variable in the class. For each input in our model, we wrote action methods (*@Action*) to define the transitions that link the states of our model. In addition to these methods, we define in our model the *getState* method that returns the current state and the *reset* method that takes the machine to the initial state.
- 2) **The Adapter**: in this step we implemented the Adapter class that allows our model to communicate with and take control of our SUT. For each one of the action method define in the model that trigger an event, we added a similarly named method in the adapter class. In our model defined in Step 1, we call the correct adapter method in each action method. In addition, in the Adapter class we need to instantiate an object for each class of the SUT.
- 3) **Generation Tests**: in this step, we initially need to instantiate the model defined in Step 1. Then, we have

to choose the test strategy that will be used. ModelJUnit offers four different strategies: AllRoundTester, GreedyTester, LookaheadTester and RandomTester. In our approach we used the LookaheadTester test strategy, since it is a more sophisticated algorithm and can cover all transitions and states quickly [17]. Finally, we call the *buildGraph* method to build the graph and generate the tests. This graph will also be used to calculate coverage metrics for transitions, states, and action.

- 4) **Test Concretization**: In this step, the test cases were implemented in Java using the JUnit library.

These four steps described above were automatically generated by Model-To-Text (M2T) transformation using Aceleo. Aceleo is a template-based technology including authoring tools to create custom code generators. It allows you to automatically produce any kind of source code from any data source available in EMF format [7]. We have implemented the *generateClassModel*, *generateClassAdapter*, *generateClassTest* and *generateClassJUnit* generators modules. The input of these modules is the EFSM generated in step 1 of our approach.

These code generators implemented in Aceleo are available in the *Transformation/Efsm2ModelJUnit/src/Common/* folder of the approach [repository](#)¹.

IV. EXAMPLE

In this section, we use an example to illustrate the application of our approach. The UML Sequence Diagram of Figure 4 presents interactions of an ATM (Automatic Teller Machine) for the withdrawal scenario.

Initially, using the Sequence Diagram editor implemented in the EMF, we created the Sequence Diagram model described in Figure 4. Then, using the transformation rules implemented in ATL, the UML Sequence Diagram is converted into an Extended Finite State Machine. At the end of the execution of the transformation rules we will have an EFSM as shown in Figure 5.

In Step 2 of our approach, from the EFSM extracted in Step 1, the test cases are generated. Using the generator modules implemented in Aceleo, the classes (*AtmModel*, *AtmAdapter*, *AtmTest* and *AtmJUnit*) are generated automatically.

The *AtmModel* class is an implementation of the *FsmModel* interface. In this class is defined the variable enumeration *State* that represents all the states (*S0*, *S1*, *S2*, *S3*, *S4*, *S5*, *S6*, *S7*, *S8*, *S9*, *S10*, *S11*, *S12* and *S13*) of our EFSM. The following *@Action* annotated methods have been implemented: *insertCard()*, *validateCard()*, *requestPassword()*, *enterPassword()*, *validatePassword*, *requestValue()*, *enterValue()*, *validateBalance()*, *value()*, *unavailableBalance()*, *exit()* and *cardOut()*. In addition, the *getState* method, the *reset* method and context variables (*cardOk*, *pswOk* and *valueOk*) were defined.

The objects of type *User*, *ATM* and *Bank* that belong to the SUT were instantiated in the *AtmAdapter* class. In this class, a method was created for each event triggered in EFSM transitions. These methods (*insertCard()*, *validateCard()*, *enterPassword()*, *validatePassword()*, *enterValue()* and

¹<https://github.com/TESTSD2EFSM/SEKE2019>

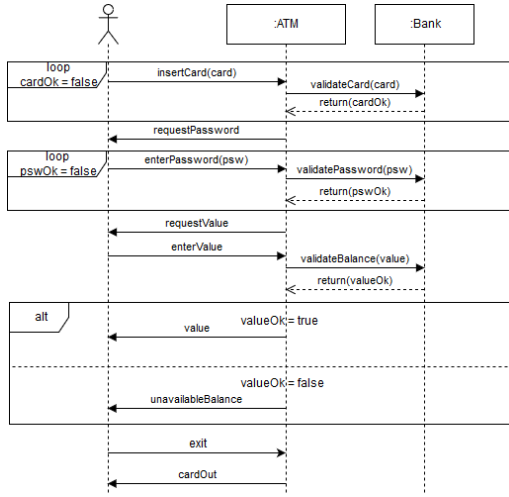

Fig. 4. ATM Sequence Diagram.

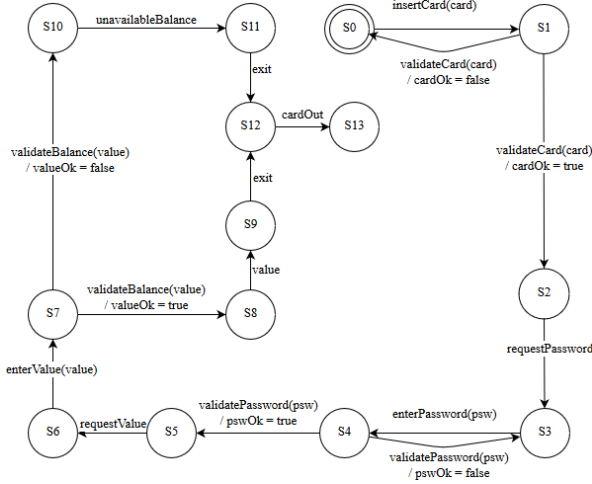

Fig. 5. ATM EFSM Model.

validateBalance()) are what make the communication of the model with the SUT.

In *ATMTest* class was instantiated the objects of type *ATMModel* and we used the *LookaheadTester* test strategy. To traverse all the transitions we configure the algorithm to generate a sequence of 70 test steps. To perform the tests we set the *card* attribute equal to 111, the *psw* attribute equal to 123 and the *balance* attribute equal to 100.00. These attributes belong to the Bank class of the SUT.

To verify the behavior of our approach, we performed the following test cases shown on the Table I. In addition to the test data (*card*, *psw* and *value*), the Table I shows action, state and transition coverages.

In addition to the metrics presented in Table I, the test cases *TestValidateCard01*, *TestValidateCard02*, *TestValidatePassword01*, *TestValidatePassword02*, *TestValidateBalance01* and *TestValidateBalance02* were concretized in Java through the JUnit library. Figure 6 shows an example of the

concrete test case of the *AtmJUnit* class.

These Java classes (*AtmModel*, *AtmAdapter*, *AtmTest* and *AtmJUnit*) are available in the *ModelJUnit/src/test/java* folder of the approach repository 1.

V. RELATED WORKS

One of the strengths of our approach is the automatic model transformation. As we have developed a tool to support our method, this task can be facilitated by the use of MDE concepts. Another advantage is the formulation of a UML model into formal model, since the UML has semantics problems and the formal models provide a set of techniques based on precise notation that can accurately translate the behavior of a system. In addition, since the main objective of our work is the generation of tests, our approach uses the ModelJUnit library to concretize the test cases in the Java programming language. On the other hand, we identified as a limitation of our work the use of only one UML diagram. Therefore, in this section of related works, we will compare our approach taking into consideration four aspects: used UML diagrams, tool support, use of formal models and concretization of test cases in some programming language.

In [18] is described a systematic test case generation method performed on Model-Based Testing (MBT) approaches by using UML Sequence Diagram. The UML Sequence Diagram is converted into a graph sequence and the graph is traversed to select the predicate functions. These predicates are transformed into Extended Finite State Machine (EFSM). From the EFSM, test cases are generated taking into account state coverage, transition coverage and action coverage. This technique is similar to ours, but EFSM is not automatically generated from the sequence diagram. Moreover, the technique does not use some important constructions of the Sequence Diagrams, such as the combined fragment. In this approach the test cases are concretized in the Java programming language.

In [19] an approach is presented to generate test cases using UML Activity and Sequence Diagrams. The approach consists of transforming the Sequence Diagram into a graph

called *Sequence Graph* and transforming the Activity Diagram into the *Activity Graph*. The software graph is formed by integrating the two graphs that are traversed to generate the test suite. The proposal uses UML models for generating tests, but differs from ours since it does not use MDE concepts and does not use formal models for test generation. In addition, the approach does not concretize test cases in some programming language.

In [20] an approach is presented to generate test cases using UML Sequence Diagrams. The approach consists of transforming Sequence Diagram in to Sequence Diagram Graph (SDG) and generate test cases from SDG. The Sequence Diagram is built with Object Constraint Language (OCL) and the SDG defines the activities as nodes and the interactions in the form of paths. The test case is generated by visiting the nodes and edges in the SDG. This proposal uses UML models to generate tests, but differs from ours since it does not use MDE concepts and formal models. In addition, test cases are not implemented in any programming language.

In the work of Seo et al. [16] is presented a method for generating test cases from Sequence Diagrams. This method suggests to generate test cases after conducting an intermediate transformation from a Sequence Diagram to an Activity Diagram. The proposal is similar to ours, since it uses model transformation, but does not use a formal model for generating test cases. Also we can not identify in the work if the transformation of models is carried out using MDE concepts, because it does not describe the manipulated metamodels in the process. In addition, the approach does not concretize test cases in some programming language.

VI. CONCLUSIONS AND FUTURE WORK

In this paper, we present a systematic procedure to generate test cases from UML Sequence Diagrams. Our approach uses concepts of Model-Driven Engineering to formalize UML Sequence Diagrams into EFSM and uses the ModelJUnit and JUnit libraries for automatic generation of test cases.

In Step 1, for the transformation of UML Sequence Diagram to EFSM, we perform the mapping of the elements of the respective metamodels through transformation rules. With this, we can provide a precise semantics to a widely used UML model.

In Step 2 of the approach, the formal model can be used as basis for automating the testing process, making it more efficient and effective. We used the ModelJUnit library to provide an interface to implement a formal test model, an adapter that communicates our model with the SUT and some test strategies already implemented. In addition, the execution of the tests is measured by coverage of state, actions and transitions. We use the JUnit library to perform tests in the Java programming language.

From the example, we can observe the applicability of our proposal, mainly in the generation of functional tests, since the approach starts with UML Sequence Diagrams that are important tools to model software scenarios and we end with test cases materialized in the Java programming language. These

tests were performed and metrics were generated allowing to analyze the behavior of the SUT according to the test model created.

As future work, other UML diagrams can be incorporated into the systematic procedure of generating tests and applying it to real examples through case studies or controlled experiments. In addition, the generated EFSM can be used for formal verification, such as checking safety, liveness and fairness properties.

The Smell of Blood: Evaluating Anemia and Bloodshot Symptoms in Web Applications

Zijie HUANG, Junhua CHEN, Jianhua GAO*

Department of Computer Science and Technology, Shanghai Normal University, Shanghai, 200234, China
hzjdev@foxmail.com, {chenjh, jhgao}@shnu.edu.cn

Abstract—In web applications that adopt layered architecture, Domain Layer is formed by Domain Model. Without any behavior, Anemic Domain Models contain only data. Those behaviors are dispersed into other layers and causing bloodshot symptoms in them. Most empirical studies suggest that symptoms of anemia and bloodshot degrade the maintainability of web applications, but no quantitative research has been done. This paper evaluates intensities of anemia and bloodshot symptoms based on metrics of three Code Smells, i.e. Data Class, Feature Envy and Blob. Furthermore, correlations of the intensities are evaluated using Spearman's rank correlation coefficient. The achieved results of experiments made on multiple versions of open-sourced projects show that over 65% of the applications are affected by anemia and bloodshot symptoms, and their intensities rarely decrease over time. Correlations of the intensities are also discovered within a single version and among multiple versions.

Keywords—anemic domain model; code smell; web application; domain driven design

I. INTRODUCTION

Domain Driven Design (DDD) [1] is a model-driven methodology aims to tackle the complexity of software systems. DDD introduced a layered architecture consisting of four layers including Interface, Application (also known as Service [2]), Domain, and Infrastructure Layer. Data in Domain Layer is presented by Domain Models. Fowler [3] defines the Domain Model as an object model of the domain that incorporates both behavior and data, while Anemic Domain Model (ADM) is a Domain Model containing little or no such behavior.

Applying ADMs to Domain Layer triggers the anemia of Domain Layer accompanied by the bloodshot of other layers. Firstly, the domain behaviors are dispersed into other layers notably the Service Layer, but those behaviors still depend on ADMs' data structure, causing tight coupling of the Service Layer to the Domain Layer. As a result, the Service Layer becomes oversized while its cohesion is reduced. Secondly, the object-oriented program degrades into process-oriented program [2] with reduced comprehensibility.

Evans [1] suggests the Service Layer should be kept "thin," while Fowler [2] concludes that ADM is a common anti-pattern and their usage should be avoided. Both of them point out that the core business logic of web applications should be concentrated on the Domain Layer. However, ADMs are still widely adopted in enterprise systems [4]. There have been several discussions questioning whether ADM is an anti-pattern, which suggests the advantages of ADM should be refocused, and in some cases, ADM may be the best practice [5, 6].

* Corresponding Author. The work of this paper was supported by the National Natural Science Foundation of China (Grants 61672355).
DOI reference number: 10.18293/SEKE2019-061

Above-mentioned symptoms and discussions are presented in empirical studies. To the best of our knowledge, the pros and cons of ADMs have not been quantified by any research.

Code Smell is the symptom of poor design and bad implementation choices [7]. Fowler [8] proposes 22 Code Smells for object-oriented programming including God Class (also known as Blob), Feature Envy, and Data Class. Code Smell intensities could be evaluated by proper metrics.

In this paper, we apply metrics of Blob and Feature Envy to quantify bloodshot symptoms, and Data Class for anemia symptoms. The source code of 112 MVC-based Java application together with 96 versions of 10 Java web application are analyzed, while over 65% of them are affected by anemia and bloodshot symptoms. The analysis shows that there is a positive correlation between anemia and bloodshot symptoms, and intensities of these two symptoms rarely decrease over time. The results also reveal that although ADMs are built to separate business logic and data structure completely, most ADM-based applications are not strictly following the design.

The main contributions of this paper are:

- 1) *Fills the gap in the quantification method of anemia and bloodshot symptoms in web applications.*
- 2) *Confirms Fowler's empirical discoveries of the negative impact of ADMs on software systems, while the advantages of ADMs have not been proved by any experiment.*
- 3) *Reveals the persistence and correlations of anemia and bloodshot symptoms.*

The rest of this paper is organized as follows. Section II introduces the background and related works. Section III details the Code Smell detection approach and the quantification methods of anemia and bloodshot symptoms. In Section IV we have done several experiments to verify the accuracy of our approaches and presented our evaluation process together with results. Then, we detail the threats that could affect the validity in Section V. Finally, Section VI concludes the paper.

II. RELATED WORKS

A. Code Smell Detection

This paper evaluates intensities of 3 following Code Smells.

- Blob is for an oversized class with low cohesion, and it implements multiple irrelevant responsibilities [9-11].
- Data Class is a class that contains only data but no behaviors [12].
- Feature Envy describes a method more interested in a class other than the one it is in [9].

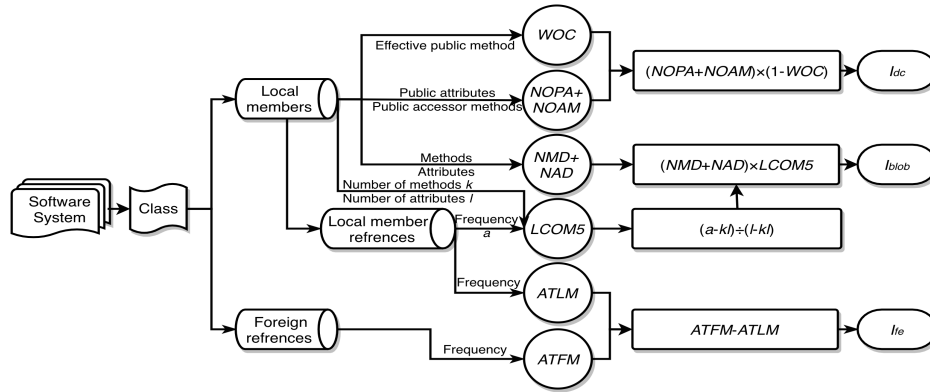

Fig. 1. Overview of Code Smell quantifying method

TABLE I. COMPARISON OF APPROACHES FOR FEATURE ENVY

Name / Approach	Lanza <i>et al.</i> [10]	Fokaefs <i>et al.</i> [14]
Couples With	Multiple classes	A single class
Precise Coupling Target	No. It detects coupling of a class generally.	Yes. It focus on both coupling source and target.
Metrics	Access to Foreign Data (ATFD), Local Attribute Access(LAA), Foreign Data Provider(FDP)	Access to Distinct Foreign Members, Access to Distinct Local Members
Chosen	No	Yes (Extended to detect multiple coupling targets)

TABLE II. COMPARISON OF APPROACHES FOR BLOB

Name / Approach	Lanza <i>et al.</i> [10]	Moha <i>et al.</i> [15]
Metrics	Structural: Access to Foreign Data (ATFD), Weighted Method Count (WMC), Tight Class Cohesion (TCC)	Structural: Number of Methods Defined (NMD), Number of Attributes Defined(NAD), Lack of Cohesion of Methods(LCOM5). Textual: Class name contains Manager, Process, Control, etc. Coupling: Access to at least one Data Class.
Chosen	No	Yes

Lanza *et al.* [10] quantified Code Smells and proposed several metrics and relevant thresholds, which are widely adopted in modern Code Analysis tools such as PMD [13]. JDeodorant [14] and DECOR [15] are notable tools detecting coupling and cohesion Code Smells.

Palomba *et al.* [11] proposed a pure textual detection approach called TACO, which is significantly different to traditional structural approach, aiming to discover conceptual coupling and cohesion problems. Furthermore, Palomba *et al.* [12] built a detection model based on multiple metrics, and they also evaluated the co-occurrence of Code Smells.

While Data Class metric is commonly accepted [10,12], multiple approaches of Feature Envy and Blob detection exists and their compatibilities to tasks in this paper is worth discussing. The difference in detection approaches is listed in Table I and Table II.

For Feature Envy, the main difference of the two approaches is whether an actual coupling target should be detected. Clarifying actual coupling targets is a must, as the identification of layer connections is vital. For Blob, both two methods refer to low cohesion, while Moha *et al.* [15]'s approach is more convenient due to its coupling detection and textual rules. In layered web application, classes and package names follow specific rules, and coupling with a Domain Model is the cause of the bloodshot symptom.

B. Web Application Design Problems

Aniche *et al.* [16] defined several MVC specific Code Smells, and evaluated their variation together with lifecycles based on a public dataset of 120 open-sourced GitHub repositories. This work developed metrics concerning specific web application code components such as Data Access Object (DAO), Repository, Controller and Service.

Cemus *et al.* and Cerny *et al.* [17,18] empirically investigated the negative impacts of ADMs and RDMs, and proposed a generic modeling method to ensure maintainability. According to their case studies, ADMs could cause Information Restatement and Concerns Tangling. RDMs also trigger coupling and cohesion problems, but intensities of design problems among Domains are decreased. The coupling problems within a single Domain could be resolved using Aspect Domain Model (AsDM).

C. Class Role Inference and Layering

Sakar *et al.* [19] generated Dependency Graph of modules and determined layer of each vertex according to their number of indegree and outdegree, while Hayashi *et al.* [20] inferred the role of code component in MVC-based applications using Dependency Graph.

Hickey *et al.* [21] split classes into layers according to their names, this method could lose its accuracy due to different naming strategies. Fokaefs [14] *et al.* and Aniche *et al.* [16] mentioned role detection of code components using class name and annotation name in their works.

III. APPROACH

Several fundamental data, i.e. Code Smell intensities and layers of classes, should be collected before evaluating anemia and bloodshot intensities. The overview of Code Smell quantifying method is illustrated in Fig. 1. In the following paragraphs, we explain each of the steps in detail.

A. Evaluating Data Class Intensity

Data Class is a class with interfaces that (i) provide almost no functionality and (ii) declare data fields. [10]

As shown in Fig. 2, *WMC* metric is used for (i), and *NOPA+NOAM* together with *WOC* are adopted for (ii).

WOC is the number of public methods (with accessors and constructors excluded) divided by the total number of public members. *NOPA* is the number of public attributes of a class, while *NOAM* is the number of accessor methods, i.e. getter and setter. *WMC* sums the complexity of all methods of a class.

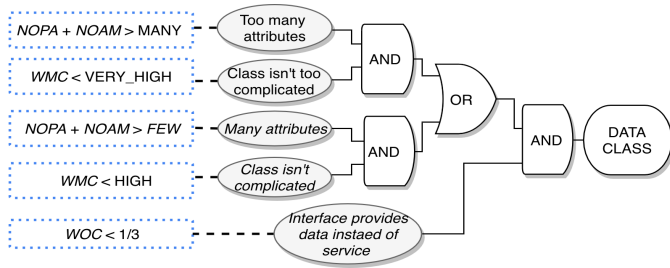

Fig. 2. Data Class detection approach

The *CYCLO* metric is used to calculate method complexity. The calculation approach of *CYCLO* defined in PMD following the standard rules given below is used in this paper:

- Methods have a base complexity of 1;
- +1 for every control flow statement (if, case, catch, throw, do, while, for, break, continue) and conditional expression (?);
- else, finally and default do not count;
- +1 for every Boolean operator (&&, ||).

Thus, the intensity of Data Class could be calculated as (1):

$$I_{dc}(C) = (1 - WOC(C)) \times (NOPA(C) + NOAM(C)) \quad (1)$$

B. Evaluating Feature Envy Intensities

A class is affected by Feature Envy if it access members of another class more frequently than its local members. [14]

Given a class $C_{current}$, the approach calculates *ATLM* as the frequency of distinct local member accessed by $C_{current}$. Then, a set C for all classes in the software system is formed, for each class C_i in C , the frequency of distinct member access from $C_{current}$ to C_i named a_i is evaluated. Finally, the classes in C is sorted by a_i in descending order. A class is affected by Feature Envy if the first class C_{top} is not equivalent to $C_{current}$.

For each a_i , calculate $diff = a_i - ATLM(C)$ and treat all negative $diff$ value as zero. Then we sum all $diffs$ to obtain the result of *ATFM* metric. For each $diff > 0$, the approach treats the related C_i as the coupling target of $C_{current}$.

The intensity is calculated as (2):

$$I_{fe}(C) = ATFM(C) - ATLM(C) \quad (2)$$

C. Evaluating Blob Intensities

As shown in Fig. 3, a Blob class is oversized, with low cohesion, having controller name pattern and couples with Data Classes. [15] We ignore name pattern as it is mentioned in Section D.

Size of a class could be measured according to the sum of *NMD* and *NAD* metrics. The cohesion of class could be evaluated by *LCOM5* metric, the main idea of *LCOM5* is to calculate the rate of access to local members.

Given a class C , the approach determines the number of method members k , the number of attribute members l , and the frequency of access to distinct local members a . *LCOM5* could be calculated as (3):

$$LCOM5(C) = \frac{a - kl}{l - kl} \quad (3)$$

Fig. 3. Blob detection approach

TABLE III. CLASS ROLE INFERENCE APPROACH

Role/ Approach	Domain	Persistence	Service	Interface
Lowercase ed name includes	{domain, vo, entity, entities}	{dao, repo, repository}	service	{controller, ctrl, api}
Expected Layer	1 (bottom)	2	3	4 (top)

We pick the 3rd-quartile in Al Dallal's work [22] as threshold of *LCOM5* metric, and the fixed value in Palomba *et al.*'s [12] work as threshold of *NMD+NAD* metric.

The intensity of Blob could be calculated as (4):

$$I_{blob}(C) = (NMD(C) + NAD(C)) \times LCOM5(C) \quad (4)$$

D. Class Layering

There is no common and generic approach for class layering. Related works mainly consider two features, class dependencies [19,20] and class names [14,16,21]. This paper proposed a mixed layering approach that fits web applications.

First, the approach generates a Directed Acyclic Graph (DAG) according to class dependencies. Given a set of all classes in an application named C , a vertex is generated for each class. Then, pairs of vertexes are connected as follows: According to Table III, the likely role of each class could be inferred. For $C_i \in C$, $C_j \in C$ and $C_i \neq C_j$, if C_i accessed or called any member of C_j , and C_i and C_j have different inferred roles, an edge from C_i to C_j should be generated.

Then, the DAG should be split into 4 layers. At the very beginning, the approach splits the DAG into 3 layers. Vertexes with 0 in-degree are moved to the bottom (i.e. Domain) while those with 0 out-degree are moved to the top (i.e. Interface). For the rest of the vertexes kept in a temporary layer, we split them into 2 new layers using the similar method but ignore the connection of middle layer vertexes with the ones in the top and the bottom layer. Vertexes with 0 in-degree are moved to the lower layer (i.e. Persistence classes of Infrastructure), while other vertexes remain in the upper layer (i.e. Service).

Additionally, there exist some exceptions. For the vertexes whose roles cannot be inferred through names, their roles could be determined according to their actual layers as mentioned in Table III. If any Data Class has the naming pattern of Data Transfer Object and are only accessed by Interface Layer classes, they should be excluded from the DAG as their sole function is to normalize data during the transfer process.

Domains of an application could also be detected according to DAG and class name patterns. A set of words could be derived through splitting the Camel-cased Domain class names. If any word in the set appears in the name set of classes in other layers,

Fig. 4. The strategy of Anemic Class detection

Fig. 5. The strategy of Bloodshot Class detection

and the two vertices of classes are connected, a domain could be determined.

E. Quantifying the symptoms of anemia and bloodshot

For now, we have collected the fundamental data including the layer of each class and their Code Smell intensities. The intensities of symptoms should be evaluated as follows.

As mentioned in Fig. 4, ADM is determined if a Data Class belongs to the Domain Layer, the intensity of anemia is I_{dc} .

As Fig. 5 illustrates, if a non-Domain-Layer class affected by Feature Envy and couples with a Data Class, we consider it bloodshot with intensities of two metrics: the extent of low cohesion I_{blob} and the extent of high coupling I_{fe} . For any bloodshot class with $I_{blob} > 0$ or couples with multiple ADMs, we regard it as a *Severe Bloodshot Class (SBC)*.

IV. EXPERIMENTS

This paper implements Code Smell metrics based on PMD [13] with necessary modifications [23]. Statistical data and plots are produced by Python scripts after generating reports of Code Smell intensities. Experiments are conducted to address the following 5 research questions:

- **RQ1 Accuracy:** *Is the approach able to evaluate class layers and Code Smell intensities accurately?*
- **RQ2 Severity:** *How severe is the symptom of anemia and bloodshot in web application?*
- **RQ3 Correlation:** *What is the relationship between the symptom of anemia and bloodshot?*
- **RQ4 Survivability:** *Do intensities of anemia and bloodshot symptom decrease over time?*
- **RQ5 Evaluation:** *What is the effect of applying ADM?*

A. Accuracy of fundamental data

A typical web application called military-shop is picked from the dataset [16] consisting of 120 open-sourced Java applications based on MVC architecture from GitHub. RQ1 is to be answered in this section using military-shop as a demo.

Precision and *Recall* metrics are used to evaluate accuracy. The metrics can be calculated as (5) and (6):

$$Precision = \frac{Correct \cap Detected}{Correct} \quad (5)$$

$$Recall = \frac{Correct \cap Detected}{Detected} \quad (6)$$

TABLE IV. ACCURACY OF LAYERING APPROACH

Role/Metric	Domain Model	Persistence	Service	Interface	Utility
Precision	100%	100%	100%	90%	85.71%
Recall	88.57%	100%	85.71%	94.73%	100%
Samples	35	7	14	19	12

TABLE V. LEVELS OF CORRELATION

Range of ρ	Correlation Level
[0.8,1.0]	Very Strong
[0.6,0.8)	Strong
[0.4,0.6)	Moderate
[0.2,0.4)	Weak
[0.0,0.2)	Very Weak

Fig. 6. Layers, dependencies and domains. The size of a vertex grows if overlapped. Edges are hidden if they connect vertices in the same layer.

where *Correct* denotes the set of items manually identified and *Detected* represents the set of items detected by the heuristic.

Fig. 6 shows the layered DAG of the project, while Table IV lists the accuracy of the layering approach. A few classes with ambiguous patterns were not correctly layered. The approach also detected all 8 domains of the project, and classes with correct inferred role were all placed into proper domain. The domain detection heuristic had a *Precision* of 100% and a *Recall* of 91.58%. Relevant Code Smell intensities were also validated.

Compared with the results of manual detection, we can conclude that fundamental data could be detected correctly. Manual detection is done independently by the first author and a developer having 3 years of enterprise web application development experience. A few disagreements were discussed and resolved later.

B. The Experiment conducted on single application

This section use Shopizer [24] as an example to demonstrate the experiment conducted on each project. The results will not be fully presented in this section as they are listed in Table VII and VIII instead.

For Q2, as shown in Table VII, 60.97% of the classes in the Domain Layer were ADMs, while Bloodshot occurred in 95.16% of the Interface and Service classes within detected Domain. About 70% bloodshot classes were SBCs.

In order to answer Q3, the correlations of I_{blob} , I_{fe} and I_{dc} should be evaluated. This paper uses the Spearman's rank correlation coefficient [25] with a *P*-value of 0.05 to analyze the correlation between every pair of intensities. The metric takes the input value of two sets of values equal in length and produces the correlation coefficient ρ together with the significance level *P*. With $P < 0.05$, the level of correlation could be considered statically significant with a level presented by ρ ranges in $[-1, 1]$ as shown in Table V. For example, the metric reported a strong

TABLE VI. DETECTION RESULTS OF 59 OPEN-SOURCED PROJECTS

correlation between I_{blob} and I_{fe} with $\rho=0.71$ ($P=2.62e-12$).

In order to answer Q4, it is necessary to analyze the variation of the 3 concerned intensities (ΔI_{blob} , ΔI_{fe} and ΔI_{dc}) among all 6 release versions. Intensities between two neighboring versions were calculated and normalized to the range [0,1]. The correlations of variations were also evaluated.

For Q5, we calculated the rate of ADMs' contributions to I_{fe} in domains, i.e. the sum of I_{fe} of every domain class coupled with at least 1 ADM divided by the sum of I_{fe} in all domains.

C. Results

Following a similar process of Section B, the experiment was conducted on 120 applications mentioned in Section A, in which 112 projects were available for access on GitHub. Among the 112 projects, 66.96% of them were affected by anemia and bloodshot symptoms (ADM rate > 0% and bloodshot class rate > 0%) and 52.68% of them had at least 1 valid ρ value ($P < 0.05$ and $0 < |\rho| < 1$). Table VI reports the result of the applications with valid ρ value.

The primary cause of the invalid ρ values were: (i) The project was too lightweight, i.e. contained few lines of code. (ii) No such correlation exists. Domains were not detected in some of the applications, in most of the cases they did not have valid ρ values owing to the fact that these projects were not layered or they were not web applications.

This dataset was collected using the filter "exists at least 10 controllers" for the analysis of MVC-based applications, most of them lacked valid release information, which were not capable for analysis based on multiple versions. So a new dataset must be picked.

We selected 10 Java web applications with more than 100 commits, more than 100 classes, and at least one commit in recent 6 months. For each project, we analyzed its latest 10 versions available. 9 out of the 10 projects were affected by anemia and bloodshot symptoms. DDDLlib was an exception that follows the DDD specification. Dataverse did not have a clear layering pattern, and the size of each layer was not enough for the metrics to evaluate correlation data.

"The proportion of decreasing anemia or bloodshot intensities" named R_{dec} was calculated as the ratio of "the number of classes with any of the three intensities decreased" to "the number of SBCs and ADMs".

Table VII reports the composition of the applications, while Table VIII lists multiple correlation coefficients (ρ), any ρ with $P > 0.05$ will be marked as unavailable(-).

D. Discussions

For Q2, more than 65% of the 112 projects analyzed by the experiment were affected by anemia and bloodshot symptoms. For web application domains based on ADMs, the proportion of bloodshot classes exceeded 90%, and most of them were SBCs, indicating the symptoms were common and severe.

For Q3, regarding the ρ values of Table VI and Table VIII, the two intensities of bloodshot correlated in most of the cases. Among different versions of the same project, the variations of the three intensities often correlated. We also analyzed the correlation of symptom intensities in different layers within single domains. But we did not find any significant correlation. The cause might be a large number of design problems within the domain are related to other domains instead of itself.

For Q4, as shown in the last column of Table VIII, the symptoms of anemia and bloodshot rarely reduced, which also confirms the conclusion about structural Code Smells that they tend to become more severe and are rarely removed [9,15].

For Q5, the result of our experiment is not showing any advantages of ADM, but confirmed the widely-accepted conclusion that there are a lot of coupling and cohesion problems within an ADM-based domain resulting in SBCs. To our astonishment, applying ADM will not result in a complete separation of data and business logic as it is designed for in most of the cases. The ADM-based applications often contain 30% to 70% of non-ADM domain models, in which domain behaviors are implemented. In conclusion, ADM has an obvious shortage of keeping single responsibilities.

V. THREATS TO VALIDITY

A threat to Internal Validity is that the layering approach uses name patterns. If the layering pattern in class name is ambiguous, the detection will be completed only according to dependency information, and accuracy will be affected.

Threats to External Validity are listed as follows: (1) Detection process could lose its validity on small applications, as thresholds derive from enterprise applications. (2) There exist a few applications that do not follow layered design. (3) Our approach analyses Java-based web application, the conclusion may not satisfy applications based on weakly-typed languages.

VI. CONCLUSIONS AND FUTURE WORK

It has been 15 years since Fowler first proposed the concept of ADM and its negative impacts, but ADM-based domain modeling is still popular. This paper analyzed source code of 112 MVC patterns based Java applications in a public dataset and 96 versions of 10 Java web applications, and concluded that over 65% of applications are affected by anemia and bloodshot symptoms. The analysis also suggests a positive correlation between the two symptoms, and they rarely decrease over time. The shortage of ADM are confirmed by experiment results, furthermore, in most of the cases, the complete separation of data and business logic are not implemented as ADMs are designed for.

Our future work involves the investigation of the impact of commit changes on anemia and bloodshot symptoms, and the application of Deep Learning approaches to improve the accuracy of class role detection is also worth trying.

Abstract—The Real Time Publish Subscribe protocol (RTPS), as a Data Distribution Service (DDS) protocol for computer systems, is composed of several modules. We focus on RTPS StatefulWriter Module which has two patterns, reliable pattern and best-effort pattern. As the main module of sending and receiving messages, its security and reliability are of great concern. The formal method can analyze whether it is a highly credible model from the mathematical point of view. Our research pays attention to the reliable pattern. Thus it is of great importance to model and verify whether the pattern is reliable through formal methods. In this paper, we model seven components of the module using Communicating Sequential Processes (CSP). By feeding the models into the model checker Process Analysis Toolkit (PAT), we verify four properties, divergence free, acknowledgement mechanism, data consistency and sequentiality. Consequently, it can be apparently concluded that the pattern of this module is reliable, which totally caters for its specification.

Index Terms—RTPS StatefulWriter Module, CSP, PAT, Modeling, Verification

I. INTRODUCTION

Data Distribution Service (DDS) is a new generation of distributed real-time communication middleware technology specification developed by Object Management Organization (OMG) based on HLA and CORBA standards. It adopts publish/subscribe architecture, emphasizes data-centric and provides abundant quality of service strategies. The Real Time Publish Subscribe protocol (RTPS), as a Data Distribution Service (DDS) protocol for computer systems, transfers data from publishers to subscribers. StatefulWriter module is one module of RTPS protocol. It has two modes, which are reliable pattern and best-effort pattern. Reliable pattern means the data must be always transferred to subscribers in the specification. Thus, we follow with interest the reliability of the reliable pattern in the module.

The behavior of the module contains acknowledgement mechanism and heartbeat mechanism. The former guarantees all messages to be received by subscribers and the latter assures the messages to reach the subscribers. Besides, data consistency and sequentiality need to be ensured in the reliable pattern. Our work is to model and verify the reliable pattern of

the module. Thus, through formal modeling and verification of StatefulWriter module, the specification can be more precisely modeled and validated, avoiding the ambiguity of natural language description, which has certain guiding significance.

The most related prior work we identified is a study by Liu et al. [5] that mainly verified the security, activity and priority of DDS in ROS2. In addition, Alaerjan et al. [1] defined the missing functional behavior in DDS dynamic model and the semantics of the new operation using Object Constraint Language (OCL). Some recent research projects [2], [7], [10] have explored analysis and verification of many aspects of DDS, such as real-time performance, security of DDS-based middleware and so on. Our work focuses on the communication dependability of the module's reliable pattern using formal methods.

The remainder of this paper is organized as follows. Section II gives a brief introduction to RTPS StatefulWriter Module, the process algebra CSP and model checker PAT. In Section III, we formalize the seven core components in the module using CSP. We apply the model checker PAT to implement the model and verify four properties in Section IV, including divergence free, acknowledgement mechanism, data consistency and sequentiality. Section V describes the conclusion and future work.

II. BACKGROUND

This section detailedly describes the flows of the module which are used in the next section and briefly introduces the process algebra CSP and model checker PAT.

A. RTPS StatefulWriter Module

RTPS StatefulWriter Module has seven components. There are Publisher, DDSWriter, RTPSWriter, HistoryCache, Subscriber, DDSReader and RTPSReader. Fig. 1 shows the 22 communications in the module. It can be divided into four submodules, which are writing data, heartbeat mechanism, reading data and removing data. Here we combine all of them in Fig. 1. The detailed messages are as follows.

Writing data submodule contains the first six interactions. Publisher writes data by invoking the **write** operation on

*Corresponding authors: hbzhu@sei.ecnu.edu.cn (H. Zhu).
yuanfei@shnu.edu.cn (Y. Fei).

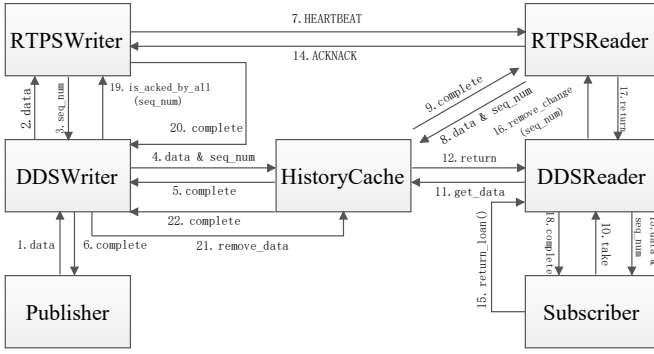

Fig. 1. Communications of RTPS StatefulWriter Module

DDSWriter. Then, DDSWriter invokes the **new_change** operation on RTPSWriter to create a new CacheChange. Each CacheChange has a unique sequence number. Also, DDSWriter uses the **add_change** operation to store the CacheChange into RTPSWriter's HistoryCache. When functions are invoked, they return the message that means operation has been executed successfully.

HeartBeat submodule is used to send message heartbeat to Reader endpoint. If the message is received smoothly within the specified time and checked by the Subscribers, RTPSWriter receives the information **ACKNACK** indicating confirmation.

Reading data submodule consists of four interactions. Subscriber reads data by invoking the **take** operation in DDSReader. Then, DDSReader accesses the changes with data and sequence number from HistoryCache. Ultimately, the **take** operation returns the data and sequence number to Subscriber.

Removing data submodule is composed of the remaining communications. Subscriber invokes the **return_loan** operation on DDSReader to notify that it no longer uses the data. Next, DDSReader uses the **remove_change** operation to remove the data from HistoryCache. Then, DDSWriter invokes the **is_acked_by_all** operation to determine whether all the changes are all received by the Reader endpoints. At length, DDSWriter calls the **remove_change** operation to remove the data from HistoryCache.

B. A Brief Introduction to CSP and PAT

CSP [3], [4] is a process algebra proposed by Hoare in 1978. As one of the most mature formal methods, it is tailored for describing the interaction between concurrent systems by mathematical theories. For its well-known expressive ability, CSP has been widely used in many fields [6], [8], [9]. CSP processes are constituted by primitive processes and actions. We use the following syntax to define the processes in this paper, whereby P and Q represent processes, a and b denote the atomic actions and c stands for the name of a channel.

$$P, Q = \text{Skip} \mid \text{Stop} \mid a \rightarrow P \mid c?x \rightarrow P \mid c!e \rightarrow P \mid \\ P \square Q \mid P \parallel Q \mid P \mid\mid Q \mid P;Q \mid P[[X]]Q$$

where:

- *Skip* stands for a process which only terminates successfully.
- *Stop* represents that the process does nothing and its state is deadlock.
- $a \rightarrow P$ first performs action a , then behaves like P .
- $c?x \rightarrow P$ receives a message by channel c and assigns it to variable x , then behaves like P .
- $c!e \rightarrow P$ sends a message e through channel c , then performs P .
- $P \square Q$ acts like either P or Q and the environment decides the selection.
- $P \parallel Q$ shows the parallel composition between P and Q . The \parallel means that actions in the alphabet of both operands require simultaneous participation of them.
- $P;Q$ executes P and Q sequentially.
- $P[[X]]Q$ indicates that processes P and Q perform the concurrent events on the set X of channels.

PAT Analysis Toolkit (PAT), is designed as an extensible and modularized framework for automatic system analysis based on CSP. It supports specifying and verifying systems in many different modeling languages and there are already various systems such as concurrent real-time systems, probabilistic systems, activity recognition and in other domains that have been verified in PAT. PAT can be applied in verifying various properties such as divergencefree, reachability and LTL propertites with assertions in distributed systems. Here we list some notations as below.

- $\#define N \ 0$ defines a global constant N with the initial value 0.
- *channel* $c \ 1$ stands for a channel which has the name c and the buffer size 1.
- $var \ cond = false$ represents a boolean condition with the initial value *false*.
- $[cond] \ P$ indicates a guarded process, which only executes when its guard condition is satisfied.
- $\#define \text{goal } n>0; \ \#assert \ P \text{ reaches goal};$ defines an assertion that checks whether process P can reach a state where the condition goal is satisfied.
- $\#assert \ P() \mid = F;$ defines an assertion that checks whether process P satisfies the formula F .

III. MODELING RTPS STATEFULWRITER MODULE

In this section, we give the formal model of RTPS StatefulWriter Module. The formalization is proceeded based on the communications in Fig. 1. Our model is constituted by seven core components: *Publisher*, *DDSWriter*, *RTPSWriter*, *HistoryCache*, *Subscriber*, *DDSReader* and *RTPSReader*.

A. Sets, Messages and Channels

Fig. 2 gives the channels of communication in the module. For more convenience, we give the definitions of sets used in

the model. We define the set of **Publisher** of Publisher component, **DDSWriter** of DDSWriter component, **RTPSWriter** of RTPSWriter component, **HistoryCache** of HistoryCache component, **DDSReader** of DDSReader component and **RTPSReader** of RTPSReader component. In addition, we define the set: **REQ** of request, **SEQ** of sequence number messages and **DATA** of data information; for simplicity, **ALLSETS** defines the unions of all sets of RTPS StatefulWriter module.

Based on the sets defined above, the messages transmitted among components are defined as follows:

$$\begin{aligned}
 MSG &= MSG_{req} \cup MSG_{rep} \cup MSG_{data} \\
 MSG_{req} &= \{msg_{req}.A.B.content \mid A \in (ALLSETS-Publisher), \\
 &\quad B \in ALLSETS, content \in REQ\} \\
 MSG_{rep} &= \{msg_{rep}.A.B.content \mid A \in ALLSETS, \\
 &\quad B \in ALLSETS, content \in SEQ \cup REQ\} \\
 MSG_{data} &= \{msg_{data}.A.B.content \mid A \in ALLSETS, \\
 &\quad B \in ALLSETS, content \in DATA\}
 \end{aligned}$$

where, MSG_{req} represents the set of request messages, MSG_{rep} stands for the set of all kinds of response requests and MSG_{data} represents the set of messages transmitting data. Each message contains a tag from the set $\{msg_{req}, msg_{rep}, msg_{data}\}$.

Then, we give the definitions of channels. In this paper, the channels using **COM_PATH** to represent can be defined as follows:

$$\begin{aligned}
 &ComPW, ComWP, ComWR, ComRW, ComWC, \\
 &ComCW, ComCT, ComTC, ComRT, ComTR, \\
 &ComCD, ComDC, ComSD, ComDS, ComDT, ComTD
 \end{aligned}$$

The declarations of the channels are as follows:

Channel $COM_PATH : MSG$

Table I shows the meanings and functionalities of representative messages transferred in the channels.

TABLE I
THE EXPLANATIONS OF TYPICAL MESSAGES OF THE MODEL

Messages	Functionalities
<i>data, DATA</i>	data transferred in the module
<i>seq_num, SEQ_NUM</i>	sequence number
<i>heartbeat</i>	judge whether data is received within required time
<i>noinvoke</i>	judge whether invoke functions
<i>complete</i>	judge whether execute the function
<i>take</i>	read data from cache
<i>remove</i>	remove data from cache
<i>get_change</i>	get changes from cache

B. Overall Modelling

System process is composed of all seven subprocesses running in parallel through their own corresponding channel. The subprocesses are *Publisher*, *DDSWriter*, *RTPSWriter*, *HistoryCache*, *Subscriber*, *DDSReader* and *RTPSReader*. The behavior of System process is modelled as below.

$$\begin{aligned}
 System &=_{df} Publisher \parallel DDSWriter \parallel RTPSWriter \parallel \\
 &\quad HistoryCache \parallel Subscriber \parallel DDSReader \parallel RTPSReader
 \end{aligned}$$

Fig. 2. Channels of RTPS StatefulWriter Module

C. Publisher

Publisher process is the core part in writing data submodule. It is used to write data to HistoryCache and receives the complete information from DDSWriter. The behavior of *Publisher* process is modelled as below.

$$\begin{aligned}
 Publisher() &=_{df} ComPW!msg_{data}.P.W.data \\
 &\quad \rightarrow ComWP?msg_{rep}.W.P.complete \rightarrow Publisher()
 \end{aligned}$$

D. DDSWriter

DDSWriter process plays an important role in writing data and removing data submodule. First, it sends and receives messages to write data from Publisher. Then, it applies the acknowledgement mechanism to check if the data has been totally received. If the return message is *ACK*, it invokes function to remove data and sequence numbers from HistoryCache. The behavior of *DDSWriter* process is modelled as below.

$$\begin{aligned}
 DDSWriter() &=_{df} ComPW!msg_{data}.P.W.data \\
 &\quad \rightarrow ComDR?msg_{req}.W.R.data \\
 &\quad \rightarrow GetSeqNum(); ComRD?msg_{rep}.R.D.complete \\
 &\quad \rightarrow ComWC!msg_{req}.W.C.data.seq_num \\
 &\quad \rightarrow ComCW?msg_{rep}.C.W.complete \\
 &\quad \rightarrow ComWP!msg_{rep}.W.P.complete \\
 &\quad \rightarrow if (id_acked_by_all(seq_num) == true) \{ \\
 &\quad \quad ComRD?msg_{rep}.R.D.complete \\
 &\quad \quad \rightarrow ComWC!msg_{req}.W.C.remove \\
 &\quad \quad \rightarrow remove_change(seq_num); \\
 &\quad \quad ComCW?msg_{rep}.C.W.complete \\
 &\quad \quad \rightarrow DDSWriter() \} else \{Skip\}
 \end{aligned}$$

In the above formula, *GetSeqNum()* is used to set the number of the sequence; *id_acked_by_all(seq_num)* is a function that judges whether the data with the *seq_num* is acknowledged; *remove_change(seq_num)* is used to remove the changes in the HistoryCache component.

E. RTPSWriter

RTPSWriter process works in writing data and heartbeat mechanism submodule. First, it produces the unique sequence number for the uploaded data. Second, it uses heartbeat mechanism to send heartbeat to RTPSReader for assuring the data can be transferred within the required interval. Finally, it helps to check whether the sequence numbers are checked by

all Subscribers. The behavior of *RTPSWriter* is modelled as below.

```

RTPSWriter() =df ComDR?msgreq.D.R.data
  → ComRD!msgrep.R.D.complete
  → DATAHeartBeat(); ComRW?msgrep.R.W.ACKNACK
  → if(head(ACKNACK)==ACK){
    acked_changes_set(seq_num); ComDR?msgreq.D.R.seq_num
    → ComRD!msgrep.R.D.complete
    → RTPSWriter() } else {Skip}

```

ACKNACK contains *ACK* and *seq_num*, so we use *head(ACKNACK)* to retrieve the message *ACK*. *acked_changes_set(seq_num)* checks whether the changes are set. HeartBeat mechanism is very important in the model. Its detailed behavior is modelled as follows:

```

DATAHeartBeat() = Clock(0)|{time}|SendHBeat();
Clock(i) = (tick → Clock(i+1))
  □(time?request → time!i → Clock(i));
SendHBeat() = time!request → time?startTime1{
  startTime=startTime1
  if (lastTime - startTime > HBeatInterval){
    SendHBeat()
  } else{ ComWR!msgreq.W.R.heartbeat
    → event{lastTime=startTime; }
    → SendHBeat() }

```

time is the channel between *Clock* and *SendHBeat()*; *Clock(i)* process returns the current time if receives the *request* message. *SendHBeat()* process sends the *heartbeat* message if the time difference is less than *HBeatInterval*; otherwise, the process cycle continues.

F. HistoryCache

HistoryCache process is like a database mainly for storing data and corresponding sequence number. It functions in every submodule, such as writing data and removing data. When receiving the request from Publishers or Subscribers, it invokes the homologous function to handle. The behavior of *HistoryCache* process is modelled as below.

```

HistoryCache() =df ComWC?msgreq.W.C.data.seq_num
  → ComCW!msgrep.C.W.complete
  → ComTC?msgreq.T.C.data.seq_num
  → ComCT!msgrep.C.T.complete
  → complete12:=get_changes(seq_num);
    ComCR!msgrep.C.R.complete12
  → ComWC?msgreq.W.C.remove_change
  → complete23:=remove_changes(seq_num);
    ComCW!msgrep.C.W.complete23
  → HistoryCache()

```

In the above formula, function *get_changes(seq_num)* and *remove_changes(seq_num)* is used to get and remove changes from *HistoryCache* component, respectively. Both of them can return the value 1 to indicate the operation is successful; otherwise, they return 0.

G. Subscriber

Subscriber process is designed for reading data and removing data submodule. First of all, it calls *take* function to receive data from *HistoryCache*. Next, it notifies other components that the data will not be used and gets the corresponding feedback. The behavior of *Subscriber* process is modelled as below.

```

Subscriber() =df ComSR!msgreq.S.R.take
  → DATA := take(); ComRS?msgrep.R.S.DATA
  → ComSR!msgreq.S.R.loan → noinvoke := return_loan();
    ComRS?msgrep.R.S.noinvoke → Subscriber()

```

In the above formula, function *take()* reads data from *HistoryCache* component and *return_loan()* indicates the data is not invoked any more, whose value is assigned to *noinvoke*.

H. DDSReader

DDSReader process is used for reading data and removing data submodule. First, it helps the *Subscriber* get data and sequence number from *HistoryCache*. Then, it invokes *remove_change* function to remove changes in *HistoryCache*. The behavior of *DDSReader* is modelled as below.

```

DDSReader() =df ComSR?msgreq.S.R.take
  → ComRC!msgreq.R.C.get_change → ComCR?msgrep.C.R.complete
  → ComRS!msgrep.R.S.DATA → ComSR?msgreq.S.R.loan
  → ComRS!msgrep.R.S.noinvoke → ComDT!msgreq.D.T.remove
  → noinvoke2 := remove_changes(); ComTD?msgrep.T.D.noinvoke2
  → DDSReader()

```

In the above formula, function *remove_changes()* is the same as that in process *HistoryCache*. *take* and *get_change* are the messages to invoke *take()* and *get_changes()* function, respectively; *loan* and *remove* message are to invoke *return_loan()* and *remove_changes()* function, respectively.

I. RTPSReader

RTPSReader process is applied to heartbeat mechanism and removing data submodule. First, it receives the heartbeat from *RTPSWriter* and sends the timely feedback to *RTPSWriter*. Then, it assists the *Subscriber* to remove the changes and data in *HistoryCache*. The behavior of *RTPSReader* is modelled as below.

```

RTPSReader() =df ComWR?msgreq.W.R.heartbeat
  → ComTC!msgreq.T.C.data.seq_num → ComCT?msgrep.C.T.complete
  → ComRW!msgrep.R.W.ACKNACK → ComDT?msgreq.D.T.remove
  → ComTD!msgrep.T.D.noinvoke2 → RTPSReader()

```

In the above formula, *RTPSReader* receives *heartbeat*, sends *data* and *seq_num* and most importantly, sends *ACKNACK* to complete the procedure of the acknowledgement mechanism.

IV. IMPLEMENTATION AND VERIFICATION

In this section, the model in Section III is implemented in the model checker PAT and the properties abstracted from the specification are all verified.

A. Implementation

First, we need to define important channels, message type flags and delivery objects as enumerations, and define messages communicated between channels as global variables. For the definition of the above variables, we give the following list as a reference:

```
channel ComPW 0;  enum {msg_req, msg_rep, msg_data};
enum {P, W, D, R, C, T, S};  var seq_num;
var ACK = 0;          var index = 0;
var DATA1;          var SEQ_NUM;
var dt[5][2];        #define HBeatInterval 5;
```

All other channels in the model are defined by the above channel format syntax like *ComPW*; the enumerated types are the type of the flag message, including *msg_req* to represent the request, *msg_rep* to stand for the reply, and *msg_data* to represent the data; *P, W, D, R, C, T, S* represent the English capital initials of the seven modules in the RPTS StatefulWriter module section. Global variable *ACK* initialized to 0 means no data received is checked by the Subscriber; global variable *index* initialized to 0 means the number of the data stored in the array in HistoryCache. *seq_num* means the initialized sequence number is zero; *DATA1* and *SEQ_NUM* are the variable representing data and sequence number in Subscriber component. Array *dt[5][2]* stores data and corresponding sequence number in HistoryCache component. Also, we give the definitions of some constant variables, for example, *HBeatInterval*, whose manual value is set to 5.

Then, we give the code of one of the processes in PAT as an example. Here we take the implementation of the *DDSWriter()* process as an example:

```
DDSWriter() = ComPW?msg_data.P.W.data1{data=data1}
→ComWR!msg_req.W.R.data → GetSeqNum();
ComRW?msg_rep.R.W.complete3{complete=complete3}
→ComWC!msg_req.W.C.data.seq_num
→ComCW?msg_rep.C.W.complete5{complete=complete5}
→ComWP!msg_rep.W.P.complete
→ComWR!msg_req.W.R.is_acked_all
→if (call(is_acked_by_all,seq_num)==1) {
ComRW?msg_rep.R.W.complete21{complete=complete21}
→ComWC!msg_req.W.C.remove
→Remove()} else {Skip};
```

From the above process execution code, it can be seen that *data1* event assigns variables and ensures variable values of all processes in the entire system are consistently changed. The function *is_acked_by_all* is invoked by *call*. *GetSeqNum()* and *Remove()* are other processes used to enhance the readability. Apparently, *GetSeqNum()* is used to get the sequence number; *Remove()* is used to remove the changes from the HistoryCache component. Their details are as follows.

```
GetSeqNum() = getSeqNum{
seq_num = seq_num + 1; } → Skip;
```

If *GetSeqNum()* is executed once, *seq_num* pluses 1, which can keep the sequence number always different and unique.

```
Remove() = atomic{
if(call(remove_change,seq_num)==1) {
ComCW?msg_rep.C.W.complete23{
complete=complete23} → Skip}
else{ ComCW?msg_rep.C.W.nocomplete23{
complete=complete-1;
complete=nocomplete23} → Skip};
```

We use *atomic* to define *Remove()* process, which means that the event cannot be disturbed until it is finished. *complete23* and *nocomplete23* are the event used to transmittting corresponding *complete* message.

Finally, the full definition of the entire system is given as follows:

```
SYSTEM() = Publisher() || DDSWriter() ||
RTPSWriter() || HistoryCache() ||
Subscriber() || DDSReader() || RTPSReader();
```

B. Properties Verification

Based on the implementation of the model in PAT above, we verify four properties as follows:

1) Divergence free

```
#assert System() divergencefree;
```

Divergence free means that any traces of the system can diverge rather than behave chaotically.

2) Consistency

Property data consistency is so important that the data from Publisher or HistoryCache or Subscriber component must be completely identical. In the implementation, the original value of the transferred data is equal to 2 and its corresponding sequence number should be equal to 1. If the data and sequence number are consistent in different components, the property is satisfied. Thus, we give the definition and assertion as follows:

```
#define goal1(dt[0][0]==1&&dt[0][1]==2)
&&(DATA1==2&&SEQ_NUM==1)
&&(dt[0][0]==SEQ_NUM&&dt[0][1]==DATA1);
#assert SYSTEM() reaches goal1;
```

3) Acknowledgement Mechanism

The reliable pattern has an acknowledgement mechanism. In our model, if the final value of the global variable *ACK* and *index* are all changed from 0 to 1, the property is satisfied. Thus, we give the LTL formula and reachability to verify whether the property is safe. Their definitions and assertions are as follows:

```
#define goal2(ACK==1&&index==1);
#assert SYSTEM() reaches goal2;
#assert SYSTEM() |=<> goal2;
```

4) Sequentiality

If the Publisher component sends several pieces of data in sequence, the pattern needs to guarantee that the data stored in the HistoryCache component must be in order. Thus, we give three atomic processes *SYSTEM02()*, *SYSTEM03()*

and *SYSTEM04()* on the basis of process *SYSTEM()*. If their storage order is correct in *HistoryCache*, the property is satisfied. Their definitions and assertions are as follows:

```
SYSTEM02() = atomic{event{data=2;} → SYSTEM();}
SYSTEM03() = atomic{event{data=4;} → SYSTEM();}
SYSTEM04() = atomic{event{data=6;} → SYSTEM();}
SYSTEM05() = SYSTEM04()||SYSTEM03()||SYSTEM02();
#define goal3 (dt[0][1] == 2&&dt[1][1] == 4&&dt[2][1] == 6);
#assert SYSTEM05() reaches goal3;
```

C. Verification and Results

According to the definitions and assertions, we implement the code in PAT and as a result, Fig. 3 shows the properties are all valid, which means the pattern of the module with no intruders is exactly reliable and also caters for the specification.

V. CONCLUSION AND FUTURE WORK

RTPS StatefulWriter module is a vital component in RTPS protocol. This paper has formalized seven components comprising the *Publisher*, *DDSWriter*, *RTPSWriter*, *DDSReader*, *HistoryCache*, *Subscriber*, *DDSReader* and *RTPSReader* with CSP. Our work also has applied the model checker PAT to implement the constructed model. Four properties abstracted from the specification, including divergence free, acknowledgement mechanism, data consistency and sequentiality, have been verified. The results are all valid. Consequently, we conclude that from the perspective of process algebra, the constructed model meets these properties and the pattern is absolutely reliable and caters for the specification.

It is naturally a great challenge to model and verify the whole RTPS protocol. We will explore security analysis and verification of the module by adding intruders in the future.

A Sound and Complete Axiomatisation for Spatio-Temporal Specification Language

Tengfei Li, Jing Liu*, Dongdong An, Haiying Sun

Shanghai Key Laboratory of Trustworthy Computing, East China Normal University, Shanghai, China

Abstract—Specifying spatio-temporal aspects is one of the important areas in cyber-physical systems. Spatio-temporal logic with changes of truth value in discrete time and dense time has been researched, but a combination of spatial and temporal components with changes of spatial entities in dense time hasn't been well-done. The major problem is dense time and real-valued variables of the spatio-temporal properties of cyber-physical systems. In this paper, we propose a spatio-temporal specification language, named STSL, which integrates Signal Temporal Logic (STL) with a spatial logic $S4_u$ to deal with the changes of real-values spatial entities in dense time. The combined language is divided into two formalisms, $STSL_{PC}$ and $STSL_{OC}$, which is applied to interpret the Boolean semantics and quantitative semantics, respectively. The syntax of the two formalism and the corresponding semantics are provided. Besides, we present a Hilbert-style axiomatization for the proposed STSL and provide the soundness and completeness result by the spatio-temporal extension of maximal consistent set and canonical model.

Index Terms—Signal Temporal Logic (STL) $S4_u$ Spatio-Temporal Specification Language (STSL) $STSL_{PC}$ $STSL_{OC}$ Soundness Completeness Axiomatization System

I. INTRODUCTION

It is a challenging work to model cyber-physical systems, not only because cyber-physical systems integrate cyber systems, physical environment and the interactive part of them, but also because cyber-physical systems combine temporal and spatial aspects, discrete and continuous behavior, and uncertainty. Describing spatio-temporal aspects is one of the important areas in cyber-physical systems. Many works have been done with hybrid [1] and stochastic behaviors of cyber-physical systems, but fewer researchers concentrate on spatio-temporal aspects. The major problem is multidimensional expressiveness and expensive verifiability for modeling and analysis of the spatio-temporal behaviors of cyber-physical systems.

This work aims at building a spatio-temporal specification language (STSL) by solving spatio-temporal constraints concerning dense time and real-valued variables, as an intelligent object in physical environment is provided with changes in specified space and continuous time. More specifically, we confine ourselves to the combination of topological space and time constraints with real-valued interval, which may

be an open, half-open and half-closed, half-closed and half-open, or closed interval in a flow of time. We adopt the modal spatial logic $S4_u$ to express topological constraints, which is one of the most influential formalism and the most expressiveness for topological relations. As for signal temporal logic (STL) [2], [3], there are two approaches that can cope with signals, quantitative semantics and Boolean semantics. Quantitative semantics obtains real-valued signals from *satisfaction degree* of a trace in real-valued interval. While Boolean semantics evaluates Boolean signals from a trace which can be booleanized through a set of threshold predicates.

Combining spatio-temporal constraints from temporal logics and modal spatial logics is a very important problem. Given a spatio-temporal model \mathfrak{M} and a STSL formula φ , the satisfiability problem of the formula φ is to check if φ is satisfiable in model \mathfrak{M} .

Since the changes of spatial entities and the flows of time are not independent, the combination between modal spatial logics and temporal logics is divided into two formalism, $STSL_{PC}$ and $STSL_{OC}$. $STSL_{PC}$ means the changes of spatial propositions over time, while $STSL_{OC}$ represents the changes or evolution of spatial objects over time. Each formalism is equipped with different expressiveness, so Boolean semantics and quantitative semantics need to be provided.

Many works have been done on the axiomatization and completeness of modal logics. Patrick Blackburn [4] present the completeness of normal modal logic through maximal consistent set and canonical model. J.M. Davoren [5] proposes topological semantics for intuitionistic tense logics and multi-modal logic and provide the Hilbert-style axiomatization and the completeness result. F.D. David [6] prove the absolute completeness of $S4_u$ for its measure-theoretic semantics. In this paper, we present an axiomatization system for STSL and provide the soundness and completeness result of the axiomatization system.

In this work, there are three contributions:

- 1) We propose a spatio-temporal specification language **STSL**, based on STL and $S4_u$, to specify the changes in topological space and dense time,
- 2) We interpret the **STSL** language from two formalisms: $STSL_{PC}$ and $STSL_{OC}$, and provide Boolean semantics and quantitative semantics for the language,

*Corresponding Author: jliu@sei.ecnu.edu.cn
DOI reference number: 10.18293/SEKE2019-222

- 3) We present an axiomatization system and provide the completeness result for the proposed language **STSL**.

The next section introduces temporal logic STL and modal spatial logic $S4_u$. Section 3 presents the spatio-temporal specification language **STSL** and section 4 presents an axiomatization system for the language **STSL**. In section 5, we conclude the work and talk about the future work.

II. SIGNAL TEMPORAL LOGIC AND $S4_u$

The section provides the background to the proposed spatio-temporal logic, including signal temporal logic (STL) and spatial logic $S4_u$.

A. Signal Temporal Logic (STL)

An STL signal [2], [7] is defined on dense-time domain \mathbb{T} . A *signal function* $\varepsilon: \mathbb{T} \rightarrow \mathbb{E}$ associates a set of time domain with a set of signals. Signals with $\mathbb{E} = \mathbb{B} = \{0, 1\}$ are called Boolean signals, while those where $\mathbb{E} = \mathbb{R}^+$ are called real-valued or quantitative signals. A Boolean signal, transformed from real-valued one, can be represented by Metric Temporal Logic [8], [9]. The comparison of some temporal logics is listed in Table I.

TABLE I
THE COMPARISON OF LTL, MTL AND STL

Logic	Time domain	Variable
Linear Temporal Logic (LTL)	Discrete time	Boolean value
Metric Temporal Logic (MTL)	Dense-time	Boolean value
Signal Temporal Logic (STL)	Dense-time	Real-value

An execution trace w is a set of real-valued signals x_1^w, \dots, x_k^w bound in some interval I of \mathbb{R}^+ , which is called the time domain of w [3]. Such an interval $I \subseteq \mathbb{R}^+$ is open (t_1, t_2) , half-closed and half-open $[t_1, t_2)$, half-open and half-closed $(t_1, t_2]$ or closed time interval $[t_1, t_2]$. For instance, a running car checks in and enters a highway at t_1 and checks out and leaves it at t_2 . We say, the car keeps running on the highway in the interval $[t_1, t_2]$.

The syntax of STL is given by

$$\varphi ::= \top \mid x_i \geq 0 \mid \neg\varphi \mid \varphi_1 \wedge \varphi_2 \mid \varphi_1 \mathcal{U}_I \varphi_2$$

where $x_i \geq 0$ is an atomic predicate whose truth value is determined by the sign of an evaluation based on a signal x_i . The Boolean operators \neg and \wedge are negation and conjunction, respectively. The time *bounded until* operator \mathcal{U}_I is defined on the time interval I .

The formula $\varphi_1 \vee \varphi_2$, $\diamond_I \varphi$ and $\square_I \varphi$ can be defined by:

$$\begin{aligned} \varphi_1 \vee \varphi_2 &= \neg(\neg\varphi_1 \wedge \neg\varphi_2) \\ \diamond_I \varphi &= \top \mathcal{U}_I \varphi, \\ \square_I \varphi &= \neg \diamond_I \neg\varphi. \end{aligned}$$

Formula $\diamond_I \varphi$ indicates that at some time $t \in I$, φ is eventually satisfiable, while $\square_I \varphi$ denotes that φ is always satisfiable at each time $t \in I$.

B. An axiomatisation system for STL

The fundamental composition of the axiomatization system for STL contains all the tautologies like atomic proposition, boolean and quantitative operator in first-order logic. Temporal expressiveness and inference rules are shown as follows:

A0 All classical tautologies of first-order logic

$$A1 \quad \Box(\phi \rightarrow \varphi) \rightarrow (\Box\phi \rightarrow \Box\varphi)$$

$$A2 \quad \neg \circ \phi \leftrightarrow \circ \neg \phi$$

$$A3 \quad \circ(\phi \rightarrow \varphi) \rightarrow (\circ\phi \rightarrow \circ\varphi)$$

$$A4 \quad \Box(\phi \rightarrow \circ\varphi) \rightarrow (\phi \rightarrow \Box\varphi)$$

$$A5 \quad (\phi \mathcal{U} \varphi) \leftrightarrow \varphi \vee \circ(\phi \mathcal{U} \varphi)$$

$$A6 \quad (\phi \mathcal{U} \varphi) \rightarrow \diamond\varphi$$

$$MP \quad \frac{\phi \quad \phi \rightarrow \varphi}{\varphi}$$

$$N_{\Box} \quad \frac{\phi}{\Box\phi}$$

$$N_{\circ} \quad \frac{\phi}{\circ\phi}$$

C. Spatial Logic: $S4_u$

$S4$ [10] is a proposition modal logic and τ are spatial terms under the topological space interpretation. In the absence of ambiguity, the terminology spatial terms denote spatial objects. According to an observation by [11], $S4$ is a logic of topological spaces, and the propositional variable p is interpreted as a subset of the topological space. From the perspective of the topological space, propositional variables of $S4$ will be understood as spatial variables [12]. The formula of $S4$ is defined as follows:

$$\tau ::= p \mid \bar{\tau} \mid \tau_1 \sqcap \tau_2 \mid \mathbb{I}\tau$$

where p is named as spatial variables and $\bar{\tau}$ is the complementary of τ , $\tau_1 \sqcap \tau_2$ the *intersection* operation of τ_1 and τ_2 . \mathbb{I} is an *interior* operator under the topological space interpretation. The *union* and *closure* operator can be defined by:

$$\tau_1 \sqcup \tau_2 = \overline{(\bar{\tau}_1 \sqcap \bar{\tau}_2)}, \quad \mathbb{C}\tau = \overline{\mathbb{I}\tau}$$

$\mathbb{C}\tau$ refers to the *closure* of a spatial object τ . For example, In order to ensure safety, the rear car c_{rear} can't reach the edge of the front car, the formula can be described by $\mathbb{C}_{c_{rear}} \sqcap \mathbb{C}_{c_{front}}$.

A topological model is a pair of the form $\mathfrak{M} = (\mathfrak{L}, \mathfrak{V}(p))$, where $\mathfrak{L} = (U, \mathbb{I})$ is a topological space. U is a nonempty set denoting the universe of the space, and \mathbb{I} is the interior operator on U . $\mathfrak{V}(p)$, as a set of valuations on spatial variables, is a subset of U . Therefore we get the valuation of other spatial formulas as follows:

$$\begin{aligned} \mathfrak{V}(\bar{\tau}) &= U - \mathfrak{V}(\tau), \mathfrak{V}(\tau_1 \sqcup \tau_2) = \mathfrak{V}(\tau_1) \cup \mathfrak{V}(\tau_2), \\ \mathfrak{V}(\mathbb{I}\tau) &= \mathbb{I}\mathfrak{V}(\tau), \mathfrak{V}(\tau_1 \sqcap \tau_2) = \mathfrak{V}(\tau_1) \cap \mathfrak{V}(\tau_2), \\ \mathfrak{V}(\mathbb{C}\tau) &= \mathbb{C}\mathfrak{V}(\tau). \end{aligned}$$

A spatial logic is a formal language interpreted over a class of structures featuring geometrical entities and relations. Among the well-known spatial logics such as RCC-8 [13], [14], BRCC-8 and $S4_u$, the most expressive spatial formalism is $S4_u$ [15]. $S4_u$ extends $S4$ with the *universal* and *existential* quantifiers \boxtimes , \boxdot based on a spatial term τ . $\boxtimes\tau$ refers to that

there is at least one element in space τ ; $\boxtimes \tau$ means that all elements in the space belong to τ). The formula φ is defined in the form of BNF:

$$\varphi ::= \boxtimes \tau \mid \neg \varphi \mid \varphi_1 \wedge \varphi_2$$

where, $\neg \varphi$ is the negation of φ and $\varphi_1 \wedge \varphi_2$ the conjunction of φ_1 and φ_2 . Correspondingly, the *disjunction* and *existential* operator can be defined by:

$$\varphi_1 \vee \varphi_2 = \neg(\neg \varphi_1 \wedge \neg \varphi_2), \Diamond \tau = \neg \boxtimes \bar{\tau}$$

The axiomatization system for $\mathcal{S4}_u$ includes the classical propositional logic in topology \mathcal{L} , the modal logics K, T, 4 and \neg and inference rules.

CP axioms of classical propositional logic in \mathcal{L}

$$\Box K \quad \Box(\phi \rightarrow \psi) \rightarrow (\Box \phi \rightarrow \Box \psi)$$

$$\Box T \quad \Box \phi \rightarrow \phi$$

$$\Box 4 \quad \Box \phi \rightarrow \Box \Box \phi$$

$$\neg \quad \neg \Diamond \phi \leftrightarrow \Box \neg \phi$$

and the inference rules

$$\text{MP} \quad \frac{\phi \quad \phi \rightarrow \psi}{\psi}$$

$$N_{\Box} \quad \frac{\phi}{\Box \phi}$$

$$N_{\Diamond} \quad \frac{\phi}{\Diamond \phi}$$

III. SPATIO-TEMPORAL SPECIFICATION LANGUAGE

STL provides an approach that combines the truth value and quantitative value of general signals. But it is inadequate to represent the changes of a spatial entity and the binary relation between spatial entities and temporal aspects. We propose the spatio-temporal specification language that combines STL and $\mathcal{S4}_u$ to describe the evolution in spatial and temporal domain.

A. Spatio-temporal signal

A spatio-temporal signal is defined with continuous time and topological space [16], [17]. The time domain \mathbb{T} will usually be a real-valued interval $[0, t]$, where $t \in \mathbb{R}_{\geq 0}$. The *signal function* is extended to spatial-temporal domain with $\varepsilon: \mathbb{T} \times \mathbb{L} \rightarrow \mathbb{E}$, where \mathbb{L} denotes the topological space. The domain of Boolean and quantitative signals extends the domain of STL signals to topological space.

A spatio-temporal trace $w(t, l)$ provides a notation about execution sequence of time t and space l . For a spatio-temporal trace, there are two different interpretations:

- A trace represents a sequence of spatial objects and time point and each point in the trace evaluates a pair of spatial objects and time.
- Another interpretation means that a spatio-temporal trace takes spatial objects as the basic entities and spatio-temporal primitive relations could be obtained by the changes of ontology of space over time.

In this work, we treat the spatio-temporal trace as the second interpretation. The changes of spatial objects are influenced by the flow of time.

Definition III.1 (Spatio-temporal signal). A *spatio-temporal signal* $\varepsilon(t, l)$ is an evaluation of spatial entities in a trace w over time. A *Boolean signal* $\mu(t, l)$ is an evaluation of an atomic proposition transferred from quantitative signals $\mathbf{x}(t, l)$ by atomic predicate $\mu(t, l) = (\mathbf{x}(t, l) \geq 0)$ in a trace w .

$$\varepsilon(t, l) := \begin{cases} \mu(t, l) & \text{if } \mathbb{T} \times \mathbb{L} \rightarrow \mathbb{B} \\ \mathbf{x}(t, l) & \text{if } \mathbb{T} \times \mathbb{L} \rightarrow \mathbb{R}_{\geq 0} \end{cases}$$

where boolean function $\mu: \mathbb{T} \times \mathbb{L} \rightarrow \mathbb{B}$ gives rise to the Boolean signals $\varepsilon(t, l) = \mu(t, l)$, while quantitative signals are obtained as the real-valued function $\mathbf{x}: \mathbb{T} \times \mathbb{L} \rightarrow \mathbb{R}_{\geq 0}$, with $\varepsilon(t, l) = \mathbf{x}(t, l)$.

B. The interpretation of the combined logic

It is essential that a combined spatio-temporal formalism should be provided with enough expressiveness to contain the three parameters [12]:

- 1) the expressiveness of the spatial component;
- 2) the expressiveness of the temporal component;
- 3) the interaction between the two components allowed in the combined logic.

The interaction between the spatial and temporal components should comply with the principle of *PC* and *OC*, which is used to evaluate the interaction:

- 1) $STSL_{PC}$: the language should be able to express changes over time of the truth-values of purely spatial propositions.
- 2) $STSL_{OC}$: the language should be able to express changes or evolution of spatial objects over time.

$STSL_{PC}$ expresses the change of truth-value of proposition and it is the elementary requirement for a combined spatio-temporal logic. For instance:

- * Eiffel Tower is located in Paris.
- * Two cars running on the road never occupy the same location simultaneously.

For $STSL_{OC}$, spatio-temporal properties are described about the changes of spatial objects over time. We use spatial objects in topological space to interpret the principle such as

- * One wave gradually formed in the sea and disappeared eventually on the shore.
- * If train A will pass the location in one hour that train B occupies now on the railway, train B must run within one hour.
- * A package from a courier service company will eventually be delivered to its destination through several transfer stations.

The spatio-temporal signals are divided into Boolean and quantitative signals. According to the category of spatio-temporal signals, we will present syntax and semantics for the proposed spatio-temporal specification language from two sides:

- The Boolean semantics returns true if the trace of spatio-temporal model satisfies the properties described by $STSL_{PC}$ formulas.

- The quantitative semantics returns a real value in different time that can be interpreted as an evaluation of satisfaction of the $STSL_{OC}$ formulas.

The Boolean semantics of the spatio-temporal specification language interprets that a formula of **STSL** over spatio-temporal traces returns true or false, so it is able to express changes of the truth-values concerning purely spatial propositions of PC . Meanwhile, the \mathcal{U}_I and \Box_I operators of the quantitative semantics are able to express changes or evolution of spatial objects over some fixed finite periods and the whole duration of time of OC , respectively. So, the expressiveness power of the combined spatio-temporal logic is enough to describe the spatio-temporal behavior.

C. The syntax of $STSL_{PC}$

We extend the real-value interval into spatio-temporal domain. Formally, we define the spatial temporal interval I as $[(t, l), (t', l')]$, $\forall t, t' \in \mathbb{T}$ and $t < t'$. The $STSL_{PC}$ is defined on spatio-temporal terms τ over the spatio-temporal interval I , combining temporal logic STL and modal spatial logic \mathcal{S}_{4u} . The syntax of $STSL_{PC}$ is given by:

$$\begin{aligned}\tau &::= p \mid \bar{\tau} \mid \tau_1 \sqcap \tau_2 \mid \mathbb{I}\tau \\ \varphi &::= \Box\tau \mid x_i \geq 0 \mid \neg\varphi \mid \varphi_1 \wedge \varphi_2 \mid \varphi_1 \mathcal{U}_I \varphi_2\end{aligned}$$

- τ is a spatio-temporal term,
- p is a spatio-temporal variable,
- $\bar{\tau}$ is the complementary of τ ,
- $\tau_1 \sqcap \tau_2$ is the intersection of τ_1 and τ_2 ,
- \mathbb{I} is the *interior* operator under the topological space interpretation. Moreover, the dual operator of \mathbb{I} is the *closure* operator \mathbb{C} , which means possible or consistent,
- $x_i \geq 0$ is an atomic predicate,
- \neg, \vee and \wedge are the Boolean operators,
- \mathcal{U}_I is the *until* operator.

We can define equivalence of operators as syntactic abbreviations:

$$\begin{aligned}\mathbb{C}\tau &= U - \mathbb{I}\tau \\ \tau_1 \sqcup \tau_2 &= \overline{\tau_1 \sqcap \tau_2} \\ \varphi_1 \vee \varphi_2 &= \neg(\neg\varphi_1 \wedge \neg\varphi_2) \\ \bigcirc_I \varphi &= \perp \mathcal{U}_I \varphi \\ \Diamond_I \varphi &= \top \mathcal{U}_I \varphi \\ \Box_I \varphi &= \neg \Diamond_I \neg \varphi.\end{aligned}$$

Atomic predicates, Boolean operators, and the spatio-temporal *bounded until* operator \mathcal{U}_I are from STL. The new spatial operators are the *interior* operator \mathbb{I} , the *closure* operator \mathbb{C} with reference to \mathcal{S}_{4u} . The \bigcirc_I, \Diamond_I and \Box_I operators are derived unary operators. $\Box_I \varphi$ denotes that φ holds within the whole trace of spatio-temporal interval I , and $\Diamond_I \varphi$ means that φ holds in at least one time point of the spatio-temporal interval I .

D. The semantics of $STSL_{PC}$

A spatio-temporal model is defined on topological space and temporal model. Formally, a spatio-temporal model $\mathfrak{M} = (\mathfrak{T}, \mathfrak{L}, \mathfrak{V})$, where

- \mathfrak{T} is a pair $(\mathbb{T}, <)$, where \mathbb{T} is a set of time point and $<$ \mathbb{R} an irreflexive, transitive and asymmetric relation on \mathbb{T} with a linear strict time flow,
- \mathfrak{L} is a topological space domain with the definition of U, \mathbb{I} in which U is a nonempty set, the universe of the space, and \mathbb{I} is the interior operator on U satisfying the standard Kuratowski axioms: $\forall X, Y \subseteq U, \mathbb{I}(X \cap Y) = \mathbb{I}X \cap \mathbb{I}Y, \mathbb{I}\mathbb{I}X \subseteq \mathbb{I}X$ and $\mathbb{I}(U) = U$,
- \mathfrak{V} is a valuation on the time point set \mathfrak{T} and the spatial variable set \mathbb{P} , i.e., $\forall p \in \mathbb{P}$, and $t \in \mathfrak{T}$ and $\mathfrak{U}(p, t)$ which means the space occupied by p at time point t . As for the spatial term τ , the valuation can be defined as: $\mathfrak{V}(\bar{\tau}, t) = U - \mathfrak{V}(\tau, t), \mathfrak{V}(\tau_1 \sqcap \tau_2, t) = \mathfrak{V}(\tau_1, t) \cap \mathfrak{V}(\tau_2, t), \mathfrak{V}(\mathbb{I}\tau, t) = \mathbb{I}\mathfrak{V}(\tau, t)$.

We define a spatio-temporal trace w as the changes of spatial objects over time. In spatio-temporal model \mathfrak{M} , $\mathfrak{V}(p)$ evaluates the spatial object p . Further, the spatio-temporal trace w represents $\mathfrak{V}(p)$ changes over time t , where t belongs to the domain \mathbb{T} .

The satisfaction relation for a $STSL_{PC}$ formula φ over a spatio-temporal model \mathfrak{M} is given by:

- $(\mathfrak{M}, t) \models \Box\tau \Leftrightarrow \mathfrak{V}(\Box\tau, t) = \top$
- $(\mathfrak{M}, t) \models x_i \geq 0 \Leftrightarrow \mathfrak{V}(x_i \geq 0, t) = x_i$
- $(\mathfrak{M}, t) \models \neg\varphi \Leftrightarrow (\mathfrak{M}, t) \not\models \varphi$
- $(\mathfrak{M}, t) \models \varphi_1 \wedge \varphi_2 \Leftrightarrow (\mathfrak{M}, t) \models \varphi_1$ and $(\mathfrak{M}, t) \models \varphi_2$
- $(\mathfrak{M}, t) \models \varphi_1 \mathcal{U}_I \varphi_2 \Leftrightarrow \exists t' \in t + I$ s.t. $(\mathfrak{M}, t') \models \varphi_2$ and $\forall t'' \in [t, t'], (\mathfrak{M}, t'') \models \varphi_1$

A model \mathfrak{M} satisfies φ in t , denoted by $(\mathfrak{M}, t) \models \varphi$.

For a given formula φ and execution trace w , we define the *satisfaction signal* $\chi(\varphi, w, t, l)$ over a trace $w(t, l)$:

$$\forall t \in I, \chi(\varphi, w, t, l) := \begin{cases} \top & \text{if } (\mathfrak{M}, t) \models \varphi \\ \perp & \text{otherwise} \end{cases} \quad (1)$$

In order to compute the *satisfaction* of a formula φ , we divide the formula φ into each subformula ϕ_i until atomic formula so that formula φ can be computed through the subformula and atomic formulas instead of the entire *satisfaction signal* $\chi(\varphi, w, t, l)$. The procedure can be treated as a hierarchical structure from the full formula φ down to each atomic formula.

E. $STSL_{OC}$

The difference between $STSL_{PC}$ and $STSL_{OC}$ is that $STSL_{PC}$ involves in the change of truth-values of propositions, while $STSL_{OC}$ describes the change of extensions of predicates. The syntax of $STSL_{OC}$ is given by:

$$\begin{aligned}\tau &::= p \mid \bar{\tau} \mid \tau_1 \sqcap \tau_2 \mid \mathbb{I}\tau \mid \tau_1 \mathcal{U}_I \tau_2 \\ \varphi &::= \Box\tau \mid x_i \geq 0 \mid \neg\varphi \mid \varphi_1 \wedge \varphi_2 \mid \varphi_1 \mathcal{U}_I \varphi_2\end{aligned}$$

The change exists in that the operator \mathcal{U}_I can be applied to spatial terms τ . $\tau_1 \mathcal{U}_I \tau_2$ refers to τ_1 holds until τ_2 holds within the interval I . Similar to the atomic formulas, the \bigcirc_I, \Box_I and \Diamond_I of spatio-temporal term can also be derived from the operator \mathcal{U}_I . The unary operators \Box_I and \Diamond_I in $STSL_{OC}$ formulas fuse the \Box_I and \Diamond_I operators of STL with that of \Box and \Diamond operators of \mathcal{S}_{4u} .

A spatio-temporal trace w is a sequence over signals ε . The Boolean satisfaction relation and *satisfaction degree* for a $STSL_{OC}$ formula φ over a spatio-temporal trace w is similar to that of $STSL_{PC}$ formula.

We define ρ to quantify the *satisfaction degree* of the property φ over the trace $w(t, l)$, and it returns a real number $\rho(\varphi, w, t, l)$. The quantitative satisfaction relation for a formula φ over a spatio-temporal trace w is given by:

- $\rho(\Box \tau, w, t, l) = \top$
- $\rho(x_i \geq 0, w, t, l) = f(w(t, l))$ where $\mu \equiv (f \geq 0)$
- $\rho(\neg \varphi, w, t, l) = -\rho(\varphi, w, t, l)$
- $\rho(\varphi_1 \wedge \varphi_2, w, t, l) = \min\{\rho(\varphi_1, w, t, l), \rho(\varphi_2, w, t, l)\}$
- $\rho(\varphi_1 \vee \varphi_2, w, t, l) = \max\{\rho(\varphi_1, w, t, l), \rho(\varphi_2, w, t, l)\}$
- $\rho(\Box_I \varphi, w, t, l) = \inf_{t' \in t+I} \{\rho(\varphi, w, t', l')\}$
- $\rho(\Diamond_I \varphi, w, t, l) = \sup_{t' \in t+I} \{\rho(\varphi, w, t', l')\}$
- $\rho(\varphi_1 \mathcal{U} \varphi_2, w, t, l) = \sup_{t' \in t+I} (\min\{\rho(\varphi_2, w, t', l'), \inf_{t'' \in [t, t']} \{\rho(\varphi_1, w, t'', l'')\}\})$

The intuitive meaning for $\rho(\Box_I \varphi, w, t, l)$ refers to that we achieve the infimum of $\rho(\varphi, w, t', l'), \forall t' \in t + I$ over the trace. Similar to $\rho(\Box_I \varphi, w, t, l)$, $\rho(\Diamond_I \varphi, w, t, l)$ returns the supremum of $\rho(\varphi, w, t', l'), \forall t' \in t + I$.

Especially, if $x_i \geq 0$, the *satisfaction signal* will be

$$\forall t \in I, \chi(x_i \geq 0, w, t, l) := \begin{cases} \top & \text{if } x_i \geq 0 \\ \perp & \text{otherwise} \end{cases} \quad (2)$$

The connection is built between Boolean signals and quantitative signals by the way of predicate $x_i \geq 0$ and obtain the satisfaction signal $\chi(x_i \geq 0, w, t, l)$. In the quantitative semantics, however, atomic predicates $x_i \geq 0$ do not evaluate to \top or \perp but give a real value of the quantitative signals x_i by *satisfaction degree* $\rho(\varphi, w, t, l)$ representing the distance to satisfaction or not.

IV. AN AXIOMATIZATION SYSTEM FOR STSL

STSL is a logical system. A proof in **STSL** is a sequence of finite formula: A_0, A_1, \dots, A_n , where each of them is an axiom, or there exists $j, k < i$, such that A_i is the conclusion derived from A_j and A_k using *MP* inference rule. The last term A_n is a theorem in **STSL**, using the sign $\vdash A_n$, where n is the length of proof.

The notions of *deducibility* and *consistency* [4], [18] is fundamental to deduce the logic system **STSL**. A formula A is *deducible* from a set of formulas Γ in a system \mathcal{ST} , written $\Gamma \vdash_{\mathcal{ST}} A$, if and only if \mathcal{ST} contains a theorem of the form $(A_1 \wedge \dots \wedge A_n) \rightarrow A$, where the conjuncts $A_i (i = 1, \dots, n)$ of the antecedent are formulas in Γ . A set of formulas Γ is consistent in \mathcal{ST} , written $Con_{\mathcal{ST}} \Gamma$, just in case the formula \perp is not \mathcal{ST} -deducible from Γ .

Definition IV.1 (\mathcal{ST} -MCS). A set of formulas Γ is maximal \mathcal{ST} -consistent iff

- (i) Γ is \mathcal{ST} -consistent, and
- (ii) for every formula A , if $\Gamma \cup \{A\}$ is \mathcal{ST} -consistent, then $A \in \Gamma$.

If Γ is a maximal \mathcal{ST} -consistent set of formulas then we say it is an \mathcal{ST} -MCS. The (ii) condition refers to that any set of formulas properly containing Γ is \mathcal{ST} -inconsistent.

The canonical model defined by [18] to induce the soundness and completeness of modal logics. We extend the notation of *canonical model* to spatio-temporal systems for completeness of **STSL**.

Definition IV.2 (\mathcal{ST} -canonical Model). The \mathcal{ST} -canonical model \mathfrak{M}^Γ for a spatio-temporal logic is a triple $(W^\Gamma, R^\Gamma, V^\Gamma)$ where:

- (i) W^Γ is the set of all Γ -MCSs;
- (ii) R^Γ is a topological relation on topological space over a quasi-order on time. It is the canonical binary relation on W^Γ defined by $sR_i^\Gamma s'$ over state s and s' if for all formulas ϕ , $\phi \in s$ implies $\phi \in s'$.
- (iii) V^Γ is the valuation defined by $V^\Gamma(p) = \{s \in W^\Gamma \mid p \in s\}$. V^Γ is called the canonical valuation.

Lemma IV.1 (Truth Lemma). Let \mathcal{ST} -canonical model be a class of *tt-model*. For all $\phi \in \mathcal{ST}$ -MCS, $\mathcal{ST} \models \phi$ iff $\phi \in \mathcal{ST}$ -MCS.

Proof. The proof is by induction on the structure of ϕ .

Base case: Suppose ϕ is a spatial formula $\Box \tau$ or an atomic predicate $x_i \geq 0$.

$$(\mathcal{ST}, s) \models \Box \tau \Leftrightarrow V^\Gamma(\Box \tau, s) = \top \Leftrightarrow \Box \tau \in s,$$

$$(\mathcal{ST}, s) \models x_i \geq 0 \Leftrightarrow V^\Gamma(x_i \geq 0, s) = x_i \Leftrightarrow x_i \geq 0 \in s.$$

Inductive step: Suppose ϕ is an atomic predicate $\neg \phi$, $\phi_1 \wedge \phi_2$, $\phi_1 \vee \phi_2$, $\Box \phi$, $\Diamond \phi$, $\phi \mathcal{U} \varphi$. We show the proof of the case $\Box \phi$, and leave the others to reader. We have $(\mathcal{ST}, s) \models \Box \phi \Leftrightarrow \Box \phi \in s$ (assuming the inductive hypothesis).

$$(\mathcal{ST}, s) \models \Box \phi$$

$$\Leftrightarrow \forall s', sR_i^\Gamma s' \Rightarrow \mathcal{ST}, s' \models \phi$$

$$\Leftrightarrow \forall s', sR_i^\Gamma s' \Rightarrow \phi \in s'$$

we need to show that $\Box \phi \in s \Leftrightarrow \forall s', sR_i^\Gamma s' \Rightarrow \phi \in s'$.

\Rightarrow follows immediately from the definition IV.2.

As for \Leftarrow : suppose $\Box \phi \notin s$. We need to show

$$\exists s', sR_i^\Gamma s' \text{ and } \phi \notin s'$$

$$\Leftrightarrow \exists s', sR_i^\Gamma s' \text{ and } \neg \phi \in s'$$

$$\Leftrightarrow \exists s', \{\varphi \mid \Box \varphi \in s\} \subseteq s' \text{ and } \neg \phi \in s'$$

$$\Leftrightarrow \exists s', \{\varphi \mid \Box \varphi \in s\} \cup \{\neg \phi\} \subseteq s'$$

It is easy to show that $\{\varphi \mid \Box \varphi \in s\} \cup \{\neg \phi\}$ is \mathcal{ST} -consistent. Suppose not, i.e., $\{\varphi \mid \Box \varphi \in s\} \cup \{\neg \phi\}$ is \mathcal{ST} -inconsistent. Then $\vdash_{\mathcal{ST}} (\varphi_1 \wedge \dots \wedge \varphi_n) \rightarrow \phi$ for some $\{\Box \varphi_1, \dots, \Box \varphi_n\} \subseteq s$. But \mathcal{ST} is canonical and s is \mathcal{ST} -MCS, so s must contain $(\Box \varphi_1 \wedge \dots \wedge \Box \varphi_n) \rightarrow \Box \phi$. From $\Box \varphi_i \in s$, it follows $\Box \phi \in s$. This contradicts the hypothesis that $\Box \phi \notin s$. \square

Definition IV.3. The Hilbert-style proof system for the logic **STSL** has the following axiom schemes:

A0 All classical tautologies of first-order logic

A1 $\neg \circ \phi \Leftrightarrow \circ \neg \phi$

A2 $\neg \Diamond \phi \Leftrightarrow \Box \neg \phi$

- A3 $\circ(\phi \rightarrow \varphi) \rightarrow (\circ\phi \rightarrow \circ\varphi)$
A4 $\Box(\phi \rightarrow \circ\varphi) \rightarrow (\phi \rightarrow \Box\varphi)$
A5 $(\phi U \varphi) \leftrightarrow \varphi \vee \circ(\phi U \varphi)$
A6 $(\phi U \varphi) \rightarrow \Diamond\varphi$
 $\Box K$ $\Box(\phi \rightarrow \varphi) \rightarrow (\Box\phi \rightarrow \Box\varphi)$
 $\Box T$ $\Box\phi \rightarrow \phi$
 $\Box 4$ $\Box\phi \rightarrow \Box\Box\phi$

And the inference rules:

- MP $\frac{\phi \quad \phi \rightarrow \varphi}{\varphi}$
 N_{\Box} $\frac{\phi}{\vdash \Box\phi}$
 N_{\Diamond} $\frac{\phi}{\vdash \Diamond\phi}$

Soundness refers to that all the theorems in **STSL** are logically valid. Equivalently, A spatio-temporal logic is *sound* with respect to *tt*-model if for all the formula ϕ , $\vdash_{ST} \phi$ implies $\models \phi$. Let \mathcal{ST} be a class of *tt*-model, A spatio-temporal logic is *strongly complete* in \mathcal{ST} if for any set of formulas $\Gamma \cup \{\phi\}$, if $\Gamma \models_{ST} \phi$ then $\Gamma \vdash_{ST} \phi$. If the semantics of Γ satisfies ϕ on \mathcal{ST} then ϕ is deducible from Γ .

Theorem IV.2. *The above axiomatization is sound for tt-model.*

Proof. This follows from the fact that all axioms are valid and all rules preserve validity. \square

Theorem IV.3. *The system for STSL is weakly complete with respect to tt-model. i.e., for every STSL formula, $\models_{ST} \phi$ implies $\vdash_{ST} \phi$.*

Proof. We will present the proof with weak completeness of **STSL** based on the work [19], [20]. The *strong completeness* is equal to *frame completeness* and compactness in *universal modal logic* [19]. Temporal logic in the flow of real time has weak completeness [20], which proposes *finitely complete* and *expressively complete*, but fails compactness theorem. Further, a complete result based on the lexicographic products of modal logics with linear temporal logic is present in [21]. Those conclusions contribute greatly to the proof of weak completeness. \square

V. CONCLUSION AND FUTURE WORK

In this paper, we build a spatio-temporal specification language, combining STL with spatial logic $S4_u$, specifically containing dense time and topological space. We provide the syntax and semantics of the spatio-temporal language, and guarantee the seamless integration of spatial logic with temporal aspect from the perspective of the changes of purely spatial proposition $STSL_{PC}$ and spatial objects $STSL_{OC}$ over time. A Hilbert-style proof axiomatization system and the soundness and completeness result is present for the language.

The proposed **STSL** has a powerful expressiveness. It will be interesting to find a strongly complete fragment of **STSL**. For that, a more constrained axiomatization system need to be present, and more restricted inference and proof should be provided.

Abstract—We have conducted a case study in which an autonomous vehicle intersection control protocol is formally specified in Maude and model checked with Maude model checking facilities. We found that a function used in the protocol should be revised while formally specifying it and a logical clock such that times are total order should be used to avoid deadlock states during model checking experiments.

Keywords—Autonomous vehicle; Intersection control; LTL; Maude; Model checking

I. INTRODUCTION

It is predicted that vehicles would be fully autonomous (<https://www.wired.com/2012/09/ieee-autonomous-2040/>). To this end, multiple new technologies should be emerged and used. One of them is a protocol to control vehicles on an intersection such that collision must be avoided and vehicles can eventually cross the intersection. Lim, Jeong, Park & Lee have proposed such a protocol [1], which is called the LJPL protocol in this paper. Because such a protocol is intricate, formal methods should be utilized to formally verify that the protocol enjoys desired properties.

We have conducted a case study in which the LJPL protocol is formally specified in Maude [2], a rewriting logic-based specification/programming language, and model checked with the Maude model checking facilities (a reachability analyzer and an LTL model checker). While carefully reviewing the protocol, we found that one function used in the protocol should be revised. We also found that a logical clock such that times are total order should be used to avoid deadlock states during model checking experiments.

Related studies have been conducted, two among which are mentioned. Ölveczky and Meseguer [3] have reported on a case study in which a distributed embedded system (DES) family has been specified and model checked in Real-Time Maude, where the DES is for a pedestrian and car 4-way traffic intersection in which autonomous devices communicate by asynchronous message passing without a

centralized controller. Asplund, et al. [4] have demonstrated how a Satisfiability Modulo Theory (SMT) solver can be used to prove that a distributed coordination protocol for autonomous vehicles satisfies the intersection collision avoidance property. Z3 has been used as an SMT solver. Our approach uses a high abstract notion of time to formally specify the LJPL protocol, contributing to reduction of reachable state space sizes. Thus, it is unnecessary to use any realtime-related concepts and techniques.

The rest of the paper is organized as follows: § II Preliminaries, § III Lim-Jeong-Park-Lee Autonomous Vehicle Intersection Control Protocol, § IV Formal Specification, § V Model Checking, and § VI Conclusion.

II. PRELIMINARIES

A Kripke structure K is $\langle S, I, T, P, L \rangle$, where S is a set of states, $I \subseteq S$ is the set of initial states, $T \subseteq S \times S$ is a total binary relation over S , P is a set of atomic propositions and $L \in S \rightarrow 2^P$ is a labeling function. $(s, s') \in T$ is called a state transition from s to s' and T may be called the state transitions. For $s \in S$, $L(s)$ is the set of atomic propositions that hold in s . The semantics of LTL is defined over infinite sequences of states generated from K . The LTL formula used in the paper is in the form $\Diamond p$, where p is a state formula that does not have any temporal connectives. K satisfies $\Diamond p$ iff for all $s_0 \in I$, for all infinite sequencers of state starting with s_0 , there exists a state in the sequence such that p holds.

There are multiple possible ways to express states. We express a state as a braced associative-commutative (AC) collection of name-value pairs. AC collections are called soups, and name-value pairs are called observable components. That is, a state is expressed as a braced soup of observable components. The juxtaposition operator is used as the constructor of soups. Let oc_1, oc_2, oc_3 be observable components, and then $oc_1 \ oc_2 \ oc_3$ is the soup of those three observable components. A state is expressed as $\{oc_1 \ oc_2 \ oc_3\}$. There are multiple possible ways to specify state transitions. We specify them as rewrite rules. Concretely, we use Maude [2], a programming/specification

DOI reference number: 10.18293/SEKE2019-021

language based on rewriting logic. Maude makes it possible to specify complex systems flexibly and is also equipped with model checking facilities (a reachability analyzer and an LTL model checker). Maude allows us to use what are called matching equations in the conditional part of a conditional rewrite rule. A conditional rewrite rule (or just a rule) is in the form $\text{crl } [lb] : l \Rightarrow r \text{ if } \dots / \wedge p_1 := p_2 / \wedge \dots$, where lb is the label given to the rule and $p_1 := p_2$ is a matching equation, where p_1 may have fresh variables and p_2 does not. $p_1 := p_2$ holds if p_1 matches p_2 , making a substitution in which fresh variables in p_1 are mapped to some terms (values) in p_2 . Matching equations are similar to **let** expressions in functional programming languages.

The search command tries to find a state reachable from t such that the state matches p and satisfies c :

```
search [1] in M : t => * p such that c .
```

where M is a specification of the S and T parts of K . t typically represents an initial state of K . The search command can be used to model check that K enjoys an invariant property if p and c represent the negation of the state formula concerned.

The search command can also be used to find a deadlock state:

```
search [1] in M : t => ! p .
```

Let init be the only initial state of K and φ be an LTL formula, such as $\Diamond p$. Then, the Maude LTL model checker checks that K satisfies φ by reducing $\text{modelCheck}(\text{init}, \varphi)$.

III. LIM-JEONG-PARK-LEE AUTONOMOUS VEHICLE INTERSECTION CONTROL PROTOCOL

Let us consider the intersection shown in Fig. 1, where two streets are crossed. Vehicles are supposed to run on the right-hand side of a street and each side of a street has two lanes. Each lane is named as shown in Fig. 1. When crossing the intersection, vehicles on the right lane of one side of a street, such as lane0, are supposed to go straight or turn right as shown in Fig. 1 and those on the left lane of one side of a street, such as lane1, are supposed to turn left as shown in Fig. 1. The space overlapped by the two streets is a critical section as shown in Fig. 1, where vehicles should be controlled so that they never crash into each other.

Vehicles on lane0 and those on lane4 are allowed to go through the intersection simultaneously, while vehicles on lane0 and those on lane2 are not. lane0 and lane4 are concurrent, while lane0 and lane2 are conflict. For $i = 0, 2, 4, 6$, the conflict lanes of lane i are lane j for $j = (i + 2) \bmod 8, (i + 5) \bmod 8, (i + 6) \bmod 8, (i + 7) \bmod 8$, and the concurrent lanes of lane i are lane j for $j = (i + 1) \bmod 8, (i + 3) \bmod 8, (i + 4) \bmod 8$. For $i = 1, 3, 5, 7$, the conflict lanes of lane i are lane j for $j = (i + 1) \bmod 8, (i + 2) \bmod 8, (i + 3) \bmod 8, (i +$

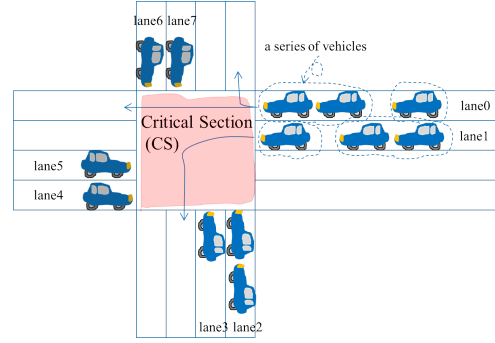

Figure 1. An intersection

$6) \bmod 8$, and the concurrent lanes of lane i are lane j for $j = (i + 4) \bmod 8, (i + 5) \bmod 8, (i + 7) \bmod 8$.

Each vehicle is given its status, which is running, approaching, stopped, crossing or crossed. Note that running and approaching are not used in the paper[1] in which the LJPL protocol is proposed. When a vehicle is far enough from the intersection¹, its status is running. Each lane is given a queue. When vehicles are approaching the intersection shortly enough, their statuses become approaching, their IDs are enqueued into a queue specific to each lane, and they never change the lane and never pass the vehicles in front of them. Vehicles then estimate the time when they are supposed to get to the intersection. The paper[1] in which the the LJPL protocol is proposed says that “To control the intersection traffic correctly, we assume that the time for vehicles is synchronized by retrieving GPS time or using a logical clock.” The present paper assumes that GPS is retrieved to synchronize vehicles, namely that there is a global clock shared by all vehicles. When a vehicle is enqueued into a queue and there is no other vehicle whose status is stopped in front on it (note that there are two such cases: (1) the vehicle is the top of the queue, namely that there is no other vehicle in front of the vehicle on the lane and (2) there is another vehicle that is followed by the vehicle and whose status is crossing on the lane), the vehicle becomes lead and its status becomes stopped. Otherwise, the vehicle becomes non-lead and its status becomes stopped. Any lead vehicle checks if there is no vehicle on any conflict lanes crossing the intersection and the time given to the vehicle is earlier than those given to the lead vehicles on the conflict lanes. If so, the lead vehicle is allowed to go through the intersection and its status becomes crossing. At the same time all non-lead vehicles whose statuses are stopped and that follow the lead vehicle are also allowed to go through the intersection and their statuses become crossing. The LJPL protocol treats a series of vehicles as a

¹When the LJPL protocol is implemented, we need to define “being far enough from,” say, 100m or longer. In this paper, however, we leave it abstract in the specification.

train so that the series of vehicles are allowed to go through the intersection simultaneously. For example, let us consider the vehicles on lane0 shown in Fig. 1 and let us suppose that the first one is lead, the second one is non-lead, the third one is lead and there is no more. When the first one is allowed to go thorough the intersection, so is the second one and then the series of the first and second ones are treated as a train.

A lead vehicle whose status is stopped on a lane exchanges some pieces of information with the lead vehicles on the four conflict lanes. One piece of information exchanged is the time (called the arrival time in this paper) when each other vehicle will arrive at the intersection. If the lead vehicle arrival time is earlier than all the four lead vehicles' arrival times on the four conflict lanes, then the status of the lead vehicle becomes crossing. Moreover, the statuses of all follower vehicles whose statuses are stopped also become crossing. When a vehicle has crossed the intersection, the status of the vehicle becomes crossed and its ID is dequeued from the queue. Such exchanges of pieces of information among lead vehicles are conducted by Algorithm 1 and Algorithm 2 [1]:

Algorithm 1. Basic IVC protocol (active thread)

```

1: begin at each round
2:    $vehicle_{target} \leftarrow selectVehicle();$ 
3:    $send(information_{local}, vehicle_{target});$ 
4:    $information_{target} \leftarrow receive(vehicle_{target});$ 
5:    $updateInformation(information_{local},$ 
                      $information_{target});$ 
6: end

```

Algorithm 2. Basic IVC protocol (passive thread)

```

1: repeat
2:    $vehicle_{target} \leftarrow waitForVehicle();$ 
3:    $information_{target} \leftarrow receive(vehicle_{target});$ 
4:    $updateInformation(information_{local},$ 
                      $information_{target});$ 
5:    $send(information_{local}, vehicle_{target});$ 
6: until forever;

```

where IVS stands for inter-vehicle-communication [5]. $information_x$, where $x = target, local$, consists of the following pieces of information:

- $lane$ – Lane number from 0 to 7
- $arrivalTime$ – Arrival time for its own vehicle
- $arrivalTime_{lead}$ – Arrival time for lead vehicle
- $lead$ – True or false
- $conflictLane$ – List of conflict lanes
- $concurrentLane$ – List of concurrent lanes
- $concurrentLanePassing$ – List of concurrent lanes for passing vehicles
- $status$ – stopped, passing, or passed

Note that running and approaching are also used as status values in this paper.

The LJPL protocol itself is described as Algorithm 3 [1]:

Algorithm 3. Mutual exclusion algorithm via IVC

```

1: begin initialization
2:    $infoVehicles_i[j] \leftarrow null, \forall i \in \{1, \dots, max_{lane}\},$ 
    $\forall j \in \{1, \dots, max_{vehicle}\};$ 
3: end
4: begin when entering the intersection
5:    $lane \leftarrow getLaneNum();$ 
6:    $arrivalTime \leftarrow getCurrentTime();$ 
7:   if no vehicle on the lane,
   where  $status == stopped$  then
8:      $lead \leftarrow true;$ 
9:      $arrivalTime_{lead} \leftarrow arrivalTime;$ 
10:  else
11:     $lead \leftarrow false;$ 
12:  endif
13:   $status \leftarrow stopped;$ 
14: end
15: begin at each cycle
16:   update  $infoVehicles_i[j]$ 
   according to Algorithm 1 and Algorithm 2;
17:   check  $infoVehicles_{conflictLane}$ 
   for passing the intersection;
18:   if passingCondition() then
19:      $status \leftarrow passing;$ 
20:     move and cross the intersection;
21:   endif
22: end
23: begin when exiting the intersection
24:    $status \leftarrow passed;$ 
25: end
26: function passingCondition()
27:   if  $\forall arrivalTime_{lead} \in infoVehicles_{conflictLane}$ 
    $> arrivalTime_{lead}$  and
    $\forall status \in infoVehicles_{conflictLane}$ 
    $== stopped$  then
28:     return true;
29:   else if  $\exists status \in infoVehicles_{concurrentLane}$ 
    $== passing$  and
    $\exists ! lane_i \in \{lane_n, \forall n \in \{0, \dots, max_{lane}\}$ 
    $| status == passing\}$  and
    $\forall arrivalTime_{lead}$ 
    $\in infoVehicles_{concurrentLanePassing}$ 
    $> arrivalTime_{lead}$  then
30:     return true;
31:   else
32:     return false;
33:   end function

```

From a vehicle v point of view such that v is located on a lane l , function passingCondition() returns true even if there exists a lead vehicle v' on a conflict lane of l such that the status is passing (namely that the first condition is

Figure 2. An initial state

false) but if the second condition is true. If so, v is permitted to cross the intersection and may crash into v' . Therefore, `passingCondition()` is revised as follows: it returns true if the first condition is true and returns false otherwise.

IV. FORMAL SPECIFICATION

Let K_{LJPL} be the Kripke structure formalizing the LJPL protocol.

The four kinds of observable components are used:

- $(v[vid] : lid, vstat, t, lt)$ – vid is a vehicle ID (a natural number), lid is a lane ID (a natural number) on which the vehicle vid is located, $vstat$ is the status of the vehicle vid , t is the time when the vehicle vid will reach the intersection and lt is the time when the lead vehicle will reach the intersection if any.
- $(lane[lid] : q)$ – lid is a lane ID (a natural number) and q is a queue of vehicle IDs (natural numbers).
- $(clock : t, b)$ – t is a natural number that represents an abstract notion of the current time and b is a Boolean value. If time is allowed to increase without any constraints, the reachable state space can quickly explode. Therefore, the following constraint will be put: whenever b is true, t can increment and b becomes false if so. When a vehicle obtains the current time t (which does not change t , though), b becomes true.
- $(gstat : gstat)$ – $gstat$ is either `fin` or `nFin`. If it is `fin`, then all vehicles concerned have crossed the intersection.

Let us consider the initial state as shown in Fig. 2 such that two vehicles are running on lane0, one vehicle is running on lane1, two vehicles are running on lane5 and there is no vehicle on the other lanes. The initial state (referred as `init`) is expressed as follows:

```
{(gstat: nFin) (clock: 0, false)
 (lane[0]: oo) (lane[1]: oo) (lane[2]: oo)
 (lane[3]: oo) (lane[4]: oo) (lane[5]: oo)
 (lane[6]: oo) (lane[7]: oo)
 (v[oo]: 0, stopped, oo, oo) (v[oo]: 1, stopped, oo, oo)
 (v[oo]: 2, stopped, oo, oo) (v[oo]: 3, stopped, oo, oo)
 (v[oo]: 4, stopped, oo, oo) (v[oo]: 5, stopped, oo, oo)
 (v[oo]: 6, stopped, oo, oo) (v[oo]: 7, stopped, oo, oo)
 (v[0]: 0, running, oo, oo) (v[1]: 0, running, oo, oo)
 (v[2]: 1, running, oo, oo) (v[3]: 5, running, oo, oo)
 (v[4]: 5, running, oo, oo) }
```

Each queue for each lane, such as the one represented by $(lane[0] : oo)$, only consists of `oo` that represents ∞ , which means that there is no vehicle on the lane close enough to the intersection. There are eight $v[oo]$ observable components that are used to represent dummy vehicles. The $v[0]$, $v[1]$, $v[2]$, $v[3]$, and $v[4]$ observable components represent the five vehicles, the first two of which are on lane0, the third of which is on lane1 and the last two of which are on lane5. The global clock represented by $(clock : 0, false)$ is initially 0. Because the second value of the `clock` observable component is `false`, the abstract notion of the current time cannot increment. The value of the `gstat` observable component is initially `nFin`.

T_{LJPL} is specified by 12 rewrite rules. The following rule is used to make T_{LJPL} total:

```
rl [stutter] : {(gstat: fin) OCs}
=> {(gstat: fin) OCs} .
```

where `OCs` is a Maude variable of observable component soups.

```
cr1 [fin] : {(gstat: nFin) OCs}
=> {(gstat: fin) OCs} if fin?(OCs) .
```

where `fin?(OCs)` returns true if and only if each vehicle in `OCs` has crossed the intersection.

```
rl [tick] :
{(gstat: nFin) (clock: T, true) OCs}
=>
{(gstat: nFin) (clock: (T + 1), false) OCs} .
```

where T is a Maude variable of natural numbers. If the second value of the `clock` observable component is `true`, the abstract notion of the current time T increments and the second value becomes `false`.

Two rules are used to specify a set of transitions that change a vehicle status from running to approaching. One rule deals with the case in which there is no vehicle close enough to the intersection on the lane where the vehicle is running, and the other deals with the case in which there exists at least one vehicle close enough to the intersection on the lane. The two rules are as follows:

```
rl [approach1] :
{(gstat: nFin) (clock: T, B) (lane[LI]: oo)
 (v[VI]: LI, running, oo, oo) OCs}
=>
{(gstat: nFin) (clock: T, true)
 (lane[LI]: VI) (v[VI]: LI, approaching, T, oo)
 OCs} .

rl [approach2] : {(gstat: nFin) (clock: T, B)
 (lane[LI]: (VI' ; VS))
 (v[VI]: LI, running, oo, oo) OCs}
=> {(gstat: nFin) (clock: T, true)
 (lane[LI]: (VI' ; VS ; VI))
 (v[VI]: LI, approaching, T, oo) OCs} .
```

where B is Maude variable of Boolean values, LI , VI & VI' are Maude variables of natural numbers, VS is a

Maude variable of queues of natural numbers & ∞ , and $_;$ is the constructor of queues, where an underscore $_$ is a place holder where an argument is put. $_;$ is associative, meaning that $(q_1 ; q_2) ; q_3 = q_1 ; (q_2 ; q_3)$, and a single element (a natural number or ∞) is treated as the singleton queue that only consists of the element.

Three rules are used to specify a set of transitions that change a vehicle status from approaching to stopped. The first rule `check1` deals with the case in which the vehicle is the top of the queue concerned, where the vehicle will be lead on the lane concerned, the second rule `check2` deals with the case in which there exists a vehicle in front of the vehicle on the lane concerned such that the preceding vehicle status is stopped, where the vehicle will be non-lead on the lane, and the third rule `check3` deals with the case in which there exists a vehicle in front of the vehicle on the lane concerned such that the preceding vehicle status is crossing, where the vehicle will be lead on the lane. The three rules are as follows:

```

r1 [check1] :
{(gstat: nFin) (lane[LI]: (VI ; VS))
 (v[VI]: LI,approaching,T,oo) OCs}
=> {(gstat: nFin) (lane[LI]: (VI ; VS))
 (v[VI]: LI,stopped,T,T) OCs} .

r1 [check2] : {(gstat: nFin)
 (lane[LI]: (VS' ; VI' ; VI ; VS))
 (v[VI']: LI,stopped,T,T')
 (v[VI]: LI,approaching,T'',oo) OCs}
=> {(gstat: nFin)
 (lane[LI]: (VS' ; VI' ; VI ; VS))
 (v[VI']: LI,stopped,T,T')
 (v[VI]: LI,stopped,T'',T') OCs} .

r1 [check3] : {(gstat: nFin)
 (lane[LI]: (VS' ; VI' ; VI ; VS))
 (v[VI']: LI,crossing,T,T')
 (v[VI]: LI,approaching,T'',oo) OCs}
=> {(gstat: nFin)
 (lane[LI]: (VS' ; VI' ; VI ; VS))
 (v[VI']: LI,crossing,T,T')
 (v[VI]: LI,stopped,T'',T') OCs} .

```

where T' & T'' are Maude variables of natural numbers and VS' is a Maude variable of queues. The reason why $v[vid]$ observable components, where vid is a vehicle ID, do not have any values that correspond to *lead* in *information_x* is that it is possible to use queues, etc. to manage which vehicles are lead or not.

Two rules are used to specify a set of transitions that change a lead vehicle status from stopped to crossing. One rule deals with the case in which the ID of the lane on which the lead vehicle is located is even and the other deals with the case in which it is odd. The first rule `enter1` is as follows:

```

cr1 [enter1] :
{(gstat: nFin) (lane[LI]: (VI ; VS))
 (v[VI]: LI,stopped,T,T) OCs}

```

```

=> {(gstat: nFin) (lane[LI]: (VI ; VS))
 (v[VI]: LI,crossing,T,T) OCs'}
if isEven(LI) /\
  LI1 := (LI + 2) rem 8 /\
  (lane[LI1]: (VI1 ; VS1))
  (v[VI1]: LI1,VSt1,T11,T12) OCs1 := OCs /\
  VSt1 = stopped /\ T < T12 /\
  LI2 := (LI + 5) rem 8 /\
  (lane[LI2]: (VI2 ; VS2))
  (v[VI2]: LI2,VSt2,T21,T22) OCs2 := OCs /\
  VSt2 = stopped /\ T < T22 /\
  LI3 := (LI + 6) rem 8 /\
  (lane[LI3]: (VI3 ; VS3))
  (v[VI3]: LI3,VSt3,T31,T32) OCs3 := OCs /\
  VSt3 = stopped /\ T < T32 /\
  LI4 := (LI + 7) rem 8 /\
  (lane[LI4]: (VI4 ; VS4))
  (v[VI4]: LI4,VSt4,T41,T42) OCs4 := OCs /\
  VSt4 = stopped /\ T < T42 /\
  OCs' := letCross(VS,OCs) .

```

where LI_i for $i = 1, \dots, 4$ is a Maude variable of natural numbers, VI_i & T_j for $i = 1, \dots, 4$ & $j = 11, 12, \dots, 41, 42$ are Maude variables of natural numbers & ∞ , VS_i for $i = 1, \dots, 4$ is a Maude variable of queues, VSt_i for $i = 1, \dots, 4$ is a Maude variable of vehicle statuses, and OCs_i & OCs' for $i = 1, \dots, 4$ are Maude variables of observable component soups. `isEven(LI)` holds if LI is even. For the front-most vehicle (which may be a dummy one whose ID is `oo`) of each of the four conflict lanes of lane LI , the rules checks if it is not crossing the intersection and its arrival time is greater than the arrival time T of the vehicle VI concerned. If the conditions are fulfilled, the status of the vehicle VI concerned becomes crossing from stopped and the statuses of all vehicles that follow VI and whose statuses are stopped also become crossing, which is done by `letCross(VS,OCs)`. The second rule `enter2` can be described likewise.

Two rules are used to specify a set of transitions that change a vehicle status to crossed from crossing. The first rule deals with the case in which the vehicle concerned is one and only one vehicle in the queue that corresponds to the lane concerned, and the second rule deals with the case in which the queue that corresponds to the lane concerned contain two or more vehicles. The two rules are as follows:

```

r1 [leave1] :
{(gstat: nFin) (lane[LI]: VI)
 (v[VI]: LI,crossing,T,T') OCs}
=> {(gstat: nFin) (lane[LI]: oo)
 (v[VI]: LI,crossed,T,T') OCs} .

r1 [leave2] :
{(gstat: nFin) (lane[LI]: (VI ; VI' ; VS))
 (v[VI]: LI,crossing,T,T') OCs}
=> {(gstat: nFin) (lane[LI]: (VI' ; VS))
 (v[VI]: LI,crossed,T,T') OCs} .

```

When a vehicle status changes to closed from crossing, it is deleted from the queue that corresponds to the lane concerned.

V. MODEL CHECKING

The paper [1] in which the LJPL protocol is proposed takes into account three desired properties the protocol should enjoy:

- *Safety (version 2)* No vehicles in conflict lanes are in CS at the same time.
- *Deadlock-freedom* If a vehicle is trying to pass the intersection (CS), then some vehicle, not necessarily the same one, finally pass the intersection.
- *Starvation-freedom* If a vehicle is trying to pass the intersection (CS), then the vehicle must finally pass the intersection in finite time.

The *Safety (version 2)* property can be checked by the following search command:

```
search [1] in IMUTEX : init =>*
{ (v[VI]: LI, crossing, T, T')
  (v[VI']: LI', crossing, T2, T2') OCS }
such that areConflict(LI, LI') .
```

where IMUTEX is the specification of the protocol and `areConflict(LI, LI')` holds if and only if the lanes LI and LI' are conflict. The search commands tries to find a state from the initial state `init` such that two vehicles are crossing the intersection on two conflict lanes LI and LI'. It does not find any such states, meaning that the protocol enjoys the *Safety (version 2)* property for the case as shown in Fig. 2.

The *Deadlock-freedom* property can be checked by the following search command:

```
search [1] in IMUTEX : init =>! {OCS} .
```

The search commands tries to find a state from the initial state `init` such that no transition can be conducted. It finds such a state that contains the following observable components:

```
(lane[0]: 0 ; 1) (lane[5]: 3 ; 4)
(v[0]: 0, stopped, 0, 0) (v[1]: 0, stopped, 0, 0)
(v[3]: 5, stopped, 0, 0) (v[4]: 5, stopped, 0, 0)
```

Vehicle 0 is the lead one on lane0, while vehicle 3 is the lead one on lane5. The both lead vehicles' arrival times are 0. Therefore, either one is not permitted to cross the intersection.

The counterexample of the *Deadlock-freedom* property implies that it does not suffice to use a global clock, which may create a symmetry. To break the symmetry, lane IDs could be used. When there are multiple lead vehicles on conflict lanes such that their arrival times are exactly the same, higher priorities are given to those on lanes whose IDs are less. That is, a logical clock such that times are total order is used. In the specification, the two rules `enter1` and `enter2` should be revised such that $T < T1i$ for $i = 1, \dots, 4$ used in the conditions is replaced with $(T < T1i \text{ or } (T == T1i \text{ and } LI < LIi))$. The protocol in which a logical clock such that times are

total order is used enjoys both the *Safety (version 2)* and *Deadlock-freedom* properties for the case as shown in Fig. 2. Let the protocol refer to the one in which a logical clock such that times are total order is used.

To model check that the protocol enjoys the *Starvation-freedom* property, it is necessary to define P_{LJPL} and L_{LJPL} . P_{LJPL} consists of one atomic proposition `fin`. L_{LJPL} is defined as follows:

```
eq {(gstat: fin) OCS} |= fin = true .
eq {OCS} |= PROP = false [otherwise] .
```

where PROP is a Maude variable of atomic propositions. The two equations say that for all states $s \in S_{LJPL}$ $L_{LJPL}(s) = \{\text{fin}\}$ if and only if s contains `(gstat: fin)`. The *Starvation-freedom* property is then defined as follows:

```
eq halt = <> fin .
```

where `<>` is the LTL eventually connective \Diamond . We model check if the protocol enjoys the *Starvation-freedom* property by reducing `modelCheck(init, halt)`. No counterexample is found. Thus, the protocol enjoys the property for the case as shown in Fig. 2.

VI. CONCLUSION

We have reported on a case study in which the LJPL protocol is formally specified in Maude and model checked with Maude model checking facilities. We found that a function used in the protocol should be revised while formally specifying it and a logical clock such that times are total order should be used to avoid deadlock states during model checking experiments.

We have encountered the state explosion problem when we tried to model check that the protocol enjoys some property for the case as shown in Fig. 1. One piece of our future work is to remedy the situation, say, by using the divide & conquer approach to (leads-to) model checking [6].

Abstract

One challenge in constructing a Bayesian network (BN) is defining the node probability tables (NPTs), which can be learned from data or elicited from domain experts. In practice, for large-scale BN it is common not to have enough data for learning and elicitation from experts is unfeasible. Previous work proposed a solution to this problem: the Ranked Nodes Method (RNM). However, this solution needs to be applied by a RNM expert who, through the elicitation of expert judgement, identifies the necessary parameters for the RNM algorithm to generate the NPTs. Hence, this paper presents a novel approach to define NPT using the RNM with no ranked nodes-specific knowledge. The solution is named Simulated Bayesian Network Expert (SBNE). It consists of eliciting a subset of the NPT from the domain experts which is used as input to an algorithm that estimates the optimal parameters for the RNM to generate the NPTs. To validate our solution, we conducted an experiment with multiple domain experts and compared the results with other methods. Our solution outperformed the other methods (producing NPTs at least 12% more accurate) and is, therefore, a promising approach to apply RNM without relying on RNM experts.

1 Introduction

Bayesian Network (BN) is a mathematical model that graphically and numerically represents the probabilistic relationships between random variables through Bayes theorem. Recently, given the evolution of the computational capacity, which enabled the calculation of complex BNs, it has become a popular technique to assist on decision-making [7] and it has been applied in several areas such as large-scale engineering projects [12], software engineering [16, 14], and sports management [4].

The challenges for the construction of BNs can be divided into two sub-problems: (i) construct the directed acyclic graph (DAG) and (ii) define the NPTs. In this research, we focus on (ii). In cases where there is historical data with enough information about the domain to be modelled it is possible to automate the process of NPT definition through batch learning [10].

Unfortunately, in practice, in most cases, there is not enough data [7] to apply batch learning. In such cases, it is necessary to manually define the NPTs through the elicitation of domain experts knowledge. However, given that the complexity of building NPTs grows exponentially, depending on the number of parents and states, the manual definition of the NPT becomes unfeasible.

To reduce the complexity of manually defining a NPT through the elicitation of knowledge from domain experts, Fenton et al. [7] proposed the Ranked Nodes Method (RNM). This method is limited to nodes (i.e., random variables) with an ordinal scale (e.g., “Good”, “Medium”, “Bad”), which are called ranked nodes.

In ranked nodes, the ordinal scale is mapped into a scale monotonically ordered in the interval $[0, 1]$. The solution is based on a Normal distribution truncated between $[0, 1]$

(i.e., TNormal) to represent the NPTs. Hence, the NPT of a child node is a TNormal calculated as the mixture of the TNormals of its parent nodes. There are four expressions to model the mixture's mean (μ): weighted mean (*WMEAN*), weighted minimum (*WMIN*), weighted maximum (*WMAX*) and the mixture of the classic minimum and maximum functions (*MIXMINMAX*).

Hence, to properly use the RNM it is necessary to understand the mixture process to select the appropriate parameters: the weighted expression; a set of weights of the parent nodes; and the variance (σ). However, even when RNM experts are available, the application of the RNM method still presents challenges.

The means to identify a suitable expression to mix the TNormals of the parent nodes based on mode assessments of the domain experts is straightforward, as described in Laitila and Virtanen [11]. Conversely, the discovery of the weights and variance parameters are far more complex. Such tasks are usually performed by the RNM experts using a trial and error strategy. This strategy comes down to a cycle of generating, verifying and adjusting the parameters to regenerate the NPTs, which is repeated until a satisfying result is discovered [7, 11].

In this paper, we present a novel approach to improve the applicability of RNM. Our main goal is to encapsulate its complexity, allowing for its use by domain experts with no prior knowledge about ranked nodes. We use “what if” analysis (i.e., truth tables) to elicit knowledge from experts using visual aids. Given the information collected, we use the expert system proposed in Silva et al. [5] to obtain the weighted expression to mixture the TNormals and an algorithm named “Simulated Expert” to estimate the optimal variance and set of weights of the parent nodes.

We evaluated our solution with an experiment in which multiple domain experts applied our approach to RNM and two other methods to quantify a BN model related to the evaluation of cohesion of agile software development teams. The NPTs generated with the three methods were compared in terms of accuracy using manually defined NPTs as benchmark. The results showed that our solution is promising as it has achieved greater accuracy compared to the other methods.

2 Background

BNs are probabilistic graph models used to represent knowledge about uncertain domains. A BN, B , is a directed acyclic graph that represents a joint probability distribution over a set of random variables V [9]. The network is defined by the pair $B = \{G, \Theta\}$. G is the directed acyclic graph in which the nodes X_1, \dots, X_n represent random variables and the arcs represent the direct dependencies between these variables. Θ represents the set

Table 1. Example of a truth table.

Parent A	Parent B	Parent C	Child D
Very low	Very high	Very low	Low
Very high	Very low	Very low	Low
Very low	Very low	Very high	Low
Very low	Very high	Very high	High
Very high	Very low	Very high	Low
Very high	Very high	Very low	Medium

of probability functions. This set contains the parameter $\theta_{x_i|\pi_i} = P_B(x_i|\pi_i)$ for each x_i in X_i conditioned by π_i , the set of parents of X_i in G . Equation 1 presents the joint distribution defined by B over V .

$$P_B(X_1, \dots, X_n) = \prod_{i=1}^n P_B(x_i|\pi_i) = \prod_{i=1}^n \theta_{X_i|\pi_i} \quad (1)$$

We present an example of a BN in Fig. 1, in which ellipses represent the nodes and arrows represent the arcs. The probability functions are usually represented by NPTs. Even though the arcs represent the causal connection's direction between the variables, information can propagate in any direction [13].

Figure 1. A Bayesian network example.

According to Fenton et al. [7], to define the NPT, the RNM user should define the resulting TNormal parameters constructing “truth tables” using example scenarios, which they define as “what if” analysis. An example is shown in Table 1. By analysing it, we can conclude that defining the parameters is not straightforward and there is a need to understand the TNormal mixture process to apply the RNM.

In Perkusich et al. [15], a simplified approach to use the RNM whenever there is a need to collect data from multiple experts was presented. Instead of using “what if” analysis, it asks the experts to order the relationships between the child and parents nodes given their relative magnitude. The collected data is analysed statistically and used to define the weights for the function of μ , having the function type defined to *WMEAN* and a fixed variance of $5.0E^{-4}$. Therefore, although it encapsulates the complexity of the RNM approach, it has limited modelling capabilities and, as discussed in Perkusich et al. [16], it might produce incorrect NPTs.

In da Silva et al. [5], an approach based on production rules was proposed to encapsulate the complexity of calibrating the NPTs. Given a set of input values, the developed expert system automatically calibrates the NPTs. In this work, the modelling capabilities of the approach presented in Fenton et al. [7] is combined with ranked nodes specific knowledge encapsulation of the approach presented in Perkusich et al. [16]. However, the proposed approach also fixed the variance in $5.0E^{-4}$, which is a limiting factor.

3 Solution

SBNE is an approach to elicit expert knowledge and apply the RNM method without relying on the assistance of RNM experts. SBNE stands for Simulated Bayesian Network Expert. This approach can be divided into three steps: (i) direct or indirect probability assessment from domain experts; (ii) use of production rules¹ to define the weighted expression; and (iii) use of the “Simulated Expert” algorithm to estimate the input parameters required to apply the RNM method. In (i) domain experts use a GUI (still a prototype) that allows them to evaluate probability distributions directly (i.e., using numbers), or indirectly (i.e., using a visual tool).

3.1 Knowledge Elicitation Process

Figure 2. Component Prototype (A).

The prototype used in the probability elicitation process is here decomposed into two separate figures (for presentation purposes only). Hence, for each combination of extreme cases of the parent nodes (i.e., each row in the truth table) domain experts provides the expected probability distribution using an interactive bar chart (see Fig. 2) or sliders horizontally arranged (see Fig. 3). During

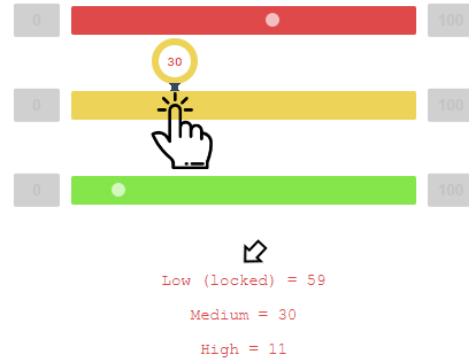

Figure 3. Component Prototype (B).

the elicitation process the domain experts directly interacts with the vertical bars so that by raising or lowering one of the bars the others automatically adjust itself. Strictly speaking, the natural order, which would be to inform the probability distributions with numbers and update the bar chart, is subverted so that users can interact and evaluate probability distributions by reasoning in terms of proportion rather than numerical terms, if they so wish. The sliders shown in Fig. 3 behave the same way.

A commonly employed strategy by domain experts is to first set up the bar relative to the state that they have greater confidence in estimating, and adjust the other states accordingly. To apply this strategy, the users can lock or unlock states by clicking over it, as shown with an arrow in Fig. 2, so that changes in other states do not modify the locked states. In short, the domain experts are able to provide the input data to the “Simulated Expert”, reasoning in terms of proportion, in which case they ignore the numerical information of the prototype, or reasoning directly in numerical terms, in which they use the elements presented in Fig. 3.

That been established, let us consider a simple case in which we have a child node C with two parent nodes, A and B, all having three states each (e.g., “low”, “medium” and “high”). To generate the child node’s NPT, the domain expert needs to assess four probability distributions as shown in Table 2. The Table 2 is basically a truth table composed by all the combinations of extreme states of the parent nodes.

In this case, each row in Table 2 is filled with data from the interaction of the domain experts with the components presented in Fig. 2 and 3. In other words, the domain experts inform four probability distributions, which constitutes a subset of the child node’s NPT. This subset is then used as input for the “Simulated Expert” to estimate the optimal parameters for the RNM algorithm. The weighted expression is defined using production rules as proposed in [5].

Rows	Parents		Child		
	A	B	C		
			Low	Medium	High
1	Low	Low	1	0	0
2	Low	High	0	0.3	0.7
3	High	Low	0	0.3	0.7
4	High	High	0	0	1

3.2 Simulated Expert

The Simulated Expert is an algorithm that receives as input the target probability distributions and a weighted expression to estimate the most suitable parameters (i.e., variance and set of weights of the parents) for the RNM algorithm to generate the NPTs.

The algorithm can be divided into three steps: (i) search for the most likely range of the optimal variance; (ii) identify the combination of weights of the parent nodes; and (iii) estimate the optimal variance parameter, as detailed below.

Step (i):

1. generate a variance vector V in range $5.0E^{-4}$ to 0.2 with step $5.0E^{-4}$;
2. set the weight of all parent nodes to 5;
3. define a “resolution” constant $\delta = 10$ in which the desired accuracy is inversely proportional to its value;
4. calculate the step $s = \frac{|V|}{\delta}$ to perform the search for the most probable interval of the optimal variance;
5. traverse V and at each s , define the variance of the child node using the current variance (e.g., shaded boxes in Fig. 4), calculate the NPT and its relative score. Do that until there is no room for improvement (e.g., row 5 in Fig. 4) or until it reaches the end of V ;
6. when the score starts decreasing return to the previous used variance index and calculate $a = index - \frac{|V|}{\delta}$ and $b = index + \frac{|V|}{\delta}$, the most likely interval where the optimal variance must be (e.g., row 7 in Fig. 4).

Step (ii):

1. set the variance of the child node using the median variance in $v \in V$ (i.e., $v = V[a : b]$), the interval at which the optimal variance is more likely to be (e.g.,

Table 3. Truth table approximation from the Simulated Expert.

Rows	Parents		Child		
	A	B	C		
			Low	Medium	High
1	Low	Low	0.9965	0.0035	0
2	Low	High	0	0.2995	0.7005
3	High	Low	0	0.2995	0.7005
4	High	High	0	0.0035	0.9965

Result obtained with the Simulated Expert for the child node C using the weighted expression $WMAX$ with the following parameters: $\sigma^2 = 0.062$; weight 4 for all parent nodes; $BS = 3.94E^{-06}$.

output of (i) illustrated in Fig. 4 row 7 in which it would be the variance located in index 5);

2. runs all combinations of weights of the parent nodes and stores the optimal set of weights.

Step (iii):

1. using the optimal set of weights obtained in previous step, traverse the subset v (e.g., row 7 in Fig. 4) performing the same actions as in item 5 from step (i).

Figure 4. Illustration of the execution of the algorithm from step (i).

For each execution of the RNM algorithm, a score of the estimated probabilities relative to the target probabilities is computed using the Brier Score, but any other similarity measure can be used (e.g., euclidean distance, Kullback-Leibler divergence).

Figure 5. BN used in the experiment.

4 Empirical Validation

An experiment was conducted with undergraduate students that work as junior software developers at the Embedded Lab – a software development lab located at the Federal University of Campina Grande, Brazil. The purpose of the experiment was to validate the proposed approach.

In the experiment, 10 developers quantified a BN (adapted from the model proposed in Freire et al. [8]) using the proposed approach and two others methods: the Weighted Sum Algorithm (WSA) and a variation of the WSA, here named WSAAHP, that employs indirect probability elicitation by means of pairwise comparisons between states in which the domain experts compare the likelihood of states using a verbal and numerical scale.

Each domain expert also manually defined NPTs that served as benchmark for comparing the methods. A Randomised Complete Block Design (RCBD) was adopted in the experiment. The methods were compared in terms of accuracy. The accuracy is defined here as how well the NPTs generated represent the mode of probability distributions in the benchmark NPTs.

We focused on the following research question and null hypothesis:

RQ1: Does the use of the SBNE approach to the RNM method maintain, improve or degrades expert-driven BNs accuracy?

H₀: The proposed approach to RNM is less accurate than the other methods.

The BN used in the experiment is presented in Fig. 5. The domain experts built 40 NPTs. Nevertheless, only the three parent nodes NPT was considered in the analysis (i.e., the one associated with the child node self-management), since it is the most complex. All the NPTs are available in an online repository².

²<https://github.com/SEKE2019/SBNE>

Table 4. Tukey simultaneous tests for differences of means

Difference of Method Levels	Difference of Means	SE of Difference	Simultaneous 95% CI	T-Value	Adjusted P-Value
WSA-RNM	-0.1267	0.0414	(-0.2323; -0.0211)	-3.06	0.018
WSAAHP-RNM	-0.1602	0.0414	(-0.2658; -0.0546)	-3.87	0.003
WSAAHP-WSA	-0.0335	0.0414	(-0.1391; 0.0721)	-0.81	0.702

Individual confidence level = 98%.

An analyse of variance (ANOVA) was performed, which indicated that there is statistically significant difference (p-value = 0.003) between the accuracy of the methods with a significance level of 0.05. Tukeys HSD post hoc test was performed to determine which methods are in fact different in regards to accuracy level.

The Table 4 summaries the Tukey simultaneous test for differences of means. As can be seen in the Table 4, the confidence interval for the difference between the means of WSA-RNM and WSAAHP-RNM do not include zero, which indicates that the difference is statistically significant between these methods. The results show that RNM is 13% and 16% (i.e., rounded values) more accurate than WSA and WSAAHP, respectively. Therefore, H₀ was rejected.

5 Threats to Validity

Despite the results obtained with the proposed approach, the comparison with different methods poses as a threat to internal validity. Nevertheless, the method WSA can be considered as a good benchmark because it has been mathematically and empirically validated in the literature [6, 2]. Moreover, the external validity may be limited, considering that the participants of the experiment were undergraduate students who work as software developers and that the experiment is bound to a specific context.

6 Conclusions

Despite recent popularity, the construction of BNs is still challenging. One of the challenges refers to defining the NPTs for large-scale BN. It is possible to automate this process using batch learning when there is a database with enough information. In practice, this is not common. The other option is to elicit data from experts, which becomes unfeasible for large scale BN. Fenton et al. [7] presented a solution based on ranked nodes. However, to apply this solution a BN expert is usually necessary.

In this paper, we complement the work of Fenton et al. [7] and Silva et al. [5] by presenting a novel approach to apply the RNM without relying on BN experts. The solution is named Simulated Bayesian Network Expert (SBNE) and it consists of eliciting a subset of the NPT from the domain

experts, which is used as input to estimate the optimal parameters (without relying on RNM experts) for the RNM to generate the NPTs.

Nonetheless, this approach can be used by RNM experts, reducing their effort to identify the optimal parameter for the RNM algorithm. We compared the proposed approach to the RNM with two other methods and the RNM outperformed them, reaching a mean accuracy of 75.78% against 63.12% of WSA and 59.77% of WSAHP. These results are promising and validate our approach, which makes RNM accessible to a wider range of users.

Notwithstanding, it is not our goal to state which method is the best. For such a purpose, more experiments would be needed to investigate the matter. That said, it is our belief that future works in this area should concentrate on examining the proposed approach against BNs derived from RNM experts and comparing multiple methods using well known BN models from the literature such as ALARM [3] and Hailfinder [1].

A systematic process to define expert-driven software metrics thresholds

Renata Saraiva¹, Mirko Perkusich¹, Hyggo Almeida¹, and Angelo Perkusich¹

¹Embedded and Pervasive Computing Laboratory, Federal University of Campina Grande, Campina Grande, Brazil

Abstract

Software metrics are usually used for quantification, not giving the necessary support for decision making. To increase their usefulness, it is necessary to give them meaning through the definition of significant thresholds. Despite its importance, the state of the art on threshold derivation is mostly based on data-driven approaches. This paper presents a systematic approach to define thresholds for metrics in the absence of data and based on eliciting knowledge from experts. The proposed approach is based on identifying context factors that influence the thresholds for a given metric and is supported by fuzzy logic concepts to model the crisp value (i.e., collected data) into a linguistic variable (i.e., interpreted information). We present context factors elicited from three experts for the metrics code coverage, static code analysis warnings count and defect count. Further, we present cases on how to implement the proposed approach. As a result, we conclude that the approach is promising.

Keywords—Software metrics; Software thresholds; Fuzzy logic.

I. Introduction

Despite their potential advantages, software metrics are usually used only for quantification purposes, not giving adequate support for decision-making [1]. For this purpose, it is necessary to give meaning (i.e., semantics) to the metrics through the definition of reference values (i.e., thresholds). Thresholds are values used to set ranges of desirable and undesirable states and indicate anomalies. The absence of thresholds for many software metrics is one of the main reasons for them to not be effectively used in the industry [4].

There are several solutions to calculate software metrics thresholds proposed in the literature [1], [18], [17], [8], [4], [23], [15], [13], [14], [5]. We summarize their characteristics and limitations in Section II. As far as our knowledge, all the proposed solutions are data-driven and focus on source code metrics. For instance, recently, two empirical studies were published comparing the existing data-driven thresholds models to predict faults on open source software [2] and fault proneness [3]. Therefore, if an organization needs to define thresholds for popular management metrics such as *team velocity*, *build status* and *lead time* [9], the literature is scarce in guiding them on how to define representative thresholds for their context. For this purpose, in practice, organizations use expert knowledge to define thresholds using ad hoc processes. For instance, for the metric *code coverage*, many development groups require 85% coverage to achieve quality targets as the status quo [20]. On the other hand, there are several factors that might influence coverage target for a given project, such as product complexity, project criticality, and cost of evolution.

To complement the current state of the art on software metrics threshold derivation, we present a systematic approach to define thresholds for metrics in the absence of data and based on eliciting knowledge from experts. The goal is to support managers when making decisions regarding the interpretation (i.e., semantics) of the collected metrics by developing models that mimics the thought process of humans when making decisions regarding the thresholds.

The proposed approach is based on identifying context factors that influence the thresholds for a given metric and is supported by fuzzy logic concepts to model the crisp value (i.e., collected data) into a linguistic variable (i.e., interpreted information). For instance, consider that the metric *code coverage* is used to decide if enough tests have been executed and, given that the *defect count* is

low enough, the product can be delivered to the customer. The crisp value of *code coverage* lies in $[0, 100]$. So, for instance, we could map the value 85 to the linguistic variable *OK*, which means that, given this metric, the product should be released. Conversely, we could map the value 50, meaning that the product should not be released.

The research question that we address in this paper is:

How can we define thresholds for software metrics in the absence of data and when the organization context cannot be reduced to an experimental setup?

Our contributions include: (1) a systematic approach for deriving software metrics thresholds in the absence of data; (2) an empirical cyclic process to continuously refine thresholds; and (3) context factors that influence the definition of popular metrics such as *code coverage*, *static code analysis warnings count* and *defect count*. Our systematic approach is demonstrated through the definition of thresholds for popular software metrics.

The remaining of the paper is organized as follows: in Section II, we present works related to deriving thresholds and discuss them in light of our approach, the proposed process; in Section III, we present the proposed approach; and in Section IV, we present our final remarks and future work.

II. Related work

The effective use of software metrics is hampered by the lack of significant thresholds [1]. In the literature, few metrics have defined thresholds. Furthermore, many researchers have proposed different approaches to define them [1], [4], [5], [13], [15], [17], [18], [23].

Alves *et al.* [1] present a method that determines threshold empirically from measurement data (i.e., benchmarking). The method is based on statistical properties of the metric such as scale and distribution. To evaluate their approach, they collected data from 100 object-oriented software systems to calculate thresholds, which were successfully used to assist on software analysis, benchmarking and certification. The main risk of such a solution is to use thresholds to assist decision-making that were calculated for a different context.

In the works of Oliveira *et al.* [15], [13], the concept of relative thresholds is proposed as well as a tool for extracting these thresholds. Their approach handles the heavy-tailed distribution of source code metrics by complementing absolute thresholds with a percentage of software code entities that must follow it. The technique is validated with an industrial case study. As Alves *et al.* [1], its limitation is that the calculated threshold and percentage might be dependent on the context.

Ferreira *et al.* [4] used the EasyFit tool to define the probability distribution with the best fit for the distribution

for a given metric. Therefore, if the defined probability distribution had a representative mean value, it was used as the reference value. Otherwise, the distribution is quantified as bad, good or moderate. By analyzing data of forty open source projects, they defined the thresholds for six metrics: LCOM (Lack of Cohesion of Methods), DIT (Depth in Tree), COF (Coupling Factor), afferent couplings, number of public methods, and number of public fields.

In Foucault *et al.* [5], a solution based on statistical methods was presented. This approach is based on (i) *double sampling* [19] to randomly selects projects samples, and (ii) *bootstrap* to estimate the thresholds based on quartiles. Despite the potential of this approach, the validation process was limited to a test to identify the best configuration for the approach itself since, according to the authors, the two statistical methods are widely used.

In Shatnawi [17], a solution based on logarithmic transformation was presented. In this approach, initially, the data is transformed using the natural log, leaving the symmetric data thus closer to a normal distribution. Afterward, a temporary reference value (T') is collected using the mean (M) and standard deviation (SD) so that $T' = M + SD$ or $T' = M - SD$. Finally, the T' is converted to the original distribution by using the exponent function of T' , generating the final reference value.

All the presented studies are data-driven and most of them focus on source code metrics. The motivation of our work is to define a systematic process that guides engineers in defining metrics thresholds in the absence of data. In this context, Marinescu [10] presents a guideline to define semantical filtering to support the analysis of source code metrics in the context of detecting design flaws based on the derivation of thresholds. They define two types of thresholds-related filters: marginal and interval. For a marginal filter, it is necessary to define the threshold value and direction, which specifies whether the threshold value is an upper or lower bound. The thresholds are described as design rules or heuristics (e.g., a class should not be coupled with more than 6 other classes). Interval filters are defined as an interval such as “between 20 and 30”. Even though Marinescu [10] describes the use of thresholds as a key component on the proposed solution, he does not present a systematic approach to define it. As shown in Section III, we use the classification of thresholds presented in Marinescu [10] and complement their work by proposing a systematic approach to define them.

III. Threshold definition strategy

In this section, we present the proposed approach with running examples. The examples are a result of a pilot study executed at a Brazilian software development

company in which we collected data from 3 project managers, all of them with over 5 years of experience managing projects with support of software metrics. The most important decision they had was defining if a version of the product had enough quality to be released. The three main metrics they used for this purpose were *code coverage*, *static code analysis warnings count* and *defect count*. *Code coverage* was used to indicate if enough tests were performed, which gave them confidence that few defects would be detected only in operation. *Static code analysis warnings count* was used as a measure of the internal quality of the product. The *defect count*, which was only representative if *code coverage* was high enough, gave a snapshot of the current quality of the product. As a status quo on the company, all projects had a lower bound threshold of 80% for *code coverage*, 10 for *static code analysis warnings count*, and 5 for *defect count*.

The main goal of the proposed approach is to provide software engineers with a systematic mechanism to enable them to work with software metrics in a more abstract level through the definition of thresholds in the absence of historical data. Since the goal of using metrics is to support decision-making, this is closer to the real intention in using metrics. An assumption of the proposed approach is that the metrics are valid for their intended purposes [12].

The proposed expert-driven threshold definition strategy is cyclic and composed of three main steps, namely: (i) thresholds characterization, (ii) thresholds modeling, and (iii) thresholds evaluation. An overview of the approach is shown in Figure 1. Our approach can be used to elicit data from a single or multiple experts. There are two main roles: threshold designer and domain experts. The threshold designer is responsible for leading the planning and execution of the threshold definition process by the elicitation of knowledge from the domain experts. The domain experts are responsible for actively participating in the process of defining the thresholds models (steps i and ii) and evaluating the models (steps iii). The domain experts might include the project manager, development lead, test lead, product manager or quality assurance manager.

In what follows, we present details regarding each of the steps of the proposed approach.

A. Step i: thresholds characterization

On the first (i) step, the goal is to characterize the thresholds through the identification of the relevant context factors and the type of the threshold, as defined in Marinescu [10]. First, it is necessary to define the decision scale to be used.

Definition 1 (Metric semantics scale) A metrics semantic scale is the scale to be used to represent the

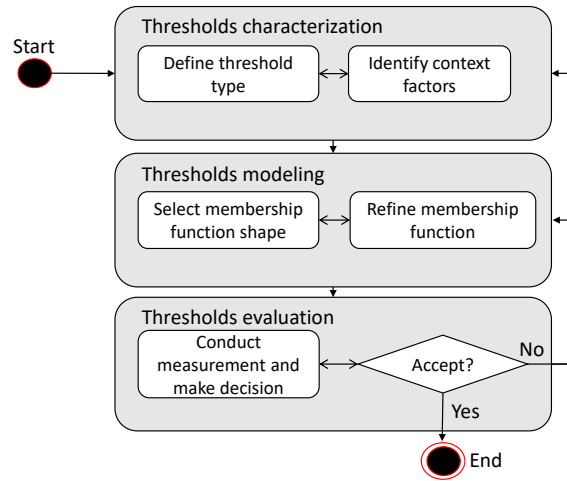

Fig. 1. Proposed approach overview.

semantics of a given metric.

The possible types of scale are Boolean and ordinal. For instance, one may use a Boolean scale for *code coverage* with the values: *OK* and *NOT OK*. Another possibility is to use an ordinal scale: *Bad*, *Moderate* and *Good*.

Afterwards, the type of threshold must be defined: marginal or interval. If a marginal threshold is selected, there are two possible types: **HigherThan**(Θ) and **LowerThan**(Θ), where Θ is the reference value. If an interval threshold is selected, by definition is of the type *Between*(α, β), which is equivalent to **HigherThan**(α) \wedge **LowerThan**(β), where α is the lower bound and β is the upper bound.

Next, the context factors must be identified. Context factors are attributes from key entities of the process that might influence the threshold. There are two types of context factors: diminishing factors and enhancing factors. The diminishing factors influence the thresholds values to be lower, and the enhancing factors influence the thresholds values to be higher. For instance, for *code coverage* metric, we elicited the following factors from the experts: *product complexity* and *project criticality* as enhancing factors, while *team experience* and *impact on evolution cost* as diminishing factors. For *static analysis warnings count* and *defect count*, *project criticality* is the enhancing factor. Finally, the factors are ranked in order of relative magnitude of their influence on the thresholds' values.

It is important to notice that the context factors are factors that influence the semantics of the metrics and not the value itself. For instance, one might reason that the factor "volatile requirements" influences the threshold of "defect

count”, because the more volatile are the requirements, less time will be available for testing and, consequently, lower will be the “defect count” in the testing phase (not necessarily, the “defect leakage”). On the other hand, even though this might be true, the reference value for the given metric should not be lower, which discards this factor.

In the case that multiple domain experts are involved in the process, the threshold designer must execute the described tasks with each one individually to avoid bias. Afterwards, with all the domain experts together, he presents the identified possibilities of threshold types and context factors and executes a meeting like the Planning Poker [7], in which each expert holds two cards: Agree and Disagree. The threshold designer mediates the meeting by enabling a structured discussion regarding a consensus of the threshold types and context factors to be considered in the models. As in a Planning Poker meeting, candidate solutions must be individually voted by experts, by turning their card simultaneously, until a consensus is reached by all the experts.

B. Step ii: thresholds modeling

After defining the type of threshold and rank the context factors, the experts will have a better understanding regarding the semantics of the given metrics. Since our approach is based on concepts of fuzzy logic, the thresholds are modeled as a linguistic variable, which is “a variable whose values are words or sentences in a natural or artificial language” [22]. For this purpose, we map the metric semantic scales defined in step i as the term set to be used for the linguistic variable. So, for instance, we could have the linguistic variable *code coverage* (c) composed of the terms {OK, Not OK}, in the case of a Boolean scale.

The main goal of this step is to fuzzify the crisp values of a metric into fuzzy linguistic terms. For this purpose, it is necessary to define the membership functions. There are several types of membership functions that can be used. In Figure 2, we show six popular types of functions.

A membership function must be defined for each term in the given linguistic variable. So, for a metric with a Boolean scale, two membership functions must be defined.

The main challenge is to define the parameters for the membership functions. For this purpose, given the type of function and the magnitude of the impact of the context factors identified in step i, the threshold designer might show the experts possible shapes for the membership functions to guide them. For instance, if the threshold is marginal, probably the experts could choose a z-shape, sigmoid, or s-shape as a reference. If the threshold is interval, the experts could choose triangular, trapezoidal or Gaussian. For instance, for the *code coverage*, we could use the Gaussian shape.

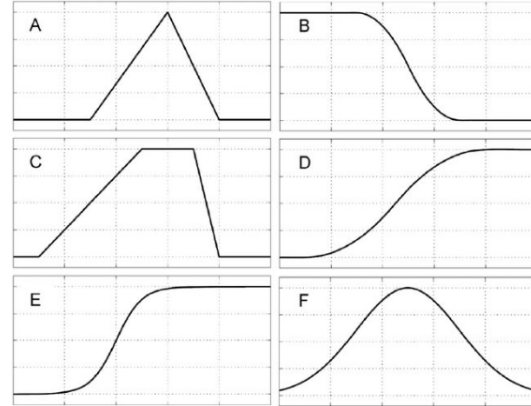

Fig. 2. Six types of fuzzy membership functions: (A) triangular, (B) z-shape, (C) trapezoidal, (D) s-shape, (E) sigmoid and (F) Gaussian, [6].

TABLE I. “What if” scenarios for *Code coverage* with a verbal scale

Code coverage crisp value	Not OK	OK
10	Certain	Impossible
20	Certain	Impossible
30	Certain	Impossible
40	Probable	Improbable
50	Expected	Uncertain
60	Fifty-fifty	Fifty-fifty
70	Uncertain	Expected
80	Improbable	Probable
90	Uncertain	Expected
100	Probable	Improbable

Afterwards, the experts should use their experience from past projects to define “what-if” scenarios to guide them in configuring the functions, in which for a set of values, they would indicate the probability of it being mapped to each of the possible terms. For this purpose, instead of directly defining the probabilities, they could use a verbal scale such as the one presented in Renooij and Witteman [16]. For instance, for *code coverage*, the scenarios shown in Table I could be used:

Afterwards, the verbal scale is converted to a numerical scale following the rules presented in Renooij and Witteman [16]. As a result, we have the values presented in TableII.

Given this, an algorithm can be used to fit the data elicited from the experts for each linguistic term into the appropriate distribution. For instance, in Figure 3, we present a fit for the membership function for the term *Not OK* using the Akima Cubic Spline. Finally, the expert can analyze visually the resulting distribution and judge if it reflects his intuition (i.e., face validity). Otherwise, they must reflect on the inconsistencies and the step should restart.

TABLE II. “What if” scenarios for *Code coverage* with a numerical scale

Code coverage crisp value	Not OK	OK
10	100	0
20	100	0
30	100	0
40	85	15
50	75	25
60	50	50
70	25	75
80	15	85
90	25	75
100	85	15

Fig. 3. Curve fit for *Code Coverage*'s linguistic term *Not OK*.

As a rule of thumb, it is preferable to set thresholds that are more conservative, since it is better to get more false positive results, rather than missing an important issue due to a very strict threshold value. The threshold can be refined during the empirical cycle which is executed on step iii.

As in step ii, this step should be, initially, executed individually with each expert. Afterwards, consensus must be achieved between all the experts in a Planning Poker-style meeting.

C. Step iii: thresholds evaluation

At this point, the thresholds models are defined, but as in other expert-driven processes [11], [21] it is necessary to have an empirical cycle in which decisions based on the thresholds are analyzed to evaluate the models. For this purpose, the threshold designer should schedule meetings according to the project's context. For agile projects with short-term releases, a meeting could be held every iteration or two. During the meeting, along with the threshold designers, the domain experts that participated on steps i and ii should participate to discuss the results of using the models.

Assuming that the metrics are valid for their intended purposes, if the model's results are not consistent with the reality, there are three possible outcomes: (1) exception case, (2) scope limitation, and (3) model needs refinement. For the first outcome, it is possible that, for instance,

the developed model indicates with 90% that the product should be released, but the release is a failure. This might occur due to a rare case for the given organization, which might be the case of an unexpected success of the product causing overload on the server. In this case, the experts could decide that the model is reliable, and the bad decision was caused by the uncertainty inherent in the process.

For the second possible outcome, a bad decision of releasing a product might have been caused by a failure of requirements elicitation such as missing an important non-functional requirement (e.g., number of requests per second). For this case, the experts can assume that the decisions based on the model assume that the product's requirements are complete and that this case is out of the scope of the model.

For the third case, the experts might decide that the model needs refinement, because they failed to, for instance, consider an important context factor or a better suited membership function. Independent of the outcome, the execution of step iii should be considered a mandatory activity in the measurement program.

IV. Conclusions

In this paper, we presented a systematic process to define thresholds for metrics in the absence of data and based on eliciting knowledge from experts. The proposed approach is based on identifying context factors that influence the thresholds for a given metric and is supported by fuzzy logic concepts to model the crisp value (i.e., collected data) into a linguistic variable (i.e., interpreted information). It is cyclic and composed of three main steps, namely: (i) thresholds characterization, (ii) thresholds modeling, and (iii) thresholds evaluation.

Our contributions are threefold: (1) a systematic approach for deriving software metrics thresholds in the absence of data; (2) an empirical cyclic process to continuously refine thresholds; and (3) context factors that influence the definition of popular metrics such as *code coverage*, *static code analysis warnings count* and *defect count*.

For further research, we will expand the proposed approach to handle the case of having multiple metrics used for a single decision. Furthermore, we will execute a case study to empirically evaluate the proposed approach in terms of practical utility.

Abstract—In complex industrial processes, complex associations are often involved. This complex relationship makes traditional fault detection and diagnosis methods difficult to achieve satisfactory results in multi-source fault detection and diagnosis. Therefore, this paper proposes a new multi-source fault detection and diagnosis framework. The method can successfully detect the state of the system, and at the same time, can locate the fault source simply and quickly. This method firstly constructs the multi-level knowledge graph in the complex industrial process, and then use the discriminant coefficient R to detect whether the system has failed. If the system fails into the fault diagnosis stage, the probability of the fault is derived based on Bayesian theory. This article describes the framework in detail. The TE process is taken as an example to prove the effectiveness of the method.

Keywords—complex industrial process, knowledge graph, bayesian theory, fault detection and diagnosis

I. INTRODUCTION

With the development of computer technology and the promotion of concepts such as Industry 4.0, modern industrial processes tend to be more automated, integrated, complex and intelligent. In the actual process monitoring, due to the large scale of industrial processes and complex business logic, there is a complex relationship between process variables in the production process. At the same time, with the increasing complexity of the process, the influencing factors are gradually increasing, and multiple faults occur frequently in complex industrial systems. However, the traditional fault diagnosis technology is mostly carried out under the condition of single fault type and simple influencing factors, and its accuracy is greatly reduced in the face of complex industrial processes. Many factors make the fault diagnosis of complex industrial system more and more difficult.

How to construct and mine the relationship in complex industrial systems and use these associations to improve the accuracy of fault detection and diagnosis is a key issue that needs to be studied at present. The Knowledge Graph (KG) [1] can describe the various entities and concepts that exist in the real world and the relationships between these entities and concepts. Based on the concept map of knowledge graph, mining the associations in complex industrial systems and displaying them in the form of graphs can more intuitively present this intricate relationship. At the same time, it can describe the abstract concepts of different levels and granularities, and integrate the larger resources in complex industrial systems. The fault source is located by inferring the constructed knowledge graph. Therefore, this paper proposes a new fault detection and diagnosis framework for many

problems in complex industrial systems, which combines knowledge graph and bayesian inference, and conducts experiments on TE data sets to verify its effectiveness.

II. RELATED WORK

Once an accident occurs in a complex industrial process, it may cause serious adverse effects on production safety, efficiency or product quality. At present, the widely used methods in fault detection and diagnosis (FDD) of complex industrial processes include: analytical mathematical model-based method, knowledge-based method, data-driven method, etc.

The analytical model-based approach [2-4] has great limitations in application due to the need to establish accurate mathematical models. Knowledge-based methods are mainly divided into two types: causal graph method [5-7] and fault tree method [8]. Zhang K et al. [5] proposed a kernel-based conditional independence test for conditional independence testing in Bayesian network learning and causal discovery. Experimental results show that it is superior to other methods. Caceres et al. [8] proposed to establish the fault tree according to the structural block diagram of the system. However, the defect of knowledge-based approach is that it relies too much on production experience and process knowledge. The data-driven FDD method [9-10] achieves fault detection and diagnosis of the system by analyzing and processing a large number of process data including system normal and fault information. However, the diagnostic accuracy of data-driven methods often depends heavily on the completeness and representativeness of the fault samples.

Both knowledge-based and data-driven approaches have their own shortcomings. Therefore, this paper proposes a method for fault detection and diagnosis combining knowledge-based methods with data-driven methods. Knowledge graph [1] is an emerging research field in recent years. It can express more information than traditional knowledge-based methods. This method is mainly used in natural language processing, medical[11], financial and other fields. However, the application of this method in complex industrial fields is rare. Knowledge graph is a graph model in essence, and fault diagnosis based on knowledge graph can be solved by graph model theory. However, Bayesian network (BN) is a typical probability graph model, which, considering the network structure and node attribute information, has a solid theoretical basis of probability theory and is widely used. It is suitable for expressing and analyzing uncertain knowledge and can make effective inference to uncertain knowledge. Therefore, this paper uses the combination of knowledge graph and Bayesian theory to detect and diagnose faults in complex industrial systems.

III. FAULT DETECTION AND DIAGNOSIS METHOD BASED ON MULTI-LEVEL KNOWLEDGE GRAPH

In complex industrial systems, there are many levels of factors that affect the state of production. For example, production level, process level, energy saving and emission reduction level, and raw material level. Therefore, the framework proposed in this paper analyzes complex industrial systems from multiple levels and constructs a multi-level knowledge graph, and then makes inferential diagnosis and fault diagnosis based on this knowledge graph. The flowchart of the framework is shown in Figure 1.

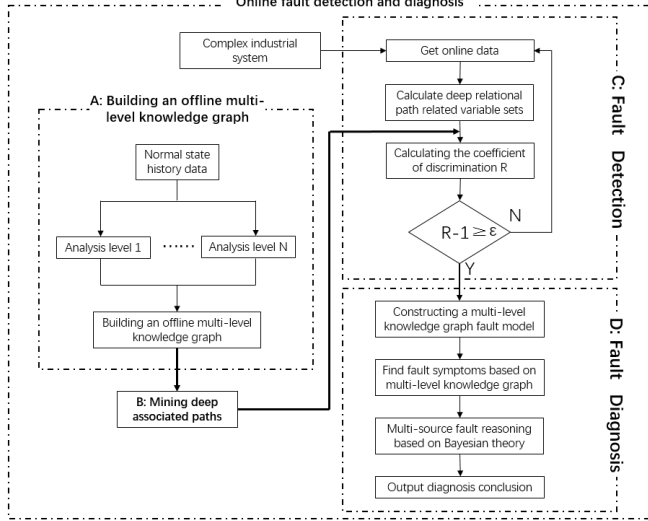

Fig. 1. Schematic diagram of fault detection and diagnosis model based on multi-level knowledge graph

A. Building an offline multi-level knowledge graph

The flow of constructing the knowledge graph in Part A of Figure 1 is shown in Figure 2.

Fig. 2. Schematic diagram of constructing a knowledge graph

There are many differences between the knowledge graph construction of complex industrial systems and the construction of general knowledge graph. Data sources in complex industrial systems come not only from the Internet, but also from all levels affecting production. If the knowledge graph is not comprehensive enough, the time for fault detection and diagnosis will become longer and the accuracy will decrease. First, collect data from multiple levels in a complex industrial system, and then extract the knowledge from the original data. Because the relationship between complex industrial system entities is particularly complex, this paper focuses on the relationship extraction in knowledge extraction. In this paper, Pearson correlation coefficient method is used to find the correlation between entities (the relationship between moderate correlation and high correlation is adopted [12]), and at the same time, prior knowledge is combined to extract the relationship. The extracted knowledge elements are then represented for further

processing. Then there is data fusion, the purpose of which is to fuse the knowledge acquired by different data sources to construct the association between the data. Knowledge graph are constructed by merging knowledge through entity alignment (judging whether two entities match) and quality assessment (inconsistency verification: identifying potential contradictions through rules). Figure 3 is a schematic diagram of the knowledge graph at four levels.

Fig. 3. Schematic diagram of multi-level knowledge graph

B. Mining deep-level associations in multi-level knowledge graphs

The method of mining deep-level associations in multi-level knowledge graphs in Part B of Figure 1 is as follows: According to the existing relationship in the multi-level knowledge graph, find the variable correlation coefficient of each variable in the knowledge graph as the weight coefficient of the variable, and select a critical path according to the size of the weight coefficient. The variables in this path must appear in the knowledge graph of each level at the same time, so that they can represent the deep relationship of the multi-level knowledge graph. Through the deep relationship in the knowledge graph, it is possible to quickly and conveniently detect whether the system has failed without considering the complex relationship in the entire knowledge graph.

C. Fault detection method based on multi-level knowledge graph

The part C fault detection method in Figure 1 is as follows: The knowledge graph is mainly composed of several triples, that is, pairs of variable correlation coefficients. After the system fails, the correlation coefficient of the variables in the original knowledge graph will inevitably change, that is, the entity changes, and the relationship (weight) between the entities changes. Therefore, this paper uses the changes in these two aspects of the knowledge graph structure to define the discriminant coefficient R rule. The discriminant coefficient R rule is defined as follows:

Suppose that T is used to represent the variable in the deep associated path in the knowledge graph under normal conditions, $T=[T_1, T_2, T_3, \dots]$, N_i represents the set of the i-th variable entity pair in T, n represents the number of pairs of entities in N_i . W_i represents the relationship weight of the i-th pair of entities in N. Similarly, T' , N'_i and W'_i are used to represent the variables under test, and m is the number of entity pairs in N'_i . The calculation rules for the discriminant coefficient R are as follows:

Let the number of the variable entity pairs in the normal state T and the variable entity pairs in the state T' to be detected be the same as t, and the set of different entity pairs in the T state and T' is T_k , and the pair of different entities in the T' state and T is T'_k . When T_k , T'_k have different entity pairs, T_k , T'_k are automatically incremented by one. When T_k , T'_k have different entity pairs, W'_i is automatically incremented by 1. When T_k , T'_k have the same entity pair, and W's relationship weight is inconsistent with the corresponding

relationship weight in W' , W' is automatically incremented by one. The mathematical model of the discriminant coefficient R is:

$$R = \frac{\sum T_k + \sum T'_{k+t}}{n} + W' = \frac{|m-t| + |n-t| + t}{n} + W' = \frac{m+n-t}{n} + W' \quad (1)$$

On the basis of an acceptable fault tolerance rate ε , if $R-1 \geq \varepsilon$ is satisfied, it indicates a system failure, otherwise it indicates a normal state.

D. Fault Diagnosis Method Based On Multi-Level Knowledge Graph

The D part fault diagnosis method in Figure 1 is as follows:

1) According to the determined fault variables, the moderately and highly correlated variable pairs of correlation coefficients are selected in the knowledge graph relationship pairs of each level to construct a multi-level knowledge graph fault model.

2) According to the fault symptoms of the system, find all possible candidate failure causes. For each candidate failure reason, the posterior probability value under the known fault symptom condition is calculated based on Bayesian theory.

3) Set a certain threshold, and consider the cause of the failure exceeding the threshold as the most likely cause of the failure.

The posterior probability calculation method is as follows:

1) Calculate the first-order cut set expression for each fault symptom E_i .

$$E_i = e_{t,i}r_t \cup e_{j,i}E_j \quad (2)$$

$$E_j = e_{k,j}r_k \quad (3)$$

Where, E_i and E_j are fault symptoms, r_t and r_k are candidate fault causes, and $e_{j,i}$ is the edge from E_j to E_i . $e_{t,i}$ is the edge from candidate failure cause r_t to failure symptom E_i .

2) Calculate the final cut set expression for each fault symptom E_i :

$$E_i = e_{t,i}r_t \cup e_{j,i}e_{k,j}r_k \quad (4)$$

The first-order cut set expression is expanded according to the relevant edge direction logic. This process can eliminate all the variable nodes in the fault model and obtain the final cut set expression consisting only of the cause node and the relevant edge.

3) Calculate the posterior probability value $P(r_i|E)$ of the fault cause r_i : Logging the fault symptoms according to (5) for all fault symptoms, and inserting the corresponding fault cause occurrence probability value and the associated edge probability value to obtain the posterior probability value $P(r_i|E)$ of the final detected fault cause r_i .

$$P(r_i|E) = \frac{P(r_i E_1 \dots E_n)}{P(E_1 \dots E_n)} = \frac{P(r_i \cap E_1 \dots E_n)}{P(E_1 \cap \dots \cap E_n)} \quad (5)$$

Where, $E = (E = E_1, \dots, E_n)$ is the set of fault symptoms, n is the number of abnormal variables, and r_i is the cause of the fault.

IV. EXPERIMENT

A. Data Sets

The data set used in this paper is the data of TE process, a simulation system of chemical process. For a detailed description of the process, refer to the relevant literature[13]. The 22 process measurement variables in the TE model are represented by V1, V2...V22 and the 20 failure types are r41, r42...r60.

B. Building a multi-level knowledge graph of the TE process

Limited by the TE process simulation data, this paper constructs the TE process knowledge graph from two levels, as shown in Figure 4. The solid line represents the technological process level, and the dotted line represents the data level of the production process.

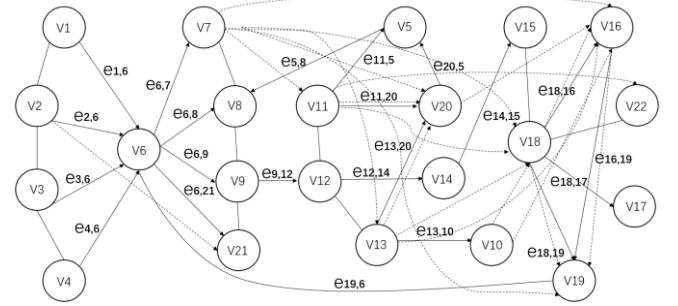

Fig. 4. Schematic diagram of the multi-level knowledge graph of the TE process

C. Mining deep-level associations in multi-level knowledge graph of TE processes

First, the weighting coefficients of each successive measured variable are analyzed according to the constructed multi-level knowledge graph. The weights corresponding to the measured variables $\{V2, V7, V10, V11, V13, V16, V18, V19, V20\}$ are $\{1, 6, 2, 3, 4, 5, 7, 2, 4\}$.

According to the TE process and the principle of large weight coefficient, the deep correlation path of the multi-level knowledge graph can be obtained as follows: V2, V7, V13, V16, V18, V20. Analysis of the four variables of the TE process feed shows that the V2 variable is highly correlated with other variables. This determines that V2 is the starting variable of the deep associated path. This path represents the deep interrelationship of the equipment (feed-reactor-separator-compressor-stripper).

D. TE process fault detection method based on multi-level knowledge graph

In order to prove the validity of the method, this experiment selected single source fault (fault 7), multi-source fault: fault (5, 7) and fault (2, 6, 13).

According to the fault detection method proposed above, the discrimination coefficient R in the four production states is calculated. It is judged whether the TE chemical system is in a fault state according to the change of the discrimination coefficient R . The parameters R in the four production states are shown in Figure 5. It can be seen from Figure 5 that the discriminant coefficient R completely separates the data of the normal state and the fault state, and accurately detects the system fault.

Fig. 5. Schematic diagram of the comparison between the normal state and the fault state discrimination coefficient R

E. TE process fault diagnosis method based on multi-level knowledge graph

In this experiment, fault 5 and fault 7 were selected as the multi-source fault data set for experiment. The specific diagnostic steps are as follows:

1) Building a knowledge graph failure model in the current state as shown in Figure 6.

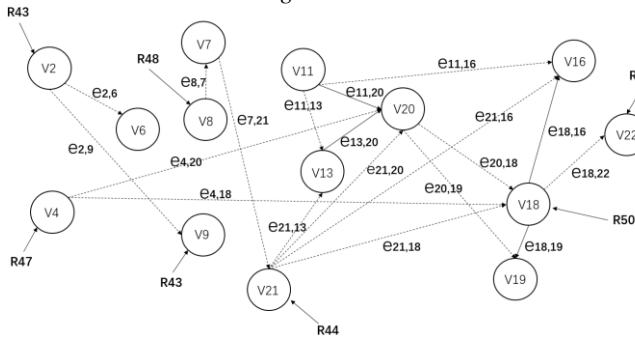

Fig. 6. Schematic diagram of multi-level knowledge graph failure model

2) Calculate the posterior probability value of each candidate failure cause.

According to (2)-(5), the diagnosis results are shown in Table 1. It can be seen from the table that the posterior probability of r_{45} and r_{47} is significantly larger than r_{43} , r_{44} , r_{48} , r_{50} . Therefore, the cause node r_{45} (condenser cooling water feed temperature) and r_{47} (flow rate 4 C pressure loss) are the cause of the failure, and the diagnosis conclusion is consistent with the original assumption.

TABLE I. DIAGNOSTIC RESULTS OF THE CAUSE NODE

Candidate failure cause	Percentage of posterior probability
r43:D temperature in flow 2	14.11%
r44: Reactor cooling water feed temperature	7.29%
r45: condenser cooling water feed temperature	65.47%
r47: C pressure loss in flow 4	50.32%
r48: Changes in A, B, and C components in Flow 4	10.51%
r50: C material temperature in flow 4	25.87%

TABLE II. DIAGNOSTIC TIME COMPARISON

Diagnosis method	Diagnostic time
PCA_KNN	0.446
PCA_SVM	0.413
PNN	0.375
KG_ Bayesian network	0.306

Table 2 compares the diagnostic time of the four methods of PCA_KNN, PCA_SVM, PNN, KG_ Bayesian network. It can be seen that the method used in this paper takes less time than the traditional fault detection and diagnosis methods.

V. CONCLUSION

Based on the strong correlation between knowledge graphs and comprehensive consideration of various factors, this paper constructs a multi-level knowledge graph in complex industrial processes. This way of building knowledge graphs maximizes the consideration of influencing factors in complex industrial systems. By mining the correlation law between variables, the discriminant coefficient method is used to detect the state of the system. The method has achieved good results in the TE process and can accurately identify the system state. The multi-level knowledge graph fault diagnosis method based on Bayesian theory provides a new idea for fault diagnosis of complex industrial systems. This method has achieved good results in reasoning the multi-source failure of complex industrial systems. At the same time, this method can diagnose the fault source easily and quickly. At present, this method is only applicable to the processing of existing fault cause data, and the next step will be to study the fault self-learning function.

Abstract—A* algorithm is formally specified in Maude and model checked with the Maude LTL model checker. We take into account a graph such that it is a DAG, a goal node is reachable from a start node and each edge is given a non-negative weight. If h is admissible, namely that $h(n)$ never overestimates the cost to the goal from n for all nodes n , then A* finds a shortest path. The condition, however, can be relaxed. Our model checking experiments make us conjecture that if there exists a shortest path such that for each node n in the path $h(n)$ plus the cost to n from the start node is less than the cost of any non-shortest path to the goal from the start, A* finds a shortest path.

Keywords—A* algorithm; Dijkstra algorithm; LTL; Maude; Model checking

I. INTRODUCTION

A* algorithm[1] is a generalized version of Dijkstra (shortest path finding) algorithm[2]. It uses an estimation of the distance between the goal node and each of the edge nodes to select the next node to be tackled. Dijkstra algorithm treats the estimation as 0.

A* is formally specified in Maude[3], a rewriting logic-based specification/programming language equipped with many facilities, among which are model checking ones (a reachability analyzer and an LTL model checker). We model check with the LTL model checker that A* terminates and finds a shortest path. Our model checking experiments say that A* always halts and if the estimation h is admissible, namely that $h(n)$ never overestimates the cost to the goal from n for all nodes n , then A* finds a shortest path. The condition, however, can be relaxed. Our model checking experiments make us conjecture that if there exists a shortest path such that for each node n in the path $h(n)$ plus the cost to n from the start node is less than the cost of any non-shortest path to the goal from the start, A* finds a shortest path.

The contribution of the work described in the present paper is to demonstrate how A* is formally specified in Maude and model checked with the Maude LTL model checker and to find a relaxed sufficient condition, through model checking experiments, that A* finds a shortest path.

DOI reference number: 10.18293/SEKE2019-022

Saberi, Groote and Keshishzadeh [4] have formally specified in the mCRL2 language a simple path planning algorithm that makes multiple robots reach a destination on a discretized planar surface, described properties in μ -calculus and conducted model checking experiments that the algorithm enjoys the properties. The desired properties they have taken into account are deadlock-freeness, collision-freeness and reachability. Their motivation to conduct the research is to demonstrate how useful model checking is to verify that the collective behavior of multiple robots satisfy some desired properties. Maragos, Kleftouris and Ziogou [5] have formally modeled a path finding planning in Colored Petri Nets (CP-Nets). Given a discretized planar space where there is one robot located in one position, there are some obstacles located in some positions and there is a goal position, the planning is to find a path along which the robot reaches the goal. Their CP-Nets model is executable with the Design/CPN tool. Their main motivation to conduct the research is to demonstrate how powerful CP-Nets are for simulating such a planning. Alphan, Smith, Belta and Rus [6] have proposed a method that automatically plans optimal paths for a group of robots that satisfy LTL properties. They formally modeled as a timed automaton a system in which multiple robots asynchronously move to some vertexes from the current vertexes on a graph if there are direct edges from the latter to the former. They use a bi-simulation relation between a timed automaton that is inherently infinite and a finite-state transition system so that they can use their earlier algorithm dedicated to a single-robot system.

The rest of the paper is organized as follows: § II Preliminaries, § III A* Algorithm, § IV Formal Specification, § V Model Checking, and § VI Conclusion.

II. PRELIMINARIES

A Kripke structure K is $\langle S, I, T, P, L \rangle$, where S is a set of states, $I \subseteq S$ is the set of initial states, $T \subseteq S \times S$ is a total binary relation over S , P is a set of atomic propositions and L is a labeling function whose type is $S \rightarrow 2^P$. Each element $(s, s') \in T$ is called a state transition from s to s' and T may be called the state transitions (with respect to K). For a state $s \in S$, $L(s)$ is the set of atomic propositions that hold in s . A path π is an infinite sequence $s_0, \dots, s_i, s_{i+1}, \dots$ of states such that $s_i \in S$ and

$(s_i, s_{i+1}) \in T$ for each i . Let π^i be s_i, s_{i+1}, \dots and $\pi(i)$ be s_i . Let P be the set of all paths. π is called a computation if $\pi(0) \in I$. Let C be the set of all computations.

The syntax of a formula φ in LTL for K is $\varphi ::= \top \mid p \mid \neg\varphi \mid \varphi \wedge \varphi \mid \bigcirc \varphi \mid \varphi \mathcal{U} \varphi$, where $p \in P$. Let \mathcal{F} be the set of all formulas in LTL for K . An arbitrary path $\pi \in \mathcal{P}$ of K and an arbitrary LTL formula $\varphi \in \mathcal{F}$ of K , $K, \pi \models \varphi$ is inductively defined as $K, \pi \models \top$, $K, \pi \models p$ iff $p \in L(\pi(0))$, $K, \pi \models \neg\varphi_1$ iff $K, \pi \not\models \varphi_1$, $K, \pi \models \varphi_1 \wedge \varphi_2$ iff $K, \pi \models \varphi_1$ and $K, \pi \models \varphi_2$, $K, \pi \models \bigcirc \varphi_1$ iff $K, \pi^1 \models \varphi_1$, and $K, \pi \models \varphi_1 \mathcal{U} \varphi_2$ iff there exists a natural number $j < i$, $K, \pi^j \models \varphi_2$ and for all natural numbers $j < i$, $K, \pi^j \models \varphi_1$, where φ_1 and φ_2 are LTL formulas. Then, $K \models \varphi$ iff $K, \pi \models \varphi$ for each computation $\pi \in \mathcal{C}$ of K . The temporal connectives \bigcirc and \mathcal{U} are called the next connective and the until connective, respectively. The other logical and temporal connectives are defined as usual as follows: $\perp \triangleq \neg\top$, $\varphi_1 \vee \varphi_2 \triangleq \neg(\neg\varphi_1 \wedge \neg\varphi_2)$, $\varphi_1 \Rightarrow \varphi_2 \triangleq \neg\varphi_1 \vee \varphi_2$, $\Diamond \varphi \triangleq \top \mathcal{U} \varphi$, and $\Box \varphi \triangleq \neg(\Diamond \neg\varphi)$. The temporal connectives \Diamond and \Box are called the eventually connective and the always connective, respectively.

There are multiple possible ways to express states. We express a state as a braced associative-commutative (AC) collection of name-value pairs. AC collections are called soups, and name-value pairs are called observable components. That is, a state is expressed as a braced soup of observable components. The juxtaposition operator is used as the constructor of soups. Let oc_1, oc_2, oc_3 be observable components, and then $oc_1 \ oc_2 \ oc_3$ is the soup of those three observable components. A state is expressed as $\{oc_1 \ oc_2 \ oc_3\}$. There are multiple possible ways to specify state transitions. We specify them as rewrite rules. Concretely, we use Maude [3], a programming/specification language based on rewriting logic. Maude makes it possible to specify complex systems flexibly and is also equipped with model checking facilities (a reachability analyzer and an LTL model checker). A conditional rewrite rule (or just a rule) is in the form $\text{crl } [lb] : l \Rightarrow r \text{ if } \dots \wedge c_i \wedge \dots$, where lb is the label given to the rule and c_i is part of the condition, which may be an equation $lc_i = rc_i$. The negation of $lc_i = rc_i$ could be written as $(lc_i \neq rc_i) = \text{true}$, where $= \text{true}$ could be omitted. If the condition $\dots \wedge c_i \wedge \dots$ holds under some substitution σ , $\sigma(l)$ can be replaced with $\sigma(r)$.

The search command tries to find a state reachable from t such that the state matches p and satisfies c :

```
search [1] in M : t => * p such that c .
```

where M is a specification of the S and T parts of K . t typically represents an initial state of K .

Let $init$ be the only initial state of K and φ be an LTL formula. Then, the Maude LTL model checker checks that K satisfies φ by reducing `modelCheck (init, φ)`.

Figure 1. A DAG (1)

III. A* ALGORITHM

Let us consider the DAG shown in Fig. 1 in which node $n0$ is the start node and node $n3$ is the goal node. Let us use the estimation $h(n)$ for each node n defined as follows: $h(n1) = 2$, $h(n3) = 0$ and $h(n) = 1$ for any other node n . Let $w(n, n')$ be the weight of the edge from node n to node n' . For example, $w(n2, n1) = 2$. For each node n , two pieces $p(n)$ and $d(n)$ of information are maintained, where $p(n)$ is the shortest path found so far to node n from the start node at any given moment and $d(n)$ is its distance. One more piece oq of information is maintained, which is an ordered queue of node & natural number pairs, where such pairs are stored in increasing order based on their second elements. When a pair $\langle n, d \rangle$ of node n and natural number d is enqueued into oq that contains some other pairs whose second elements are d , $\langle n, d \rangle$ is stored following all those pairs. When $\langle n, d \rangle$ is enqueued into oq that contains $\langle n, d' \rangle$, if $d' < d$, then $\langle n, d \rangle$ is stored at the designated place in oq and $\langle n, d' \rangle$ is deleted and otherwise $\langle n, d \rangle$ is not stored in oq . For example, let oq consist of $\langle n0, 1 \rangle$, $\langle n1, 1 \rangle$, $\langle n3, 2 \rangle$ and $\langle n2, 3 \rangle$ in this order, denoted $\langle n0, 1 \rangle \mid \langle n1, 1 \rangle \mid \langle n3, 2 \rangle \mid \langle n2, 3 \rangle$, and if $\langle n3, 1 \rangle$ is put into oq , oq is $\langle n0, 1 \rangle \mid \langle n1, 1 \rangle \mid \langle n3, 1 \rangle \mid \langle n2, 3 \rangle$. We use `empq` to represent the empty queue and suppose that `empq` is an identity of the queue constructor \mid , namely that $q \mid \text{empq} = q$ and $\text{empq} \mid q = q$ for all queues q . We also suppose that a single element e is treated as a singleton queue that only consists of e . For example, $\langle n3, 1 \rangle$ is treated as the singleton ordered queue that only consists of $\langle n3, 1 \rangle$. Node n of each $\langle n, d \rangle$ in oq at any moment is called an edge node at that moment in this paper.

Initially, $p(n0) = n0$ (which is the path that only consists of $n0$), $p(n) = \varepsilon$ (the empty path) for any other node n , $d(n0) = 0$, $d(n) = \infty$ for any other node n and $oq = \langle n0, 1 \rangle$ (which is the ordered queue that only consists of $\langle n0, 1 \rangle$, where $d(n0) + h(n0) = 1$).

While oq is not empty, the following is repeated. Let $\langle n, d \rangle$ be the top element of oq . If node n is the goal node, $p(n)$ is the path to be found from the start node to the goal node. Otherwise, for each direct successor node n' of node n , if $d(n) + w(n, n') < d(n')$, $d(n')$ is set to $d(n) + w(n, n')$, $p(n')$ is set to the path obtained by adding n' to $p(n)$ at the end and $\langle n', d(n) + w(n, n') + h(n') \rangle$ is enqueued into oq . The top element is deleted from oq .

At some moment,

- $p(n0) = n0 \ \& \ d(n0) = 0$
- $p(n1) = (n0 \rightarrow n1) \ \& \ d(n1) = 4$
- $p(n2) = (n0 \rightarrow n2) \ \& \ d(n2) = 1$
- $p(n3) = (n0 \rightarrow n3) \ \& \ d(n3) = 6$
- $p(n) = \varepsilon \ \& \ d(n) = \infty$ for any other node n
- $oq = \langle n2, 2 \rangle \mid \langle n1, 6 \rangle \mid \langle n3, 6 \rangle$

$\langle n2, 2 \rangle$ is the top element of oq . $n1$ and $n5$ are the direct successor nodes of $n2$. Since $d(n2) + w(n2, n1) = 3$, $d(n1) = 4$ and $3 < 4$, $d(n1)$ is set to 3, $p(n1)$ is set to $(n0 \rightarrow n2 \rightarrow n1)$ and $\langle n1, 5 \rangle$, where $d(n2) + w(n2, n1) + h(n1) = 5$, is enqueued into oq . Since $d(n2) + w(n2, n5) = 2$, $d(n5) = \infty$ and $2 < \infty$, $d(n5)$ is set to 2, $p(n5)$ is set to $(n0 \rightarrow n2 \rightarrow n5)$ and $\langle n5, 3 \rangle$, where $d(n2) + w(n2, n5) + h(n5) = 3$, is enqueued into oq . The top element is deleted from oq . At this moment,

- $p(n0) = n0 \ \& \ d(n0) = 0$
- $p(n1) = (n0 \rightarrow n2 \rightarrow n1) \ \& \ d(n1) = 3$
- $p(n2) = (n0 \rightarrow n2) \ \& \ d(n2) = 1$
- $p(n3) = (n0 \rightarrow n3) \ \& \ d(n3) = 6$
- $p(n4) = \varepsilon \ \& \ d(n4) = \infty$
- $p(n5) = (n0 \rightarrow n2 \rightarrow n5) \ \& \ d(n5) = 2$
- $oq = \langle n5, 3 \rangle \mid \langle n1, 5 \rangle \mid \langle n3, 6 \rangle$

$\langle n5, 3 \rangle$ is the top element of oq . $n1$ and $n3$ are the direct successor nodes of $n5$. Since $d(n5) + w(n5, n1) = 3$, $d(n1) = 3$ and $3 \not< 3$, nothing changes. Since $d(n5) + w(n5, n3) = 5$, $d(n3) = 6$ and $5 < 6$, $d(n3)$ is set to 5, $p(n3)$ is set to $(n0 \rightarrow n2 \rightarrow n5 \rightarrow n3)$ and $\langle n3, 5 \rangle$, where $d(n5) + w(n5, n3) + h(n3) = 5$, is enqueued into oq . The top element is deleted from oq . At this moment,

- $p(n0) = n0 \ \& \ d(n0) = 0$
- $p(n1) = (n0 \rightarrow n2 \rightarrow n1) \ \& \ d(n1) = 3$
- $p(n2) = (n0 \rightarrow n2) \ \& \ d(n2) = 1$
- $p(n3) = (n0 \rightarrow n2 \rightarrow n5 \rightarrow n3) \ \& \ d(n3) = 5$
- $p(n4) = \varepsilon \ \& \ d(n4) = \infty$
- $p(n5) = (n0 \rightarrow n2 \rightarrow n5) \ \& \ d(n5) = 2$
- $oq = \langle n1, 5 \rangle \mid \langle n3, 5 \rangle$

$\langle n1, 5 \rangle$ is the top element of oq . $n4$ is the direct successor node of $n1$. Since $d(n1) + w(n1, n4) = 4$, $d(n4) = \infty$ and $4 < \infty$, $d(n4)$ is set to 4, $p(n4)$ is set to $(n0 \rightarrow n2 \rightarrow n1 \rightarrow n4)$ and $\langle n4, 5 \rangle$, where $d(n1) + w(n1, n4) + h(n4) = 5$, is enqueued into oq . The top element is deleted from oq . At this moment,

- $p(n0) = n0 \ \& \ d(n0) = 0$
- $p(n1) = (n0 \rightarrow n2 \rightarrow n1) \ \& \ d(n1) = 3$
- $p(n2) = (n0 \rightarrow n2) \ \& \ d(n2) = 1$
- $p(n3) = (n0 \rightarrow n2 \rightarrow n5 \rightarrow n3) \ \& \ d(n3) = 5$
- $p(n4) = (n0 \rightarrow n2 \rightarrow n1 \rightarrow n4) \ \& \ d(n4) = 4$
- $p(n5) = (n0 \rightarrow n2 \rightarrow n5) \ \& \ d(n5) = 2$
- $oq = \langle n3, 5 \rangle \mid \langle n4, 5 \rangle$

$\langle n3, 5 \rangle$ is the top element of oq . Since $n3$ is the goal node, we have found the path $n0 \rightarrow n2 \rightarrow n5 \rightarrow n3$ whose distance (or cost) is 5. The path is one of the three shortest paths from $n0$ to $n3$ in DAG (1) shown in Fig. 1.

In this paper, we take into account a graph such that it is a DAG, a goal node is reachable from a start node and each edge is given a non-negative weight.

IV. FORMAL SPECIFICATION

Let K_{A^*} be the Kripke structure formalizing A^* that tackles a DAG in which there are N nodes.

The four kinds of observable components are used:

- $(node[ni] : d, ps_1, ps_2, p) - ni$ is a node ID, d is a natural number or ∞ that is the distance of the path found so far from a start node to the node ni , ps_1 & ps_2 are soups of the direct successor node IDs of the node ni that have not yet been tackled & that have already been tackled and p is the path found so far from a start node to the node ni ; if d is ∞ , no path from a start node to the node ni has yet been found;
- $(oq : q) - q$ is an ordered queue of node ID & natural number pairs;
- $(path : npp) - npp$ is a pair of a natural number and a path; when a path from a start node to a goal node is found, the pair of the distance of the path and the path is stored in it;
- $(gstat : gs) - gs$ is either $nFin$ or Fin ; a path from a start node to a goal node has been found if gs is Fin .

Each state in S_{A^*} is expressed as $\{obs\}$, where obs is a soup of those observable components such that there is one $gstat$ observable component, there is one $path$ observable component, there is one oq observable component and there are N node observable components.

I_{A^*} consists of one state. When DAG (1) shown in Fig. 1 is tackled, the initial state is expressed as follows:

```
{(gstat: nFin)
(oq: (< n0, 0 >)) (path: (< 0, nil >))
(node[n0]: 0, (< n1, 4 > < n2, 1 > < n3, 6 >),
empty, n0)
(node[n1]: oo, (< n4, 1 >), empty, nil)
(node[n2]: oo, (< n1, 2 > < n5, 1 >), empty, nil)
(node[n3]: oo, empty, empty, nil)
(node[n4]: oo, (< n3, 1 >), empty, nil)
(node[n5]: oo, (< n1, 1 > < n3, 3 >), empty, nil)}
```

where $\langle n0, 0 \rangle$ in the oq observable component represents the singleton ordered queue that only consists of $\langle n0, 0 \rangle$, nil is the empty path, $empty$ is the empty soup, $\langle n1, 4 \rangle \mid \langle n2, 1 \rangle \mid \langle n3, 6 \rangle$ is the soup that consists of $\langle n1, 4 \rangle$, $\langle n2, 1 \rangle$ and $\langle n3, 6 \rangle$, and oo is ∞ .

T_{A^*} is specified as six rewrite rules. Let OCs be a Maude variable of observable component soups, NI & NI' be Maude variables of node IDs, D , W , D'' & D''' be Maude variables of natural numbers, D' be a Maude variable of natural numbers or ∞ , Q be a Maude variable of ordered queues, $NNPs1$, $NNPs2$, $NNPs1'$ & $NNPs2'$ be Maude variables of node ID & natural number pair soups, and L , L' & L'' be Maude variables of paths.

The first one is as follows:

```
rl [A*-stutter] : {(gstat: fin) OCs}
=> {(gstat: fin) OCs} .
```

We need to use rule `stutter` to make T_{A^*} total.

The second one is as follows:

```
cr1 [A*-goal] :
{(gstat: nFin) (oq: (< NI,D''' > | Q))
 (path: (< D'',L'' >))
 (node[NI]: D,NNPs1,NNPs2,L) OCs}
=>
{(gstat: fin) (oq: (< NI,D''' > | Q))
 (path: (< D,L >))
 (node[NI]: D,NNPs1,NNPs2,L) OCs}
if goal?(NI) .
```

`goal?(NI)` holds if `NI` is the goal node ID. When the first element `NI` of the top element $\langle NI, D''' \rangle$ of the ordered queue stored in the `oq` observable component is the goal node ID, then the path `L` has been found and $\langle D, L \rangle$, where `D` is its cost, is stored in the path observable component.

The third one is as follows:

```
cr1 [A*-srch1] :
{(gstat: nFin) (oq: (< NI,D'' > | Q))
 (node[NI]: D,< NI',W > NNPs1,NNPs2,L)
 (node[NI']: D',NNPs1',NNPs2',L') OCs}
=>
{(gstat: nFin)
 (oq: enq(< NI,D'' > | Q,
          < NI',(D + W + h(NI')) >))
 (node[NI]: D,NNPs1,< NI',W > NNPs2,L)
 (node[NI']: D + W,NNPs1',NNPs2',L -> NI')
 OCs}
if D + W < D' /\ NNPs1 != empty .
```

Rule `srch1` says that if the `gstate` observable component is `nFin` (meaning that the path has not been found), `NI` is the node ID found in the top element pair of the ordered queue stored in the `oq` observable component, `NI'` is a direct successor node ID such that it has not been tackled and the weight of the edge between `NI` and `NI'` is `W`, `D + W` is less than `D'` and `NNPs1` is not empty, then $\langle NI', (D + W + h(NI')) \rangle$ is put into the ordered queue stored in the `oq` observable component, $\langle NI', W \rangle$ is moved to the second soup from the first soup in the `node[NI]` observable component (meaning that `NI'` has been tackled), the path to `NI'` from the start node is updated as `L -> NI'` obtained by adding `NI'` to `L` at the end and the distance of the path is updated as `D + W`.

The fourth one is as follows:

```
cr1 [A*-srch2] :
{(gstat: nFin) (oq: (< NI,D'' > | Q))
 (node[NI]: D,< NI',W > NNPs1,NNPs2,L)
 (node[NI']: D',NNPs1',NNPs2',L') OCs}
=>
{(gstat: nFin)
 (oq: enq(Q,< NI',(D + W + h(NI')) >))
```

```
(node[NI]: D,NNPs1,< NI',W > NNPs2,L)
(node[NI']: D + W,NNPs1',NNPs2',L -> NI')
OCs}
if D + W < D' /\ NNPs1 = empty .
```

The only difference between the situations dealt with by rule `srch1` and rule `srch2` is whether `NNPs1` is empty. If `NNPs1` is empty, the top element pair $\langle NI, D'' \rangle$ is deleted from the ordered queue stored in the `oq` observable component.

The fifth one is as follows:

```
cr1 [A*-srch3] :
{(gstat: nFin) (oq: (< NI,D'' > | Q))
 (node[NI]: D,< NI',W > NNPs1,NNPs2,L)
 (node[NI']: D',NNPs1',NNPs2',L') OCs}
=>
{(gstat: nFin) (oq: (< NI,D'' > | Q))
 (node[NI]: D,NNPs1,< NI',W > NNPs2,L)
 (node[NI']: D',NNPs1',NNPs2',L') OCs}
if not (D + W < D') /\ NNPs1 != empty .
```

The only difference between the situations dealt with by rule `srch1` and rule `srch3` is whether `D + W < D'` holds. If `D + W < D'` does not, nothing changes except that $\langle NI', W \rangle$ is moved to the second soup from the first soup in the `node[NI]` observable component.

The sixth one `A*-srch4` deals with the case in which `D + W < D'` does not hold and `NNPs1` is empty. If so, $\langle NI', W \rangle$ is moved to the second soup from the first soup in the `node[NI]` observable component and the top element pair $\langle NI, D'' \rangle$ is deleted from the ordered queue stored in the `oq` observable component.

V. MODEL CHECKING

Let us consider a straightforward algorithm to find all paths from a start node to a goal node for a given graph. The algorithm is formalized as part of K_{all} because we do not need to use P_{all} and L_{all} .

The two kinds of observable components are used:

- $(node[ni]: nstat, n, ps_1, ps_2, ps) - ni$ is a node ID, $nstat$ is a node status (which is one of `notYet`, `visited` and `done`), n is the number of the incoming edges that have not been tackled, ps_1 & ps_2 are soups of the direct successor node IDs of the node ni that have not yet been tackled & that have already been tackled and ps is a soup of (d, p) -pairs, where p is a path from a start node to this node that has been found so far and d is the distance; if $nstat$ is `notYet`, the node has not been tackled, if it is `visited`, the node has been visited (partially tackled) and if it is `done`, the node has been fully tackled;
- $(gstat: gs) - gs$ is either `nFin` or `Fin`; all paths from a start node to a goal node have been found if gs is `Fin`.

I_{all} consists of one state. When DAG (1) shown in Fig. 1 is tackled, the initial state is expressed as follows:

```
{(gstat2: nFin)
(node[n0]: done,0,(< n1,4 > < n2,1 > < n3,6 >),
  empty,< 0,n0 >)
(node[n1]: notYet,3,(< n4,1 >),empty,empty)
(node[n2]: notYet,1,(< n1,2 > < n5,1 >),empty,
  empty)
(node[n3]: notYet,3,empty,empty,empty)
(node[n4]: notYet,1,(< n3,1 >),empty,empty)
(node[n5]: notYet,1,(< n1,1 > < n3,3 >),empty,
  empty)}
```

T_{all} is specified as five rewrite rules. In addition to the Maude variables above-mentioned, let NLs & NLs' be Maude variables of soups of (natural number,path)-pairs, N' is a Maude variable of natural numbers and NS' is a Maude variable of node statuses. The first rule $All-stutter$ is essentially the same as the one of T_{A*} . The second one is as follows:

```
cr1 [All-done] : {(gstat2: nFin)
  (node[NI]: done,0,NNPs1,NNPs2,NLs) OCs}
=> {(gstat2: fin)
  (node[NI]: done,0,NNPs1,NNPs2,NLs) OCs}
if goal?(NI) .
```

The rule says that if all paths to the goal node from the start node have been found, the value of the $gstat2$ observable component is set to fin .

The last three rules are as follows:

```
rl [All-srch1] :
  {(gstat2: nFin)
  (node[NI]: visited,0,NNPs1,NNPs2,NLs) OCs}
=>
  {(gstat2: nFin)
  (node[NI]: done,0,NNPs1,NNPs2,NLs) OCs} .

rl [All-srch2] :
  {(gstat2: nFin)
  (node[NI]: done,0,< NI',W > NNPs1,NNPs2,NLs)
  (node[NI']: notYet,s(N'),NNPs1',NNPs2',NLs') OCs}
=>
  {(gstat2: nFin)
  (node[NI]: done,0,NNPs1,< NI',W > NNPs2,NLs)
  (node[NI']: visited,N',NNPs1',NNPs2',
    add(NLs,NI',W)) OCs} .

cr1 [All-srch3] :
  {(gstat2: nFin)
  (node[NI]: done,0,< NI',W > NNPs1,NNPs2,NLs)
  (node[NI']: NS',s(N'),NNPs1',NNPs2',NLs') OCs}
=>
  {(gstat2: nFin)
  (node[NI]: done,0,NNPs1,< NI',W > NNPs2,NLs)
  (node[NI']: NS',N',NNPs1',NNPs2',
    NLs' add(NLs,NI',W)) OCs}
if NS' /= notYet .
```

where s of $s(N')$ is the successor function of natural numbers.

If the first and second values of the node $[NI]$ observable component are $visited$ and 0 , the node NI has been fully tackled. If that is the case, the rule $All-srch1$ changes the first value into $done$.

If the node NI has been fully tackled and has a direct successor NI' that has not been treated and the first value of the node $[NI']$ observable value is $notYet$, the first

and second values of the node $[NI']$ observable value are changed into $visited$ and the number N' obtained by decrementing the original value $s(N')$; moreover, NI' and W (which is the weight of the edge from NI to NI') are added to each path in the soup NLs of the node $[NI']$ observable value. This is done by the rule $All-srch2$.

The rule $All-srch3$ does almost the same thing as the rule $All-srch2$. The difference is that the rule $All-srch3$ deals with the case where the first value of the node $[NI']$ observable value is not $notYet$, while the rule $All-srch2$ deals with the case where it is $notYet$.

The search command, where $ALLPF$ is the specification of the straightforward algorithm and $init$ is the initial state for $ALLPF$ and the DAG shown in Fig 1,

```
search [1] in ALLPF : init
=>* {(node[n3]: done,0,empty,NNPs2,NLs) OCs} .
```

finds all paths to the node $n3$ from the node $n0$, which are assigned to NLs :

```
NLs --> < 5,n0 -> n2 -> n5 -> n3 >
< 5,n0 -> n2 -> n1 -> n4 -> n3 >
< 5,n0 -> n2 -> n5 -> n1 -> n4 -> n3 >
< 6,n0 -> n3 > < 6,n0 -> n1 -> n4 -> n3 >
```

among which there are three shortest paths:

```
< 5,n0 -> n2 -> n5 -> n3 >
< 5,n0 -> n2 -> n1 -> n4 -> n3 >
< 5,n0 -> n2 -> n5 -> n1 -> n4 -> n3 >
```

Let $sPaths$ refer to the soup of the three shortest paths. The extraction of shortest paths from all paths to a goal node from a start node is done by a program written in Maude.

To model check that K_{A*} satisfies some desired properties, we define (or specify) P_{A*} and L_{A*} . P_{A*} has two atomic propositions: fin and $isSPath$. L_{A*} is specified as follows:

```
eq {(gstat: fin) OCs} |= fin = true .
eq {(path: (< D,L >)) OCs} |= isSPath
  = (< D,L > \in sPaths) .
eq {OCs} |= PROP = false [otherwise] .
```

The three equations say that fin holds a state s iff s contains $(gstat: fin)$ and $isSPath$ holds for a state s iff s contains $(path: (< D,L >))$ and $sPaths$ contains $< D,L >$ as an element. Let two LTL formulas $halt$ and $correct$ be defined as $<> fin$ and $[] (fin -> <> isSPath)$, where $<>$ is \Diamond , $[]$ is \Box and $->$ is \Rightarrow .

Let h be as follows: $h(n1) = 2$, $h(n3) = 0$ and $h(n) = 1$ for any other node n , and $init$ be the initial state for the specification $ASTAR$ of K_{A*} and the DAG shown in Fig 1. We model check that K_{A*} satisfies $halt$ and $correct$ as follows:

```
red modelCheck(init, halt) .
red modelCheck(init, correct) .
```

Figure 2. A DAG (2)

No counterexample is found for both model checking experiments. Because h is admissible, namely that it never overestimates the actual cost to the goal $n3$ from any node, K_{A^*} satisfies `correct`.

Let us use another h : $h(n1) = 3$, $h(n5) = 4$, $h(n3) = 0$ and $h(n) = 1$ for any other node n . This h is not admissible because the actual cost to the goal $n3$ from the node $n1$ is 2 and the actual cost to the goal $n3$ from the node $n5$ is 3. The first model checking experiment does not find any counterexamples, while the second one does. This is because h is not admissible. For this case, K_{A^*} finds $n0 \rightarrow n3$, which is not the shortest one.

Let us use yet another h : $h(n1) = 3$, $h(n3) = 0$ and $h(n) = 1$ for any other node n . This h is not admissible either because the actual cost to the goal $n3$ from the node $n1$ is 2. The two model checking experiments, however, do not find any counterexamples, meaning that K_{A^*} still satisfies `correct`. In this case, K_{A^*} finds $n0 \rightarrow n2 \rightarrow n5 \rightarrow n3$. This is because for each node n in the path, $h(n)$ never overestimates the cost to the goal $n3$. This case may make us conjecture that if there exists a shortest path such that for each node n in the path $h(n)$ never overestimates the cost to the goal from n , then A^* finds a shortest path.

Let us consider the DAG shown in Fig. 2. Let us suppose that h is defined as follows: $h(n) = 0$ for all nodes n , namely that A^* is equivalent to the Dijkstra algorithm. The two model checking experiments do not find any counterexamples.

Let us suppose that h is defined as follows: $h(n) = 10$ for all nodes n . This h is not admissible. Moreover, there exists no shortest path such that for each node n in the path $h(n)$ never overestimates the cost to the goal from n . The two model checking experiments, however, do not find any counterexamples. Thus, the sufficient condition that A^* finds a shortest path can be relaxed.

A relaxed sufficient condition would be that there exists a shortest path such that for each node n in the path $h(n)$ plus the cost to n from the start node is less than the cost of any non-shortest path to the goal from the start. Let us suppose that $h(n2) = 5$, $h(n4) = 0$, $h(n5) = 3$, $h(n6) = 4$, $h(n7) = 0$, $h(n8) = 2$, $h(n10) = 0$ and $h(n) = 10$ for

any other node n . This h is not admissible but does satisfy the relaxed sufficient condition. The two model checking experiments do not find any counterexamples. Let us modify h a bit as follows: $h(n8) = 2$ and for any other node n $h(n)$ is the same as the last version. This modified h does not satisfy the relaxed sufficient condition. The first model checking experiment does not find any counterexamples, while the second one finds a counterexample, where A^* finds $n0 \rightarrow n4 \rightarrow n10$ that is not a shortest path. The two cases support that the relaxed sufficient condition is likely to make sense.

VI. CONCLUSION

We have reported on a case study in which A^* algorithm is formally specified in Maude and model checked with the Maude LTL model checker. Two properties have been taken into account: the termination property and the correctness property. The former says whether A^* halts, while the latter says whether A^* finds a shortest path. If the estimation h is admissible, our model checking experiments say that A^* satisfies both properties. Our model checking experiments have also suggested that the condition can be relaxed. We have then conjectured that if there exists a shortest path such that for each node n in the path $h(n)$ plus the cost to n from the start node is less than the cost of any non-shortest path to the goal from the start, A^* finds a shortest path.

Among future directions are as follows. Many path finding algorithms have been proposed. One piece of our future work is to formally specify such algorithms in Maude and model check them with the Maude LTL model checker, coming up with a framework in which such algorithms can be systematically analyzed. Another piece of our future work is to apply Maude and the Maude LTL model checker to path planning for multiple robots or vehicles, which could contribute to a near future autonomous vehicle world.

Abstract—Software architecture design plays a vital role in software development, as it gives an overview of how the software system should be constructed and executed at runtime. The verification of software architecture design is hence important but it is an error-prone task that heavily relies on knowledge and experience of the software architect, especially for a large software system that its behaviour is complex. Automated verification can be a solution to this problem, however, the specification language must be expressive enough to describe the behaviour of different design entities. This paper presents an enhancement of an architecture description language supported by PAT. The enhancement aims to improve the expressiveness of the language, in order to support the automated behaviour verification of software architecture design. With this enhancement, different behaviour of specific component and connector can be thoroughly checked and traced. The implementation of this enhancement is presented to demonstrate how the standard model checking engine such as PAT can be extended to support an architecture description language. We evaluated our approach with a case study and the result is presented.

Index Terms—Software Architecture, Architecture Description Language, Model Checking, Linear Temporal Logic

I. INTRODUCTION

Software architecture design gives an overview of how the software system is implemented and works. If the software architecture design is made incorrectly, it can cause the project to fail or delay due to design re-correction, therefore the verification is a significant task. However, the software architecture designs are usually represented by informal notations, such as graphical diagram and text. The design interpretation can hence be inconsistent and the verification process is an error-prone and time consuming task, even to those with extensive experience and knowledge. If the software architecture design can be formally defined, the verification task can be automated. Therefore, applying the formal methods to the software architecture design would be a useful approach to this problem.

Many architecture description languages (ADL) have been proposed to formally define the software architecture design model such as [1], [2], [3], and [4]. With the formal model in ADL, different properties can be defined and automatically

verified with the model checker. Allen and Garlan [1] proposed Wright, an ADL that allows connections in software architecture design to be formally defined in communicating sequential process (CSP). The formal format of design model allows to check the architectural compatibility among connections. However, the behavioural property definition and verification had not been completely addressed so there are number of works that aim to fulfil this. Darwin [5] was proposed to allow behavioural properties to be defined in the linear temporal logic (LTL) and use LTSA [2] as a model checker to verify them. Defining and verifying behaviours in the evolving software system is a challenge. Oquendo [3] presented π -Method with an ADL based on π -calculus. The ADL for π -Method helps to formally define evolvable software system in both structural and behavioural view. In addition, the refinement model can be defined to check and preserve the behavioural properties.

Some works have applied process algebra to formalize specific behaviour in the software system because of its expressiveness in describing system behaviour. Aldini et al. [6] presented a guideline that includes a principle of formalizing system behaviour into process algebra. The manual formalization from the design model to ADL has been an obstacle to making it widely used by the software engineers, due to the fact that the majority of them do not have background knowledge in the formal methods and the verification output from model checker can be difficult to understand. Therefore, the degree of formality needs to be balanced with the practicality. Some approaches, such as Bose et al. [7], Baresi et al. [8] and CHARMY [4], hence provide a feature that translates the input model in graphical notation into formal language that can be automatically checked. While, some approaches, such as Arcade [9], aim to make the verification output from the model checker more readable. The graphical abstraction may promote the practicality and understandability of using formal ADL, but the ambiguity might occur from the lack of complete semantic mapping between the graphical input and the model checking input. In addition, most of the existing approaches use standard model checking engines that is not designed with the architecture design concept. For example, Wright uses FDR as a model checker, while Darwin and

Fig. 1. Overall Approach

CHARMY uses LSTA and SPIN [10] respectively. As a result, the constructed state model is usually not optimized in term of understandability and scalability [11].

This work aims to enhance the expressiveness of Wright# [12], an architecture description language that is supported by PAT [13]. Wright# is an extension of Wright with the support of architecture styles reusing. This enhancement provides an expressive way to describe the execution of software system through system, component and connector specification. The overall approach can be found in Figure 1, which shows the specification that consists of four major parts. The connector can be specified according to the architecture styles. The component specification includes components involved in the system under design. In system configuration, the connector instances are created and attached to the component before we define how the system is executed through the process that initiates different components. The assertion is where the number of properties are defined for checking specific behaviour in the system. Deadlock freeness, a standard PAT feature, can also be used to verify the software architecture design. As the original Wright# produces a vague event labels that are difficult to trace. Therefore, the event labelling is optimized to clearly represent specific events in the connectors and components. As a result, the LTL properties can be defined to check the specific behaviours of design entities and the verification output is easier to trace back. The PAT extension module is developed as a graphical interface tool to support Wright# and its enhancement. In addition, we demonstrate the expressiveness of the design specification and property definition with a software architecture design of e-commerce software system.

The remainder of this paper is organized as follows. Section 2 explains the formalization of behaviour specification in the software architecture design. Section 3 presents the implementation of tool and how we develop a module in PAT framework to support Wright#. We demonstrate our approach with an e-commerce case study in Section 4. Section 5 concludes this paper and addresses the directions of future work.

II. FORMALIZATION OF ARCHITECTURAL DESIGN

In this section, we present the formalization of behaviour specification of software architecture design in Wright#. Wright# notation aims to define software architecture design

in component and connector view. CSP, a process algebra notation, is used to formally describe the interactive behaviours of component and connector. We extend the PAT tool to support this ADL and transform it into native CSP that forms Labelled Transition System (LTS). With LTS, the desired behaviours of software system can be automatically checked through LTL, as well as the deadlock situation.

A. Formal Modelling

Wright# is an ADL that is inspired by Wright with four basic design entities namely the component, connector, port and role. The component represents a computational unit, while the connector represents linkage between the components. The connector can includes one or more roles representing how the communication works. The component contains a number of ports that can be attached to one or more roles defined by different connectors.

There are three parts of design model to be described in ADL namely connector definition, component definition and system configuration. Each definition of connector is corresponding to different type of communication according to the architecture style. The component are defined to represent actual component and port within the software system under design. The system configuration defines how component and connector are attached, as well as the execution process. These definition contains defined processes that are based on CSP. Table I shows the syntax of process expression that can be used to describe the processes within the software architecture design.

TABLE I
PROCESS EXPRESSION SYNTAX

$e \rightarrow P$	Event prefixing
$ch!p \rightarrow P$	Channel output
$ch?p \rightarrow P$	Channel input
$P \parallel Q$	Parallel process
$P \parallel\!\!\parallel Q$	Interleaving process
$P < \star > Q$	Coupling process
<i>Stop</i>	deadlock stop
<i>Skip</i>	terminate successfully

An event represents an abstract observation of a software system. It may refer to certain system state at a given time. Event prefixing hence represent a circumstance when an event e occurs then process P is executed next. Channel output and input are used to send and receive data from its executing environment respectively. Let ch be a channel and p is data to be sent or received; P is a process to be executed next. A pair of processes can be defined as parallel, interleaving and coupling. The coupling operator does not exist in native CSP or CSP# but it is added to the syntax to represent coupling process between components. Let P and Q be a process and $P < \star > Q$. When the process P is triggered, it contains a sequence of event that an event sequentially calls the process Q to execute and return back to where it is called on process P . In order to define coupling, process P must contain an event *process*, which is when the coupling process Q is called to execute.

1) *Connector Definition*: The connectors are firstly defined to manifest how roles interact together. The processes for role are defined with the sequence of events. The channel is used to represent communication between different roles, which results in transition between events. Below is a sample code that conveys the communication for the client-server structure. The channel *req* is used to make a request from the client to the server and channel *res* is used to return response message from the server to the client.

```
connector CConnector{
  role client(j) = request → req!j → res?j
    → process → client(j);
  role server() = req?j → invoke
    → process → res!j → server(); }
```

The connector for publisher-subscriber styles can be defined as shown below, where a channel *pub* is used to broadcast data from the publisher to the subscriber.

```
connector PConnector{
  role publisher(j) = process → pub!j → Skip;
  role subscriber() = pub?j → process → subscriber(); }
```

2) *Component Definition*: The component definition contains a set of port definition. Each port has a process defined as the sequence of event that the port performs internally within the component. The script below shows two sample component namely *SPClient* and *SPServer*. The *SPClient* component has a *test* port defined and the *SPServer* has *run* port defined.

```
component SPClient {
  port test() = precheck → output → test(); }
component SPServer {
  port run() = invoke → execution → run(); }
```

3) *System Configuration*: The system configuration contains details of how components interact among each other and can be defined as follow. Firstly, the instance of connector needs to be created with the *declare* statement based on a defined connector. Secondly, the ports of connector are attached to one of more roles of connector instances using *attach* statement. If more than one roles are attached, a process expression composed of multiple role and process operator can be defined. Lastly, the *execute* statement declares how the system are executed with a process expression.

```
system SampleCS {
  declare cslink = CConnector;
  attach SPClient.test() = cslink.client();
  attach SPServer.run() = cslink.server();
  execute SPServer.run() || SPClient.test(); }
```

Careful readers may notice an event *process* defined at the role processes. This event triggers an execution of a process defined on the attached port. According to the sample system configuration shown above, the LTS is illustrated in Figure 2, which the events of port is shown in italic.

The *process* event also serves as the point of execution when the coupling process is defined. The coupling process may occur in many situation. For example, the multi-tier architecture that a tier can accept a request and consequently make a request to the upper tier. Another example is in Service-oriented architecture when a service is invoked and

Fig. 2. LTS for the sample clien-server system

Fig. 3. LTS for the sample coupling process

calls another service. Below is a sample of attached coupling role processes. The *run* port of *SPServer* is attached to a coupling of two roles from different client-server connectors namely *cslink* and *dlnk*, which calls the component *SPServer* and *DBServer* respectively where *DBServer* is a component. In this case, the role processes are nested within one another as LTS shown in Figure 3. This coupling feature eases the complexity of defining the coupling process in native CSP.

```
attach SPServer.run() = cslink.server() < * > dlnk.client();
attach DBServer.run() = dlnk.server();
```

B. Behaviour Verification

After the software architecture design model is defined with ADL, different assertions representing the query about system behaviours can be defined. PAT supports a number of different assertion checking including linear temporal properties and deadlock freeness.

1) *Deadlock Freeness*: Deadlock is a situation when the software system can not progress further towards completion; so that the entire system halts and waits indefinitely. A well known scenario is when components wait for the mutual exclusive resource. In the software system, deadlock occurs when components call each other as circle, so the port that initializes the process loops back to itself. More concrete examples will be provided in the case study section. With the sample model explained in the previous section, a deadlock can be checked against a defined system using the *deadlockfree* statement as shown below.

assert *SampleSystem* *deadlockfree*;

2) *Linear Temporal Properties*: A full set of linear temporal logic is supported by PAT. Therefore, operators such as \Box (always), \Diamond (eventually), X (next), R (release) and U (until) can be included in the linear temporal logic defined for checking properties. Let F be a LTL formula, the assertion syntax for defining LTL properties is as follows.

assert *SampleSystem* $\models F$;

In order to support expressiveness of defining system behaviour, the property can be implicitly defined to check the behaviour of a specific component or connector.

Let *Comp* be any component, *Prt* is port of that component and *Evt* is one of the event defined in the port process. F is a LTL formula to check the behaviour of the component:

$$F = [Comp.Prt.Evt] \mid \Box F \mid \Diamond F \mid X F \mid U F \mid R F$$

Let *Comp* be any component, *Conn* be a connector, *Rle* be an attached role and *Evt* be one of the event defined in the role process. F is a LTL formula to check the behaviour of connector:

$$F = [Comp.Conn.Rle.Evt] \mid \Box F \mid \Diamond F \mid X F \mid U F \mid R F$$

For example, $\Box\Diamond SP_{Server}.run.execution$ expresses a property to check if the *execution* event always eventually occurs at the *SPServer* component. $\Diamond DB_{Server}.dblink.client.request$ expresses a property to check if the *request* event at attached client role of *DBServer* component eventually occurs.

III. TOOL IMPLEMENTATION

To support editing architecture design model in ADL and automated behaviour verification, the PAT ADL module is developed by extending PAT framework. This module includes parser that helps to parse the ADL code into objects representing different entities of software architecture design model. The parser in the original PAT tool was developed using ANTLR version 3, where different parts of parsing code in C# are merged inside the grammar file. This style of development is difficult to make any extension and maintenance. Therefore, we adopt ANTLR version 4.0, where the source code of language parsing can be separated from the grammar file. The complete source code of PAT ADL can be found at <https://bit.ly/2Vc855I>.

The overall process performed by ADL module can be illustrated in Figure 4. The editor tool allows users to edit ADL file according to the syntax explained in the previous

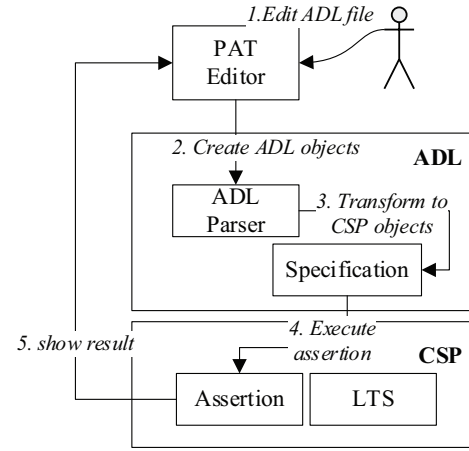

Fig. 4. Overall Process of the ADL module

section. When the user makes a verification, the source code in ADL is processed by the PAT ADL in the background and return the result back to the user interface on the editor tool. We developed a grammar file based on the CSP# and used ANTLR to automatically generate a parser program. The parser program helps to read a source code in ADL and the visitor program is developed to convert different ADL statements into objects representing entities such as component, connector, system configuration, port, role, attachment and assertion. With *Specification* module, ADL objects are later automatically transformed into PAT native objects representing the CSP processes. The ADL to CSP transformation can be briefly explained as follows.

- One process is defined corresponding to each attached role of a defined port.
- One process is defined to represent a defined port, which calls the attached role process according to the expression defined in the *attach* statement.
- One process is created for a defined system and call port processes according to expression defined in the *execute* statement.

For example, the sample client-server model explained in the previous section can be transformed into native CSP as shown below. Two channels namely *cslink_req* and *cslink_res* are defined for requesting and responding message. *SPClient_cslink_client* process is defined for the client role of *cslink*, and *SPClient_test* process is defined for the *test* port. Two processes namely *SPServer_cslink_server* and *SPServer_run* are defined in the same way for server. The *SampleSystem* process is defined to represent the main system process. The *LTS* sub-module helps to model LTS according to CSP and encapsulate the transition model. The transition model allows *Assertion* sub-module to traverse according to the depth-first search and breadth-first search algorithm, in order to make a verification. The verification result is displayed on the verification window of the editor tool.

```

channel cslink_res 1;
channel cslink_req 1;
SPClient_cslink_client(j) = (
  SPClient_cslink_client_request
  → cslink_req!j → cslink_res?j
  → (SPClient_cslink_client_result
  → (SPClient_cslink_client_process
  → (SPClient_test_precheck
  → (SPClient_test_output → SPClient_cslink_client(j)))));
SPClient_test() = SPClient_cslink_client();
SPServer_cslink_server() = cslink_req?j
  → (SPServer_cslink_server_invoke
  → (SPServer_cslink_server_process
  → (SPServer_run_invoke
  → (SPServer_run_execution
  → (SPServer_cslink_server_return
  → cslink_res!j → SPServer_cslink_server()))));
SPServer_run() = SPServer_cslink_server();
SampleSystem() = (SPServer_run() || SPClient_test());

```

IV. CASE STUDY

We select a part of real-world e-commerce software system to demonstrate and evaluate the practicality of our approach. The software architecture design of this system is shown (as UML component diagram) in Figure 5. The software system allows user to browse catalogue of the products, order and make a purchase on-line through the web store or mobile store. When the users make a purchase, the order manager component keeps the record of order and fetch the product from the inventory through the inventory control component. The inventory control automatically locates the ordering product from the warehouse and send details to the shipping control component. The shipping control allows packaging officer to prepare shipping package and log the shipping package for courier.

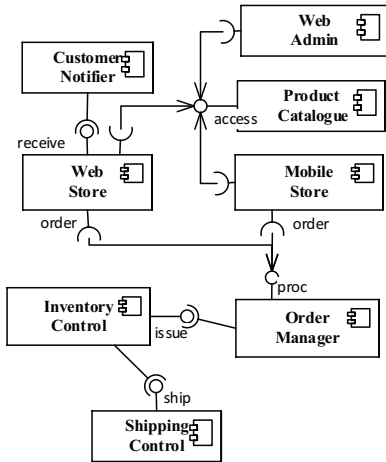

Fig. 5. Component diagram for E-commerce system

In this case study, we use the client-server and publisher-subscriber connectors as defined in the previous section. The model in ADL is partly shown below. The complete model can be found at <https://bit.ly/2EWJGCg>. The ports are defined according to the component diagram shown in Figure 5 along with the port processes that simulate what the components

perform. Some port may omit the process details such as *ProductCatalogue* and *OrderManager* component. The system configuration of this system declares 4 client-server connector and 1 publisher-subscriber connector. The number of attachments are defined to link components together. The numbers passing in as a parameter for role processes represent the signature of data passing between the component and connector. The *proc* port of *OrderManager* is attached to two roles as a coupling process: *purchasing.server()* and *issuing.client()*. This is because the order can only be processed successfully when the inventory finished fetching the product, otherwise the order is rejected. The *purchasing.server()* represents the internal process for processing order within the *OrderManager* component, while the *issuing.client()* requests to the service on *InventoryControl* component to fetch the product. The *issue* port of *InventoryControl* component is attached to two roles as a parallel process. The *issuing.server()* represents the internal execution of *InventoryControl* component, while *shipping.client()* represents a request to manage the shipping details of the *ShippingControl* component. The *execute* statement defines all port processes to be executed in parallel. The execution can be modified to focus on checking some particular scenarios in response to the functionality of the software system, such as when the product is ordered and when the product catalogue is updated.

```

component WebStore {
  port browse() = render → output → browse();
  port order() = commit → email → order();
  port receive() = acknowledge → display → receive(); }
component MobileStore {
  port browse() = render → output → browse();
  port order() = commit → email → order(); }
component WebAdmin {
  port manage() = result → manage(); }
component CustomerNotifier {
  port alert() = promo → send → alert(); }
component InventoryControl {
  port issue() = locate → fetch → issue(); }
component ShippingControl {
  port ship() = inform → log → ship(); }
...
system Shopping {
  declare purchasing, issuing = CSConnector;
  declare shipping, cataccessing = CSConnector;
  declare newswire = PSCConnector;
  attach WebStore.order() = purchasing.client(99);
  attach MobileStore.order() = purchasing.client(98);
  attach WebStore.receive() = newswire.subscriber();
  attach CustomerNotifier.alert() = newswire.publisher(77);
  attach WebStore.browse() = cataccessing.client(99);
  attach WebAdmin.manage() = cataccessing.client(98);
  attach ProductCatalogue.access() = cataccessing.server();
  attach OrderManager.proc() = purchasing.server()
    < * > issuing.client();
  attach InventoryControl.issue() = issuing.server()
    || shipping.client(88);
  attach ShippingControl.ship() = shipping.server();
  execute WebStore.order() || MobileStore.order()
    || WebStore.browse() || WebAdmin.manage()
    || ProductCatalogue.access() || OrderManager.proc()
    || InventoryControl.issue() || ShippingControl.ship();

```

Three assertions are defined as shown below. The first assertion helps to check if the software system design can leads to a deadlock. If the deadlock is found, the verification shows an invalid result with a counterexample, which gives a sequence of events leading how deadlock can occur.

```
assert Shopping deadlockfree;
assert Shopping = ◇WebStore.purchasing.client.process;
assert Shopping = □(OrderManager.purchasing.server.process
→ ◇WebStore.order.email);
```

With the system configuration above, the deadlock does not occur so it outputs a valid result. However, we can demonstrate when deadlock occurs by changing the attachment of the *ShippingControl.ship()* port to the *shipping.server()* < * > *issuing.client()*. This makes the components call each other in a loop. The verification result can be seen in Figure 6. The event labels identify both component, connector, role and port that are involved in the deadlock. The second assertion makes use of the behaviour checking on the connector. It checks if the *process* event of *client* role is eventually triggered at the attached *purchasing* connector on the *WebStore* component. The third assertion combines the behaviour checking on both the component and connector, as it checks if every time the order is processed, the email will always be sent out to the customer. The results of these two LTL properties are valid. The verification statistic of these three assertions including number of states, number of transitions, total time usage and estimated memory usage can be found in Table II. As can be seen from the table, the number of visited states, memory usage and total time are relatively low.

```
*****Verification Result*****
The Assertion (Shopping() deadlockfree) is NOT valid.
The following trace leads to a deadlock situation.
<init -> InventoryControl_shipping_client_request -> shipping_req188 -> shipping_req788 ->
ShippingControl_shipping_server_invoke -> ShippingControl_issuing_client_request -> issuing_req188 ->
issuing_req788 -> InventoryControl_issuing_server_invoke -> InventoryControl_issuing_server_process ->
WebStore_purchasing_client_request -> purchasing_req199 -> purchasing_req799 ->
OrderManager_purchasing_server_invoke -> OrderManager_issuing_client_request -> issuing_req199
```

Fig. 6. Deadlock Result from PAT

TABLE II
VERIFICATION STATISTIC

Assertion	State#	Transition#	Time (sec)	Memory
Deadlock	25	24	0.0059828	8664 KB
LTL 1	16	24	0.0105143	8696 KB
LTL 2	159	278	0.0137552	42280 KB

V. CONCLUSION

We present an enhancement to Wright# ADL that supports the formal behaviour modelling in software architecture design. The language allows users to expressively define and verify the behaviour of components and connectors. The implementation of a PAT extension module to support Wright# and our enhancement is presented, in order to demonstrate how the standard model checker can be extended to support an ADL. We evaluate our approach with an e-commerce

software system. Our approach can be used to clearly define the behaviour of different components and connectors in the design, as well as the interaction among them. The properties can be defined in LTL assertions to represent the desired system behaviour in response to the system functionalities. The deadlock analysis, a standard feature in PAT can be used. The event labels in a counterexample is informative enough to identify involved design entities that cause invalid behaviour. We found that the state space are relatively low but more evaluation need to be taken to prove the scalability.

For the future work, we plan to integrate this approach with other techniques such as ontology reasoning [14], in order to fulfil the semantics of the architecture design in the verification process. As the ontology representation is rich of semantic constrains that can help to verify and maintain the structure consistency in the design model before its behaviour is checked. More case studies in the real world could be used to evaluate the practicality and scalability of our approach. As the behaviours can be formally defined, it could be interesting to use it to detect the design smells or anti-pattern based on the system behaviours.

Leveraging Rigorous Software Specification Towards Systematic Detection of SDN Control Conflicts

Xin Sun and Lan Lin
Ball State University, Muncie, Indiana 47306, USA
{xsun6, llin4}@bsu.edu

Abstract—This paper leverages a well-established, rigorous method for software specification to approach a unique problem introduced by the emerging software-defined networking (SDN) paradigm, i.e., the potential control conflict arising from running multiple SDN apps in the same network. As individual SDN apps have different optimization objectives and each assumes full control of the network, their interaction is often unpredictable and can destabilize the network as a result. We propose a theoretical modeling framework for systematically detecting such conflicts, which is deeply rooted in automaton theory and software engineering. The key novelty and strength of our approach is its ability to model and reason about the interaction of multiple SDN apps precisely (with the capability of identifying when and how conflicts may occur), proactively (prior to running the apps), and without the knowledge of the apps' implementation details. To the extent of our knowledge our work is the first to adapt rigorous software specification to the constructive, formal modeling of SDN apps running on a network topology, and through a formal treatment not only straightforwardly detects and locates such conflicts but also examines and analyzes important network properties (e.g., safe operational regions) of interest to network managers.

I. INTRODUCTION

This paper reports an application of rigorous software specification to the emerging software-defined networking (SDN) paradigm, to approach a unique problem introduced by “SDN apps” (also called network functions), which are software applications running on top of the SDN controller platform, offering a variety of functionalities such as load-balancing, power-saving, quality of service, access control, WAN optimization, network virtualization, to name a few (a comprehensive survey is presented in [1]).

Because (i) the apps are created by different developers (virtually anyone can develop and release them; marketplace exists today for selling and buying SDN apps, e.g., Hewlett-Packard App Store [2]), (ii) each app typically manages/optimizes a single aspect of the network (e.g., performance, security, resiliency, energy usage, etc.), and has a single optimization objective, and (iii) each app assumes full control of the whole network, they may seek to change the underlying network in conflicting ways. The interaction of their conflicting outputs can be unpredictable and, as a result, destabilize the network (a case study of such conflict is presented in Sec. III).

In our preliminary work [3] a fine-grained approach was proposed that models the SDN apps and their interactions using deterministic finite state automata. However, derivation of the automata was completely *manual*, and the conflicts were manually identified afterwards based on human insight. The modeling process was tedious with much trial and error, and we were not able to prove the correctness of either the derived automata or the located conflicts.

This paper presents an advanced approach that significantly extends our previous work, with the following contributions:

- 1) We adapted a well-established, rigorous method for software specification (i.e., *sequence-based specification* [4, 5, 6, 7]) to systematically derive a formal (automaton) model for each SDN app that runs on a network topology (Sec. IV). The adapted method is inherently rigorous, systematic, and constructive, and does not require knowledge of the implementation details of the apps; as such, we believe the method is very practical.
- 2) We developed a theoretical framework for analyzing the interaction of multiple SDN apps running in parallel (Sec. V). With our new theory, important network properties of interest to network managers, such as the safe operational region (i.e., network states under which multiple SDN apps can run free of conflict), can for the first time be formally defined and precisely analyzed. We demonstrated how potential control conflicts can be straightforwardly and systematically detected (Sec. VI).

II. RELATED WORK

The problem of control conflicts caused by running multiple independently-developed SDN apps, and the resulting destabilization of the network, has recently started to receive attention from the research community. Corybantic [8] and Athens [9] take a coarse-grained approach that resolves potential conflicts at run-time (i.e., when the network is in operation). They let individual SDN apps generate “proposals” for network configuration changes, and then require each app to evaluate all proposals, based on some predefined policy or voting mechanism. While this approach can successfully resolve conflicts, it does so with significant costs: (i) it requires all SDN apps to implement the additional functionality of generating and evaluating proposals; (ii) it only selects a single proposal at a time, which can leave out potentially better solutions that combine multiple conflict-free proposals, leading to sub-optimal network configurations; (iii) it cannot identify the root cause of the conflicts. Bairley and Xie [10] take a similar approach (it thus suffers from similar drawbacks), except that it seeks to combine multiple proposals to form a globally optimal configuration using an evolutionary approach. In contrast, our approach does not have any of those drawbacks.

Prior works [11, 12] concern individual-flow-level forwarding behavior and can detect policy violations (such as black holes and loops) at that level; however, none of them can detect the network state oscillation caused by conflicts of running multiple SDN apps, since state oscillation is not a violation of flow policy (it is a higher-level issue).

Fig. 1. The Network Topology Used in the Case Study

III. CONTROL CONFLICTS AND NETWORK STATE OSCILLATION: A CASE STUDY

A software-defined network typically has a three-tier architecture [13]. The bottom layer, also called the data plane, consists of “dumb” switches and other hardware boxes that primarily focus on packet streaming. The middle layer, also called the controller or the network operating system, is a software platform that directly manages the hardware boxes and offers an abstraction of the network resources via a set of application programming interfaces (APIs). The APIs in turn enable the development of network functions, also called “SDN apps”, which form the top layer.

An SDN app generally seeks to optimize some aspect of a network, by modifying the network state. The state of a network includes multiple variables, such as traffic load, routing paths, power state of devices, up/down state of links, etc. [14] SDN apps control the network state by issuing commands to the controller via the northbound API; the controller then compiles each command down to a set of new configurations to be installed on the data plane.

We observed that, when multiple SDN apps are trying to control the network state, conflicts may occur. For the purpose of demonstrating both the problem and our solution in a tangible and unambiguous manner, we now present a concrete case study involving two popular types of SDN apps that have been extensively researched (e.g., [15, 16, 17]): a *power-saving* app and a *load-balancing* app, running on a toy network as depicted by Fig. 1. End hosts attach to Routers A and B. Between them there are two hosts routing paths: one goes through Router E and the other F. The traffic load on each link (w or v) is modeled as a step function that has three states: high (H), low (L), and zero (Z). Assume all devices and links have the same capacity. The two apps work in the following way:

Power-saving app: it seeks to aggregate traffic to one of the two paths (without loss of generality, assuming it’s always the top path), and then turn off Router E to reduce energy use. To realize this objective, it checks the utilization rates of Links w and v every M seconds, and whenever the utilization rates of both links are low or zero for two consecutive cycles, it issues a command to the controller to turn off E and route all future packets to the top path.

Load-balancing app: it seeks to spread traffic across all possible paths, to minimize the load of any link. It checks the utilization rates of w and v every M seconds. Whenever one is high and the other is low or zero for three consecutive cycles, it issues a command to the controller to route a larger fraction of new flows entering the network in the next M seconds through the less congested path. It stops issuing such commands once the utilization rates of both links become high, or both become low or zero (i.e., the load is balanced).

Intuitively, when the two apps run on the same network, control conflict might occur, as one seeks to aggregate traffic to a subset of paths, while the other seeks to spread traffic evenly on all paths. However, the simple intuition is unable to tell precisely when and how control conflict may arise, and the consequences of the conflicts. The problem can get much more complicated, as the conflict may be caused by more than two apps, and the network may oscillate among more than two states.

IV. MODELING INDIVIDUAL SDN APPS

This section first presents a formal model for individual SDN apps, and then describes our approach for deriving the model. The two SDN apps described in Sec. III are used as running examples to illustrate the modeling process.

A. An Automaton-Based Model

Our model of an SDN app running on a network topology follows the conventional definition of a Moore machine.

Definition 1 (Moore Machine): A *Moore machine* is a 6-tuple $(Q, \Sigma, \Gamma, \delta, \nu, q_0)$, where Q is a finite set of states, Σ is an input alphabet, Γ is an output alphabet, $\delta : Q \times \Sigma \rightarrow Q$ is the transition function, $\nu : Q \rightarrow \Gamma$ is the output function, and $q_0 \in Q$ is the starting state.

Specifically for the SDN apps, they can be modeled as a subset of Moore machines, of which the output alphabet includes the two special responses: 0 (the null response) and ω (the illegal response). Additionally, the model only needs to include states that are reachable from the initial state; non-reachable states can be safely ignored as they will never be realized. To model reachable states, we need to extend the transition function of a Moore machine to input sequences, as follows: $\hat{\delta} : Q \times \Sigma^* \rightarrow Q$ is defined by (1) $\hat{\delta}(q, \lambda) = q$, where λ is the empty input sequence; and (2) $\hat{\delta}(q, wa) = \delta(\hat{\delta}(q, w), a)$ for all $q \in Q$, $w \in \Sigma^*$, $a \in \Sigma$.

Definition 2 (Network Function Moore Machine): A *network function Moore machine* is a Moore machine $(Q, \Sigma, \Gamma, \delta, \nu, q_0)$ satisfying (1) $\{0, \omega\} \subset \Gamma$, and (2) for any $q \in Q$ there exists $w \in \Sigma^*$ such that $\hat{\delta}(q_0, w) = q$.

Here Q represents the set of *software states* of the SDN app (note that these are different from the *network states*); Σ represents inputs to the SDN app, which includes the network states such as link load and topology; Γ represents outputs from the SDN app, which are commands to the SDN controller that seek to change the network state; 0 and ω are special outputs representing the null output, and the illegal output (for an input sequence not possible to occur – this is defined for completeness purposes). The second condition ensures that any state in Q must be reachable from the initial state q_0 .

B. A Rigorous Approach for Deriving the Automaton

Our approach for deriving the Moore machine of a given SDN app is rigorous (based on the automaton theory), systematic (we offer a systematic process to follow), and constructive (the state machine will be discovered at the end of the process). It is based on a well-established rigorous method for software specification, i.e., *sequence-based specification* [7, 6, 5, 4]. The input to our approach is an informal description of how the SDN app is supposed to work on the given network topology

(this description is termed “functional requirements” in the field of software engineering). The output is a Moore machine representing the working mechanism of the SDN app. The approach has three key steps: identification of stimuli and responses, sequence enumeration, and automaton construction.

1) Step 1: Identification of stimuli and responses:

We first identify a list of *stimuli* (i.e., inputs) and *responses* (i.e., outputs) of the SDN app running on the given network topology. The power-saving app and the load-balancing app share a common set of inputs: $\{H_w H_v, H_w L_v, H_w Z_v, L_w H_v, L_w L_v, L_w Z_v, Z_w H_v, Z_w L_v, Z_w Z_v\}$, where H , L , and Z indicate link utilization is high, low, or zero, respectively, and the subscript indicates which link (i.e., w or v). Each input contains information about the utilization rates of both links. Outputs of the power-saving app are $\{OnE, OffE, 0\}$, where $OnE/OffE$ represents turning on/off the switch E (a request to turn on/off E , rather than a successful command or operation, as such request may be overridden [3]), respectively, and 0 represents the *null* response, i.e., no output issued by the SDN app that potentially changes the network’s state. Outputs for the load-balancing app are $\{FtoE, EtoF, 0\}$, where $FtoE/EtoF$ represents moving flows from F/E to E/F , respectively.

2) Step 2: Sequence enumeration: We start with an informal description of the requirements for each SDN app running on the given topology, and tag (number) them to facilitate tracing decisions we have made (in the specification process) to the tagged requirements or derived requirements (as a by-product the process also leads to the discovery of derived requirements that were not originally stated, and the resolution/correction of inconsistent/incorrect requirements). Requirements for the power-saving app and for the load-balancing app are listed in Tables I and II, respectively. Original requirements were retrieved from descriptions of the functions in [3]. Tags that begin with D indicate new requirements we derived in the specification process (following the same assumptions as implied by [3]).

Next we perform the key step of sequence-based specification, called *sequence enumeration*, to discover/construct every detail of the state machine. We enumerate all finite sequences of stimuli (inputs) in length-lexicographical order (i.e., first by length, and within the same length lexicographically), and for each enumerated sequence make two decisions:

- Response mapping. We map the sequence of inputs to a response (output) of the network function. The response is the output the network function produces in response to the very last input in the sequence, given the input history. For instance, the sequence $L_w L_v . L_w L_v$ (we concatenate inputs with dots) is mapped to the response $OffE$ by the power-saving function by Requirement 2 (Table I). We introduce two special responses in theory: the *null* response, denoted by 0 , for the lack of an externally observable output (there might have been an internal state update), and the *illegal* response, denoted by ω , for an operationally unrealizable sequence of inputs (the sequence cannot occur in practice). A sequence is *illegal* if it is mapped to ω ; otherwise, it is *legal*.
- Equivalence declaration. We determine if the sequence is *Moore equivalent* to (and hence can be reduced to) a

TABLE I
REQUIREMENTS FOR THE POWER-SAVING FUNCTION

Tag	Requirement
1	Assume each link exhibits a utilization rate that can vary over time. This rate can be sampled on each cycle and is either high (H), low (L), or zero (Z).
2	Suppose a power-saving machine tries to power down E when the link utilization of both links v and w is low or zero for two consecutive cycles. Any new flows are then routed to F .
3	The machine waits for two consecutive cycles when link w is experiencing heavy load before restoring power to E .
4	The machine is designed such that the attempt to turn E off may have failed or been overridden. Thus it is treated more as a request than a command.
D1	Assume there is an attempt to turn on E at system start/initialization.
D2	Assume that turning on E is also treated as a request than a command.
D3	The latest two cycles’ link utilization for both v and w is necessary to determine if a command needs to be issued to turn on/off E .
D4	Except for at system initialization, an attempt to restore power to E has to follow a recent power off attempt for which no other restore attempt has been made, and only a zero link rate of v and two consecutive high link rates of w have been observed since that power off attempt.
D5	After a recent power off attempt that appears unsuccessful (by a non-zero link utilization of v), another two consecutive cycles of both links v and w being low or zero need to be observed to power off E again.
D6	After a recent power off attempt, if v has been observed of zero utilization it suggests the latest power off attempt might have been successful, but is subject to future observations.

TABLE II
REQUIREMENTS FOR THE LOAD-BALANCING FUNCTION

Tag	Requirement
D1	Assume load is balanced at system start/initialization.
D2	Continued balanced load does not change the (load) balanced state the function is in.
D3	The load-balancing function needs to observe three consecutive cycles of the same imbalanced load patterns before functioning.
D4	If load is observed re-balanced from an imbalanced state, the load-balancing function returns to the (load) balanced state.
D5	If heavy load switches between the two links v and w , the load-balancing function transitions to the corresponding imbalanced state (based on which link has heavy load).
D6	After observing three consecutive cycles of the same imbalanced load patterns (i.e., high w and low/zero v , or high v and low/zero w), the load-balancing function directs load from the heavy link to the light link.
D7	Load-balancing operations are issued based on the most recent three consecutive cycles’ loads only, irrespective of whether the same operation has been recently issued.

previously enumerated sequence. Two sequences u and v are *Moore equivalent* if and only if for any input sequence w , uw and vw always map to the same response by the network function. This implies u and v are mapped to the same response as well (as w could be the empty sequence). For instance, $L_w L_v . L_w Z_v$ can be reduced to the prior sequence $L_w L_v . L_w L_v$ by Requirement 2 for the power-saving function. Two equivalent sequences arrive at the same state of the underlying Moore automaton starting from the initial state. We chose to model it using a Moore machine to be consistent with the transducer model in [3], whereas in software specification *Mealy equivalence* and a Mealy machine are used as they lead

to a shorter enumeration table. One could easily transform between Moore and Mealy machines. When reducing a sequence to a prior sequence, we follow the reduction chain and get to the sequence that is itself unreduced. For instance, $H_w Z_v$ is reduced to $H_w H_v$ and not $H_w L_v$ as $H_w L_v$ is further reduced to $H_w H_v$ (for the power-saving function). A sequence is *reduced* if it is Moore equivalent to a prior sequence in length-lexicographical order; otherwise, it is *unreduced*.

One starts with the empty sequence λ . To get all the sequences of Length $n + 1$ (integer $n \geq 0$) one extends all the sequences of Length n by every stimulus, and considers the extensions in lexicographical order. This inherently combinatorial process can be controlled by two observations:

- If Sequence u is reduced to a prior sequence v , there is no need to extend u , as the behaviors of the extensions are defined by the same extensions of v .
- If Sequence u is illegal, there is no need to extend u , as all of the extensions must also be illegal (i.e., physically unrealizable).

Therefore, only legal and unreduced (also called *extensible*) sequences of Length n get extended by every stimulus for consideration at Length $n + 1$. The process continues until all the sequences of a certain length are either illegal or reduced to prior sequences. The enumeration becomes *complete*. This terminating enumeration length is discovered in enumeration, and varies from application to application.

Excerpt of an enumeration for the power-saving function is shown in Table III. We show the enumeration until Length 3 due to lack of space (the enumeration terminates at Length 4). Columns of the table are for enumerated sequences, their mapped responses, possible reductions to prior sequences under Moore equivalence, and traces to requirements. We similarly performed the enumeration for the load-balancing function, but omitted it here due to lack of space.

3) **Step 3: Construction of the automaton:** We observe that the completed enumeration from the previous step encodes a Moore machine as follows. First we retrieve all the unreduced sequences; each represents a state, whose associated output is the mapped response of the unreduced sequence (that can be read off from the table). Table IV shows the mapping from unreduced sequences in the power-saving enumeration to Moore states of the power-saving automaton. The mapping table for the load-balancing function is omitted here due to lack of space.

With this observation we are now ready to construct the automaton. For doing so, we simply map each row in the enumeration table (except the empty sequence) to a transition in the Moore machine as follows: if the prefix sequence u concatenated with the current stimulus a is reduced to the sequence w (here we treat any unreduced sequence as being reduced to itself; an equivalence relation must be reflexive), then a transition triggered by the input a goes from the state represented by u to the state represented by w . For instance, $H_w H_v . H_w H_v$ being reduced to $H_w H_v$ in the power-saving enumeration implies a transition from State r_0 to State r_0 on Input $H_w H_v$ for the power-saving automaton.

The state machines for both apps constructed in this step are shown in Fig. 2 and Fig. 3. Their equivalent formal definitions

$L_w L_v . L_w L_v . L_w Z_v$	r_3	0

are omitted for lack of space.

V. MODELING JOINT EFFECT OF MULTIPLE SDN APPS

One benefit of using automata to model SDN apps is that, when two SDN apps run in parallel on the same network topology, their behavior can be modeled by the standard automaton product, which can be straightforwardly computed by applying the following definition:¹

Definition 3 (Product of Network Function Moore Machines): Given two network function Moore machines $M_1 = (Q_1, \Sigma_1, \Gamma_1, \delta_1, \nu_1, q_{1,0})$ and $M_2 = (Q_2, \Sigma_2, \Gamma_2, \delta_2, \nu_2, q_{2,0})$, the *product* of M_1 and M_2 , denoted by $M_1 \times M_2$, is defined

¹This operation can be easily extended to more than two SDN apps and performed in a successive way.

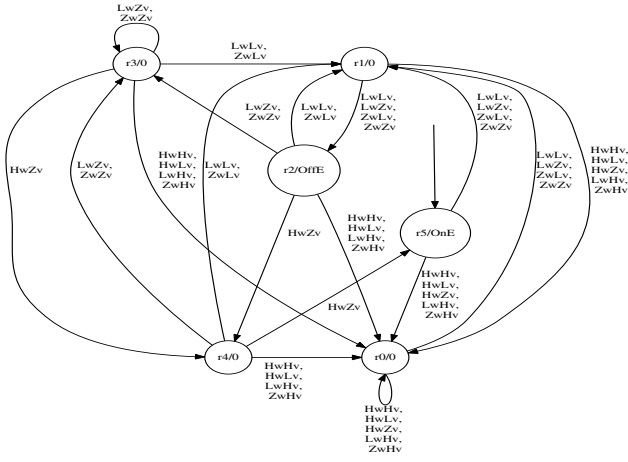

Fig. 2. The Power-Saving Moore Machine

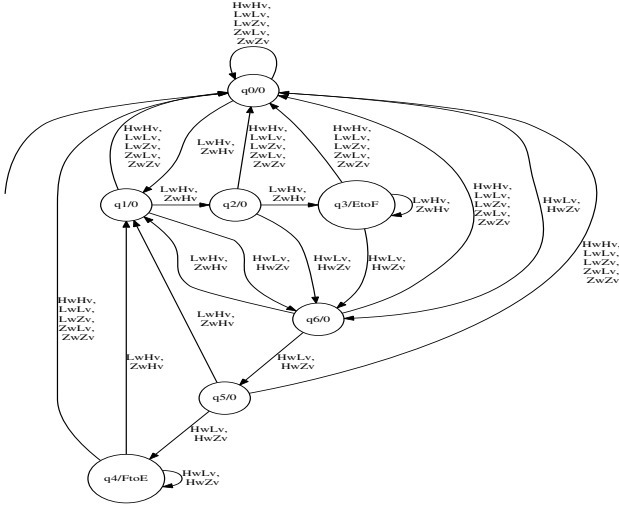

Fig. 3. The Load-Balancing Moore Machine

by $M_1 \times M_2 = (Q_1 \times Q_2, \Sigma_1 \times \Sigma_2, \Gamma_1 \times \Gamma_2, \delta, \nu, (q_{1,0}, q_{2,0}))$, where δ and ν are defined by:

$$\begin{aligned} \delta((p, q), (a, b)) &= (\delta_1(p, a), \delta_2(q, b)), \\ \nu((p, q)) &= (\nu_1(p), \nu_2(q)). \end{aligned}$$

We extend the *null* response and the *illegal* response to the product of two network function Moore machines by assuming $0 = (0, 0)$ and $\omega = (r_1, r_2)$ where either $r_1 = \omega$ or $r_2 = \omega$. An input $(a, b) \in \Sigma_1 \times \Sigma_2$ is *legal* if it is physically realizable; otherwise, it is *illegal*.

Note that we also extend the concept of being legal/illegal to inputs of a product automaton.

Example 4: The product of the power-saving Moore machine M_1 and the load-balancing Moore machine M_2 is defined by $M = M_1 \times M_2 = (Q_1 \times Q_2, \Sigma \times \Sigma, \Gamma_1 \times \Gamma_2, \delta, \nu, (r_5, q_0))$, where δ and ν are defined by:

$$\begin{aligned} \delta((p, q), (a, b)) &= (\delta_1(p, a), \delta_2(q, b)), \\ \nu((p, q)) &= (\nu_1(p), \nu_2(q)). \end{aligned}$$

Observe that $\{(a, a) : a \in \Sigma\}$ is the set of all legal inputs of M .

One interesting observation on the constructed product Moore machine is that not all its states may be reachable from the initial state. Intuitively, for a state (p_j, q_j) in the product Moore machine $M = M_1 \times M_2$ to be reachable from another

state (p_i, q_i) , there must exist paths of the same length from p_i to p_j in M_1 and from q_i to q_j in M_2 .

Definition 5 (Reachable States): Given the product $M = (Q, \Sigma, \Gamma, \delta, \nu, q_0)$ of two network function Moore machines and a set of legal inputs $I \subseteq \Sigma$, the set RS of *reachable states* of M is defined by $RS = \{q : q \in Q, \exists w \in I^*. \hat{\delta}(q_0, w) = q\}$.

This definition enabled us to develop a simple algorithm to automatically identify all reachable states in a product Moore machine, which we omitted here due to space constraint.

Definition 6 (Joint Network Function Moore Machine): Given the product $M = M_1 \times M_2 = (Q, \Sigma, \Gamma, \delta, \nu, q_0)$ of two network function Moore machines M_1 and M_2 , and a set of legal inputs $I \subseteq \Sigma$, let RS be the set of reachable states of M , δ' be δ restricted to $RS \times I$, and ν' be ν restricted to RS : $\delta'(q, a) = \delta(q, a)$, $\nu'(q) = \nu(q)$. Let $\Gamma' = \text{range}(\nu') \cup \{0, \omega\}$, where $\text{range}(\nu')$ denotes the range of ν' . The *joint network function Moore machine* M' of M_1 and M_2 can be defined by $M' = (RS, I, \Gamma', \delta', \nu', q_0)$.

Clearly a joint network function Moore machine satisfies the definition for a network function Moore machine.

Example 7: The joint network function Moore machine M of the power-saving and the load-balancing automata is omitted due to space. Only 13 out of the 42 states of $Q_1 \times Q_2$ are reachable, and included in the joint automaton.

VI. PROPERTY ANALYSIS AND CONFLICT DETECTION

We present analysis of the joint network function Moore machine, which enables detection of control conflicts as well as answers the many questions regarding the network's behavior. Our analysis focuses on three critical and closely related concepts: stable states of a Moore machine, safe operational region of a network, and conflict freeness of SDN apps.

A. Stable States of a Moore Machine

Intuitively, an SDN app enters a stable state, if it no longer attempts to modify the network state (i.e., the network has reached a desirable state from the app's perspective). This intuition can be formally defined using the automaton model. To do so, we extend the output function of a Moore machine to pairs of states and input sequences as follows. $\hat{\nu} : Q \times \Sigma^* \rightarrow \Gamma^*$ is defined by (1) $\hat{\nu}(q, \lambda) = \nu(q)$, and (2) $\hat{\nu}(q, wa) = \hat{\nu}(q, w)\nu(\hat{\delta}(q, wa))$ for all $q \in Q$, $w \in \Sigma^*$, $a \in \Sigma$.

We can now formally define the stable states of a network function Moore machine as follows:

Definition 8 (Stable State): Let $q \in Q$ be a state of the network function Moore machine $M = (Q, \Sigma, \Gamma, \delta, \nu, q_0)$. q is a *stable state* of M iff the following hold for all $a \in \Sigma$:

- (1) $\delta(q', a) = q$ implies $\hat{\nu}(q, a^n) = 0^{n+1}$ for all integer $n \geq 0$, and
- (2) $q = q_0$ implies $\nu(q_0) = 0$.

Informally, two conditions need to be satisfied for a state to be a *stable state*: (1) on any input by which there is an incoming arc to this state, if a sequence of such input continues it will never land on any state that produces a non-null response, which could potentially change this input (i.e., a network state); and (2) the starting state must have the null output to be a stable state.

It is easy to see that this definition enforces any stable state be associated with the null response, as shown by the following theorem (proof is omitted due to lack of space).

Fig. 4. An Example Sequence of Inputs and States for Analyzing the Safe Operational Region

Theorem 9: Let q be a stable state of the network function Moore machine $M = (Q, \Sigma, \Gamma, \delta, \nu, q_0)$. $\nu(q) = 0$.

Example 10: Applying Definition 8, it can be straightforwardly discovered that the constructed power-saving automaton M_1 has two stable states r_0 and r_3 ; the constructed load-balancing automaton M_2 has one stable state q_0 ; and the joint automaton M (Example 7) has two stable states (r_0, q_0) and (r_3, q_0) . We omit the proofs due to space constraint.

B. Safe Operational Region of a Network

Intuitively, a network becomes “stabilized” when none of the SDN apps running on top of it attempts to change its state; that is, all the SDN apps have entered a stable state as defined by Definition 8. Thus we consider a network state to be “safe”, if it can eventually (i.e., after a finite number of state changes) lead to a stabilized network, which guarantees no state oscillation. We term the set of all such safe states of a network to be the *safe operational region* of the network.

Note that a network’s state is already encapsulated in the stimuli (i.e., inputs) of a network function Moore machine. Hence we are able to formally define the concept of safe operational region of a network, as follows:

Definition 11 (Safe Operational Region): Given a network function Moore machine $M = (Q, \Sigma, \Gamma, \delta, \nu, q_0)$, a set of binary relations R_r over Σ for each $r \in \Gamma - \{\omega\}$ such that (1) $R_0 : \Sigma \rightarrow \Sigma$ is the identity function; and (2) $(r \neq 0, aR_rb)$ implies either $\delta(p, a) = q$, $\nu(q) = r$ for some $p, q \in Q$ or $\nu(q_0) = r$, and $x \in \Sigma$, x is in the *safe operational region* iff the alternating sequence of inputs and states $x_1, s_1, x_2, s_2, \dots, x_n, s_n$, in which $x = x_1$, $q_0 = s_1$, $x_{i-1}R_{\nu(s_{i-1})}x_i$, $s_i = \delta(s_{i-1}, x_i)$ for all $i \geq 2$, $\nu(s_i) \neq \omega$ for all $i \geq 1$, ends with some stable state s_n of M . The *safe operational region* of the network is the set of all such x ’s.

The set of binary relations R_r over I define how each output of an SDN app modifies the status of the network (notice that the null response does not modify the network status, as indicated by the identity function). Informally, a network state, as encapsulated in the input x , is in the safe operational region if and only if a stable state of the Moore machine will always be reached when starting from the initial state of the Moore machine with the input x . At that point the network state will no longer be changed by the running SDN app(s). Fig. 4 illustrates an example sequence of inputs and states that need to be examined from the initial state q_0 with a specific input (say x).

Example 12 (Safe Operational Region of Example Network): Applying Definition 11 on the joint automaton as defined in Example 7, it can be computed that the safe operational region of the example network (Fig. 1) includes H_wH_v , L_wZ_v , and Z_wZ_v . We omit the algorithm here due to lack of space.

C. Conflict Freeness of SDN Apps

An SDN network is free of conflict, if starting from any state it can eventually become stabilized; that is, every possible network state is in its safe operational region. We have the following formal definition:

Definition 13 (Conflict-Free SDN apps): Two or more SDN apps are *conflict-free* if and only if their joint network function Moore machine has the set of inputs identical to the safe operational region of the network.

Note that Definition 13 not only enables direct detection of potential conflict, but also precisely specifies under what network condition such conflict will arise.

Example 14 (Conflict in the Example Network): Applying Definition 13, we immediately see that the two SDN apps running on the example network are not conflict-free: this is because a subset of inputs to the joint network function Moore machine including H_wL_v , H_wZ_v , L_wH_v , L_wL_v , Z_wH_v , and Z_wL_v , is left out of the safe operational region.

VII. CONCLUSION AND FUTURE WORK

We presented a theoretical framework, based on rigorous software specification, for detecting conflicts caused by running multiple SDN apps in parallel. Our future work includes experimental validation and further investigation on the scalability and applicability of the framework.

Abstract

Context: Code smells are associated with poor design and programming style that often degrades code quality and hampers code comprehensibility and maintainability.

Goal: In this paper, we investigated to which extent classes affected by the God Class and Long Method code smells were more susceptible to the occurrence of software bugs.

Method: We conducted an exploratory study targeting two well known open source software projects, Apache Tomcat and Eclipse JDT Core Component. We applied correlation analysis in order to evaluate to which extent Long Method and God Class were related to the occurrence of bugs.

Results: We have found a significant correlation of Long Method and Commits and, on the other hand, a poor correlation of God Class and Commits in the two analyzed projects. Therefore, we expected that the higher the number of occurrences of Long Method, the higher the chances of more commits in a class that contains this method, which could result in the increase of occurrence of bugs.

Conclusion: Based on the results, we confirmed what other studies pointed out, regarding classes affected by Long Method being more bug-prone than others. In practice, we found evidence, from analyzed data, that the occurrence of Long Method implies more effort in maintenance tasks.

1 Introduction

Throughout releases, a software project usually includes new functionalities and fixes bugs that were found and considered relevant in previous releases. Since maintenance costs are the highest share in the development lifecycle [1], special attention should be dedicated to avoid bugs.

Martin Fowler, in his book on software refactoring [2], claimed that code smells can negatively impact software quality, namely on its understandability and reliability. For more than a decade after that, several authors have claimed

that the empirical evidence of such impact was still scarce [3, 4, 5] and, as such, Fowler's claim could not be considered as fully confirmed. Among the 22 code smells presented in Fowler's book, we selected *God Class* and *Long Method* to provide further evidence of their influence on software bugs occurrence. The former refers to classes that centralize the intelligence of the system, realizing too much work, when compared with the remainder classes, while the latter refers to methods with many statements and/or complex control flow structures [6].

To reach our stated research objective, we analyzed two projects, Apache Tomcat and Eclipse JDT Core Component. Tomcat is a "pure Java" HTTP web server environment in which Java code can run. JDT (Java Development Tools) Core Component is the Java infrastructure of Eclipse's Java IDE. We have chosen these two projects because they: (i) are open source; (ii) have a prominent popularity in the Java community; (iii) have been studied in the literature by several authors [7, 8, 9]; (iv) are related in the scope of this study.

Regarding the last reason, we found the relationship in their bug repository: 51 closed bugs from Apache Tomcat are related to the Eclipse project. These bugs were reported in classes affected by *God Class* or containing methods affected by *Long Method* in the following releases analyzed in this study: 9_0_9 of (Apache Tomcat) and Y20180725-2200 (Eclipse JDT Core). Moreover, we have also noticed that 36 bugs out of those 51 were reported in classes simultaneously affected by both code smells in those releases. Hence, we considered that the influence of the aforementioned code smells in the selected software projects deserved further analysis.

The remainder of this paper is laid out as follows. Section 2 overviews previous related research work. The experimental design of our study is presented in Section 3 and Section 4 discusses its results. Finally, in Section 5, we present concluding remarks and future work.

2 Related Work

Lehman’s second law of software evolution [10] argues that as a project grows, software complexity increases as well. Constantly changing code is the context in which code smells find favorable conditions to arise. Studies have reported that code smells usually affect a software entity, such as class or method, after a change executed to fix a bug [11]. To tackle this problem, several approaches have been proposed to support the identification of code smells, as described in secondary studies such as the ones conducted by Rasool and Arshad [12] and Fernandes et al. [13].

According to [14], code smells are indicators of poor source code quality and hamper its maintenance and reuse. The influence of the *God Class* and *Long Method* code smells on software bugs occurrence has been studied by several authors. Li and colleagues [15] reported the influence of *Shotgun Surgery*, *God Class*, and *God Method* code smells on bugs based on the analysis of post-release system evolution. They confirmed that some smells were positively associated with the class error probability in three error-severity levels (High, Medium, and Low), usually applied to classify issues. In [16], the authors unveiled the relationship among *Shotgun Surgery*, *God Class* and *God Methods* code smells and the occurrence of bugs in three Eclipse releases (3.0, 2.1 and 2.0). Olbrich and colleagues [17] presented evidence that instances of *God Class* and *Brain Class* suffered more frequent changes and contained more defects than classes not affected by those smells.

Later, Nascimento and Sant’Anna [18] analyzed five software projects (Apache Ant, Apache Jmeter, Apache Lenya, Apache Tomcat and Apache Xerces) to conclude that classes affected by the code smells *Data Class*, *Data Clumps*, *Feature Envy*, *God Class*, *Message Chain*, *Schizophrenic Class* and *Tradition Breaker* had a higher likelihood to introduce bugs than other classes from the same project. They further reported *God Class* as the smell with the greatest number of related bugs in the analyzed projects with a percentage of 20%, followed by *Feature Envy* with a percentage close to 15%, *Schizophrenic Class* with 9% and *Message Chains* with 7%. In addition, Palomba and colleagues [8] claimed that classes with code smells tend to be more change- and fault-prone than other classes and that this is even more noticeable when the same class is affected by multiple smells.

A recent systematic literature review conducted by Cairo and colleagues [19] claims that there is evidence in the literature showing that software entities, such as classes affected by code smells, tend to be more prone to change and failure than other classes.

3 The Experimental Design

This section describes the characteristics and steps applied in this exploratory study. We adopted the Goal-

Question-Metric (GQM) approach [20], as described in Table 1, to derive the following **Research Question (RQ)**: To which extent *God Class* and *Long Method* code smells influence the occurrence of bugs in Apache Tomcat and Eclipse’s JDT Core Component projects?

Table 1: Research goal based on the GQM approach

Analyze	the <i>God Class</i> and <i>Long Method</i> code smells
for the purpose of	evaluating their influence
with respect to	the occurrence of bugs
from the viewpoint of	maintainers and developers
in the context of	Apache Tomcat and Eclipse’s JDT Core Component open source software projects

To reduce the collection time and the frequent errors that arise during code smells manual detection [21], we used the PMD static code analyzer. We performed the six steps represented in Figure 1 that will be further detailed in the following paragraphs, using a common template (data input, step description, performing the step, data output).

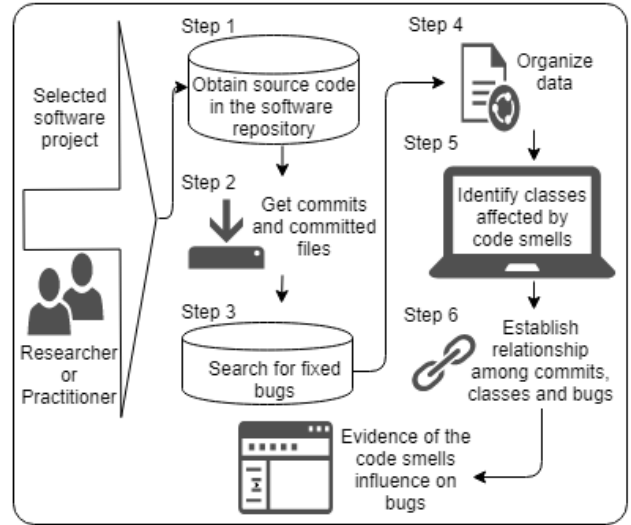

Figure 1: Proposed approach to analyze the influence of code smells on bugs occurrence in a software project

3.1 Step 1 - Obtain source code

Data input: URL of selected software projects repository.

Step description: We cloned the sources of each selected software project using Git Bash, a Windows application which provides a Git command line shell.

Performing the step: We executed the `git clone` command.

Data output: Local repository containing the source code of selected software projects.

3.2 Step 2 - Get commits and corresponding files

Data input: GitHub features that allow the collection of data related to commits performed in a software project.

Step description: We executed the command lines 1 and 2 presented below using Git Bash. Besides commits, we also collected the files involved in each commit.

Performing the step: Execute the commands as follows:

(1) `git log --pretty=format:"%H %h %an %ad %s" --grep="bug" > log-commit.txt` (stores the names of all files involved in each commit in the named file)

(2) `git show hash-numbers --pretty=format: "%H" --stat > log-arquivos.txt` (stores all commit hashes in the named file)

3.3 Step 3 - Search for fixed bugs

Data input: Bugzilla features that allow the collection of data related to bugs of a specific software project.

Step description: Identify all bugs marked as *closed* for all analyzed software projects.

Performing the step: We collected all closed bugs for Apache Tomcat until August 8th (2018) and for Eclipse until September 9th (2018). We used the Bugzilla's REST API to obtain data from the projects' repositories.

Data output: Files containing information related to bugs in JSON format from the analyzed software projects.

3.4 Step 4 - Organize data

Data input: Data about commits and bugs for each project.

Step description: We tabulated raw data to prepare them for statistical analysis.

Performing the step: All data was inserted in a database and we applied queries to get it organized in table format. After that, we exported them to a spreadsheet for applying statistical analysis. An automatic routine was implemented to capture the ID from Bugzilla repositories. Only Java files were considered and all others (e.g. configuration files) were deleted, since only the former were relevant for code smells detection. We also did not consider commits in files not related to code smells. Some long absolute paths to Java classes were incomplete, such as, for instance in `"/.../apache/catalina/connector/CoyoteAdapter.java"`. In those cases, we searched manually for the file and completed the correct absolute path string, being careful in cases of multiple files with the same name, located in different packages.

Data output: Commit data, file involved in each commit, and bugs of each project.

3.5 Step 5 - Identify classes affected by code smells

Data input: Source code of projects cloned in step 1.

Step description: We used the PMD tool to collect information about code smells.

Performing the step: The PMD tool was applied in each project to detect *God Class* and *Long Method* occurrences.

Data output: A table containing all software project classes

affected by *God Class* and *Long Method*, and the number of occurrences of each code smell, for each class.

3.6 Step 6 - Evidence of code smells influence on bugs

Data input: Each line of tabulated data contains software project name, version, absolute path of Java class, class name, occurrences of *Long Method*, occurrences of *God Class* and total amount of commits involving both projects.

Step description: We performed statistical analysis on available data to check the intensity of correlations among code smells and bugs.

Performing the step: Since the data was not normally distributed, we used the Spearman non-parametric correlation coefficient to check the correlation among the occurrences of each code smell and the amount of commits. We grouped the commits in ranges to check the correlation. *Data output:* Intensity of correlation among code smells occurrences and amount of bugs, represented by commits.

4 The Study Results

4.1 Distribution adherence testing

All data used in this analysis is available in a public Github repository¹. The total number of classes analyzed with at least one commit are 1049 and all those classes have at least one code smell. The first step of a statistical correlation analysis is to verify whether the data is normally distributed. This verification allows the selection of the most suitable statistical technique to be applied. We used the EasyFit tool² to perform the aforementioned verification. The results pointed out that the occurrences of *Long Method* and *God Class* have Poisson Distribution and the amount of commits has Geometric distribution. Since none of them has a normal distribution, that required the application of a non-parametric correlation coefficient such as Spearman's.

4.2 Correlation analysis by commit ranges

The main research question stated in Section 3 aimed at devising to which extent *God Class* and *Long Method* code smells influence (or have impact in) the occurrence of bugs in two open source projects. In this study we only considered bugs that were fixed and took as surrogate of those bugs the number of file (class) commits they cause. Therefore, the research question originated two sub-questions, one per each code smell, where we want to check if there is a statistical significant association among the variables that allow us to not discard that the aforementioned impact exists. In other words, the sub-questions are:

a) *Is there a correlation between the occurrences of Long Method in a class and the amount of commits in that class?*

¹<https://github.com/SEKE2019CodeSmell/SEKE2019EvidenceCodeSmells>

²<http://www.mathwave.com/>

b) Is there a correlation between the occurrences of *God Class* in a class and the amount of commits in that class?

To answer those questions, while eliminating some random deviations that might have occurred in collected data, we grouped the analyzed classes by consecutive ranges of 3 commits. Therefore, the first range contains classes with commits within the $[0, 3[$ range, the second in the $[3, 6[$ range, and so forth, as represented in the first two columns in Tables 2 and 3 for the Apache Tomcat and Eclipse JDT Core Component, respectively. For instance, the values of 130 and 279 on the first line of column II of the same tables represent the total number of classes with 0, 1 or 2 commits (range defined in column I) in the two analyzed software projects. We have also normalized the amount of class commits, occurrences of *Long Method* and *God Class*, by calculating their average value per class. The column labels of Tables 2 and 3 are as follows:

(I) Commit range (\geq and $<$, respectively)

(II) Class total

(III) Commits Sum

(IV) Long Method Total (occurrences)

(V) God Class Total (occurrences)

(VI) Code Smells Total (occurrences)

(VII) Average Commits Per Class

(VIII) Long Method Average (occurrences) Per Class

(IX) God Class Average (occurrences) Per Class

The highlighted lines in Tables 2 and 3 represent the data that we considered as relevant. The classes with commits above the 57-60 range were clear outliers and were ignored in the following study. To confirm this claim, we generated dispersion charts (Figures 2 and 3) to visually check the distribution of data in the ranges. The *Long Method* chart provides some evidence of correlation, because the points are around the tendency line and increasing, meaning a positive correlation. Furthermore, it is possible to obtain a curve with even better fit (as measured by the R squared coefficient of determination), what suggests that the effect of this code smell on commits may be non-linear. As for the *God Class* the chart does not provide evidence of correlation. After determining the valid data, without irrelevant lines and outliers, we calculated the Spearman correlations. The results are presented in Table 4.

To interpret the values of the coefficients in Table 4, we used the ordinal intensity scale presented in Table 5 (from [22]). Therefore, based on the obtained values of the Spearman correlation coefficient in Table 4, we can state that there is a *very high positive correlation* between *Long Method* Average and Commit Average. Consequently, that result allow us to raise the hypothesis that the number of commits in a class may be impacted by the occurrences of the *Long Method* code smell. The same cannot be claimed for the *God Class* code smell, since only a moderate positive correlation was observed. For the Eclipse project, we

...
90	93	0	0	0	0	0	0,00	0,00	0,00

have a high positive correlation for *Long Method* Average and Commit Average, and for *God Class* Average and Commit Average. Those correlations in the Eclipse project are lower than in the Tomcat project, even though both projects presented a significant correlation. When we consider both projects together, the results keep in-between, as expected.

4.3 Answering the research questions

As discussed in section 4.2, our main research question was split in two, each regarding the association between the occurrences of one code smell and the corresponding commits. Considering the observed high correlation, we cannot refute the hypothesis that the number of occurrences of *Long Method* may have a positive impact on the amount of commits. As for the *God Class* code smell, due to the observed moderate to low positive correlation, we have to say it the other way round: we cannot sustain the hypothesis that the number of occurrences of *Long Method* may have an impact on the amount of commits.

4.4 Threats to Validity

We are aware of the limitations of correlational analyses such as the used in this study. For this reason, we dubbed this paper as an *exploratory study*. The evidence raised basically allows to stand or discard hypotheses that must be tested, preferably with controlled experiments. The conclu-

87	90	1	89	0	0	0	89	0,00
90	93	0	0	0	0	0	0,00	0,00

sion validity is related to the ability to draw significant correct conclusions. For this reason, we applied the distribution adherence testing and the correlation analysis by commit ranges based on dispersion charts to support the analysis. We discussed the internal validity in terms of threats to the design of the study. For this reason, we managed to carefully plan the study and the variables to consider in the analysis as described in the six steps presented in Section 3. The use of the PMD tool for collecting code smells can be also a potential threat, since several authors have pointed out the inherent subjectivity in the code smells definition [23] can lead to unmatched detection, when using different tools. We expect to mitigate this last problem through our ongoing research work on the Crowdsourcing approach [24]. The external validity represents the possibility of generalizing the findings of this study. We identified external validity threats in our results, since the analysis was restricted to data from two open source software project systems, implemented in one programming language and focusing on two code smells from the catalogue published in [2]. However, the fact that these two open source software projects have an active community is an evidence of the representative-

Figure 2: Dispersion Chart between Average Commits and Long Method Average occurrences (both projects)

Figure 3: Dispersion Chart between Average Commits and God Class Average occurrences (both projects)

ness of these projects to support the conclusions drawn is this study for the analyzed code smells implemented in the Java language.

5 Conclusions

In this paper, we conducted an exploratory study upon two open source projects (Apache Tomcat and Eclipse JDT Core Component), in order to check if the occurrences of the *Long Method* and *God Class* code smells were associated to software defects (bugs). The PMD tool was applied to gather those code smells from all classes of those projects where code fixes occurred. The REST API of the Bugzilla tool was used to identify which were the files affected by code fixes (i.e. those where commits occurred during code fixing), by collecting data related to all closed bugs of those projects. We applied the Spearman correlation coefficient to evaluate the association between average values (per class) of a) occurrences of *Long Method* and observed commits; b) occurrences of *God Classes* and observed commits; and c) occurrences of both code smells and observed commits. We obtained a strong correlation of *Long Method* and Commits and revealed a poor correlation of *God Class*

Table 4: Spearman correlations (code smells vs commit ranges)

Project	Long Method average vs Commit average	God Class average vs Commit average
Tomcat	93%	52%
Eclipse	72%	30%
Both	85%	33%

Table 5: Interpreting the Correlation Coefficient [22]

Correlation	Interpretation of correlation
90% to 100%	Very high positive (negative)
70% to 90%	High positive (negative)
50% to 70%	Moderate positive (negative)
30% to 50%	Low positive (negative)
0% to 30%	Negligible correlation

and Commits, regarding both projects analyzed. Therefore, the higher is the number of *Long Method*, the higher is expected to be the number of commits in a class, although the effect is probably non-linear. In practice, we got strong evidence in those datasets that the occurrence of the *Long Method* may make the maintenance process harder, so we should avoid it through refactoring operations.

Abstract—Bug reports can be lengthy due to long descriptions and long conversation threads. Automatic summarization of the text in a bug report can reduce the time spent by software project members on understanding the content of a bug report. Our work further examines Rastkar et al.'s use of a logistic regression model to determine which sentences from the text of a bug report should be extracted for creating a summary. Using their publicly available bug report corpus, which contains manually annotated bug reports, we examined two aspects regarding the features used by the model. First, we examined how much of a reduction occurs in the precision and recall if some of the more complex features are not used. Second, we examined how the use of different feature combinations affects the precision and recall of the models. We found that the absence of some of the complex features resulted in a modest decrease in precision and recall, and confirmed that some features, such as sentence length, were the most significant features for bug report summarization.

Index Terms—Bug reports, text summarization, software engineering, natural language processing

I. INTRODUCTION

Bug reports¹ are useful software project artifacts that contain information about problems occurring in the past, discussion of possible or implemented solutions, and who contributed to these solutions. Bug reports contain a variety of textual information including a title, description, and comments [1]. The number of sentences in a bug report can vary widely, with some bug reports containing relatively few sentences (around 20) and some having over 50 sentences.

Bug report triage is an important software maintenance task where a project member examines each bug report and makes decisions about how the report will be handled [1]. Examples of bug report triage decisions include determining the quality, priority or severity of the report, assignment to a developer, validation of the report, and identification of duplicate reports. As software projects receive many bug reports each day [2], to effectively triage a new bug report, the person performing triage, called a *triager*, needs to understand the content of the new bug report, as well as previous bug reports. If a bug report

is long (i.e. a long description and/or many comments), the triager needs to spend a significant amount of time reading and understanding the content. Presenting a summarized version of a bug report has been proposed to reduce the time taken by triagers in examining new or existing bug reports and has been shown to reduce the time for understanding the content without necessarily reducing the meaning of the original bug report [3], [4]. By reading the summarized version, a triager could more quickly triage a bug report, such as determining whether it is a duplicate of an existing bug report or whether it needs to be fixed. Bug report summarization can also benefit developers, as they could quickly get an overview of how a particular or related problem was handled in the past.

As the content of a bug report is primarily free-form text, natural language processing techniques, specifically those for text summarization, are used [3], [5]. There are two types of text summarization techniques: abstractive and extractive. Abstractive summarization requires understanding the content of the document and paraphrasing the content in such a way that the meaning is preserved. Extractive summarization selects sentences from the document that reflect the overall meaning of the document [6]. Text summarization uses both statistical and linguistic techniques to find the meaning and importance of a text.

Rastkar et al. [3] presented an extractive approach to bug report summarization that appears to work well. Their approach selects sentences to be extracted from the bug report based on a variety of features and a linear regression model. However, some of the features used in their approach are non-standard (e.g. clue word score), and extracting those features is complex. In this work, we investigate whether reasonable extractive summaries of bug reports can be created without the use of the complex features, and how the different features contribute to the creation of a reasonable extractive summary.

We begin by presenting an overview of previous bug report summarization work. We then present an overview of the data set and the extractive bug report summarization technique used in our investigation. Next, we describe how the summarizer was evaluated and the results of our investigation. We conclude the paper with a discussion of our findings.

¹We use the general term 'bug report' to refer to any software project artifact which is used for tracking project work such as feature requests, change requests, and tasks descriptions.

II. RELATED WORK

We present in this section an overview of previous work related to bug report summarization.

Murray and Carenini [7] proposed an approach for extracting four types of features to summarize email and meeting conversation data. The extracted features were related to the length and the structure of the sentences, the lexical weights based on the conditional probabilities of each word's appearance, and the participants of the conversation.

Rastkar et al. [3], [8] observed that comments in bug reports were similar to the conversation structure found in emails and meeting transcripts. Therefore they used the same feature extraction techniques as Murray to train a logistic regression model to classify sentences as being included in an extractive summary or not. They created an annotated bug report corpus for their investigation².

Lotufo, Malik, and Czarnecki [4] conducted a study of automatic, unsupervised bug report summarization that took a different approach than Rastkar et al.. Instead of using gold standard summaries, their study considered the similarity between a sentence and the bug report title, the similarity between two sentences, and the use of a heuristic to measure the agreement of two sentences. These characteristics were used to compare the quality of generated summaries. This approach led to a more generalized approach to evaluating bug report summaries.

Mani et al. [5] also proposed an unsupervised approach to text summarization. Instead of using the gold standard summaries, they used well known general purpose textual summarizers to create bug report summaries. However, they found that these summarizers only worked well when there was no noise present in the bug reports. To reduce the noise, they used heuristics to categorize text as being either a question, an investigative sentence or a code snippet.

III. BUG REPORT SUMMARIZATION

As previously stated, the goal of our study is to investigate the use of different features for extractive summarization of bug reports as presented by Rastkar et al. [3]. They categorized the 24 features into four sets: sentence length, lexical features, structural features and features related to the participants of the conversation in the bug report. As Rastkar et al. found that the F-score statistics of the structural and participant-related features have low variability, we focused our study on the length and lexical features. We also chose to remove the complex features of clue-word-score and those related to sentence entropy to investigate how extractive summaries selected without the use of these features compare to manually created summaries. In short, we investigated the use of two sentence length features, six conditional probability scores and four cosine similarity scores. The details for these features are explained in the following two sections.

²<https://www.cs.ubc.ca/cs-research/software-practicelab/projects/summarizing-software-artifacts> verified 09/12/2018

A. Data Source

We used the bug report corpus created by Rastkar et al. [3] in our investigation. The bug report corpus consists of thirty-six (36) bug reports extracted from four open source software projects: Mozilla³, KDE⁴, Eclipse⁵ and Gnome⁶. Each bug report in the corpus has a title which indicates from which software project it comes. Each bug report's comments are given in a format such as that of two or more people taking turns when having a conversation. Therefore, each comment is considered a *turn* and each turn has the participant's name, the time when the conversation started, and the text of the individual sentences from the entire comment. Each bug report has two or more people participating in the conversation. Bug reports are stored in an XML format, each identified by a unique number.

The corpus also contains annotations made by three different annotators for each comment indicating whether the sentence should be included in an extractive summary. Following the procedure given by Rastkar et al. [3], we created gold standard summaries (GSS) for each bug report by including a sentence in the extractive summary if at least two annotators indicated it should be included in the bug report summary.

B. Extracted Features

1) *Sentence Length*: The two sentence length features extracted from each bug report comment are SLEN and SLEN2. SLEN is the length of a sentence normalized by the length of the longest sentence in all of the comments in the bug report. SLEN2 is the length of a sentence normalized by the length of the longest sentence in the specific bug report comment.

2) *Lexical*: In our investigation, ten lexical features were extracted from each sentence in a bug report comment. These lexical features are based on two different conditional probabilities known as S_{prob} (for sentence probability) and T_{prob} (for turn probability).

Equation 1 defines S_{prob} . Given a term t by a person making a comment, S_{prob} is calculated by finding the maximum probability of that term's appearance in sentences from all of the comments S . For example, assume there are three commenters for a bug report: A , B and C . If A used the word w_1 seven times, B used w_1 twice and C used w_1 once, then the maximum probability of w_1 is 0.7, and all instances of w_1 in the bug report receive 0.7 as their S_{prob} weight.

$$S_{prob}(t) = P(S|t) \quad (1)$$

Equation 2 defines T_{prob} . Given a term t by a person making a comment, T_{prob} is calculated by finding the maximum probability of that term's appearance in a comment T . For example, if a bug report has five comments and the word w_2 appears eight times in one comment, twice in another comment, and in no other comments, then $T_{prob}(w_2)$ is 0.8.

³bugzilla.mozilla.org, verified 09/12/2018

⁴bugs.kde.org, verified 09/12/2018

⁵bugs.eclipse.org/bugs, verified 09/12/2018

⁶bugzilla.gnome.org, verified 96/12/2018

$$T_{prob}(t) = P(T|t) \quad (2)$$

Using each conditional probability weight we calculated three sentence level conditional probability features for the sum of weights, maximum weight and mean of weights. For S_{prob} the features calculated were named as SMS, MXS and MNS for sum, max and mean respectively. Similarly, for T_{prob} the names were SMT, MXT and MNT.

We calculated four cosine similarity scores for each sentence using S_{prob} and T_{prob} as the word encoding. COS1 and COS2 represent the sentence wise cosine similarity using S_{prob} and T_{prob} respectively. CENT1 and CENT2 represent the similarity of a sentence to the entire conversation using S_{prob} and T_{prob} respectively.

C. Bug Report Summary Creation

A logistic regression model was used to train a recommender which classifies each sentence from the bug report comments as appearing or not appearing in the extractive summary. The Python `sklearn` package was used to implement the sentence classifier. Various logistic regression models were trained to test the effect of the individual feature types and the combined effect of the length and lexical features regarding the performance of the classifier.

Following the procedure outlined by Rastkar et al., a bug report summary was created by selecting the sentences with the highest probability of being included in the extractive summary according to the classifier until the word count of the constructed summary reached 25% of the original bug report's word count.

IV. EVALUATION

To compare our model with Rastkar et al. [3] we trained a logistic regression model using our twelve selected features. We also investigated the effect of using only one of the two feature categories and different feature combinations. To investigate the effect of different feature combinations, we paired similar features into six groups (length, sum, max, mean, cos, cent) and created logistic regression models with combinations of the different groups. For example, choosing one group at a time creates six models (i.e. $\binom{6}{1}$) and choosing two groups at a time creates fifteen models (i.e. $\binom{6}{2}$). We created a total of sixty-two (62) models by choosing all combinations of the six groups (i.e. $\binom{6}{1}$ to $\binom{6}{5}$).

We used the metrics of precision, recall and F-score to evaluate the different models.

Precision measures how many of sentences in the extractive summary were correct. It was calculated as the total number of sentences correctly classified as being in the extractive summary divided by the total number of sentences in the extractive summary.

$$Precision = \frac{\# \text{ of sentences correctly selected}}{\text{total \# sentences in the summary}} \quad (3)$$

Recall measures how close the generated summary is to the GSS summary. It was calculated as the total number of sentences correctly classified as being in the extractive summary divided by the total number of sentences which appeared in the GSS summary.

$$Recall = \frac{\# \text{ of sentences correctly selected}}{\text{total \# sentences in GSS summary}} \quad (4)$$

The F-score value is the harmonic mean of precision and recall.

$$F - score = \frac{2 \times precision \times recall}{precision + recall} \quad (5)$$

As we used a leave-one-out cross-validation approach to evaluate each model, we received thirty-six (36) data points for the precision and recall of each model. We applied a post-hock pairwise statistical test⁷ to determine if there was any statistically significant variation between the models.

V. RESULTS

In this section, we present a comparison of our extractive summarization approach with Rastkar et al.'s, the results of our investigation of using only sentence or lexical features, and the results of our investigation of combinations of our selected features.

A. Comparison to the Previous Approach

When we compare the results of our logistic regression model with a 25% threshold with that of Rastkar et al.'s, we found that our model has an average precision and recall that is less than theirs (Table I). However, this decrease is to be expected, given that fewer features are used in our model.

Our comparison with Rastkar et al.'s approach prompted us to further examine the contribution to extractive summarization of the individual features and their combinations.

TABLE I
COMPARISON OF OUR RESULTS WITH RASTKAR'S RESULTS

	Our model	Rastkar's model
Precision	44%	57%
Recall	24%	35%
F-Score	29%	40%

B. Feature Categories

We examined the use of only sentence length features and only lexical features for creating an extractive bug report summarizer.

It was found that when using only the sentence length features (SLEN and SLEN2), the classifier had an average precision of 60% and the recall was found to be very low at 18%.

Using only the lexical features (SMS, MXS, MNS, SMT, MXT, MNT, COS1, COS2, CENT1, CENT2), we found that

⁷Statistical analysis was conducted using R 3.5.1.

the recall improved to 22%, but the precision declined to 42%. The model which combined both the length and lexical features had a precision of 44% and a recall of 24%. As shown in Table II, the F-score was found to improve from 27% to 30% after adding the lexical features.

TABLE II
AVERAGE PRECISION, RECALL AND F-SCORE VALUE OF LEAVE-ONE-OUT
CROSS VALIDATION FOR CLASSIFIERS WITH 25%.

Feature set	Precision	Recall	F-Score
Length	60%	18%	27%
Lexical	42%	22%	27%
All	44%	24%	29%

C. Feature Combinations

To understand the combined contribution of the features and to discover if there was a difference in the performance if we chose different combinations of features, we created sixty-two (62) different models by choosing different group combinations.

When testing for significance in the differences between combinations of features, only the sentence length features in $\binom{6}{1}$ were found to be significant. The p-values for these comparisons are shown in Table III.

TABLE III
SIGNIFICANCE OF DIFFERENCE IN THE PRECISION FOR $\binom{6}{1}$.

Feature combinations	p-value
SLEN-SLEN2 vs. CENT1-CENT2	0.0062577
SLEN-SLEN2 vs. COS1-COS2	0.0004581
SLEN-SLEN2 vs. MNS-MNT	0.0013389

VI. DISCUSSION AND CONCLUSION

In our study, we focused on two types of features: sentence length and lexical features. According to Rastkar et al. [3] SLEN was one of the most important features when training an extractive bug report summarizer because of its high variability. Two lexical features SSM and TSM and the sentence length feature SLEN2 were also considered important. However, they also felt that all 24 features contributed to the overall performance of their model regardless of some of the features having less variability. Our results seem to corroborate this belief with our statistical analysis for different feature combinations, finding no statistically significant difference in performance when adding or removing features.

In training the logistic regression model with the sentence length and lexical features, we found that lengthy sentences often contained useful information needed to create a good summary. This is consistent with the literature which states that the sentence length is used to eliminate short sentences from the summary that do not contain useful information, such as author names or code extractions [9]–[11]. However, we also found that only using the length of the sentence was not enough to capture all of the useful sentences, as

selecting longer sentences resulted in quickly reaching the word percentage threshold. Our results for the use of lexical features also show that the recall is higher when the length is not considered, as the classifier selects more of the shorter sentences thereby increasing the recall.

Finally, as we are taking a supervised learning approach to summary creation, the results are sensitive to the summaries found in the GSS. When comparing the word count of the summaries in the GSS for each bug report, we found that some summaries had a word count of more than 50% of the original bug report's word count. As we used a word count threshold of 25% of the original bug report's word count for the summaries, our model is unlikely to choose all the sentences found in the GSS summary for some of these summaries and this results in a low recall for the trained models.

We plan to further explore the use of the more complex features that have high variability and were not included in this study, namely clue-word score and those related to sentence entropy.

Generating Integration Tests Automatically Using Frequent Patterns of Method Execution Sequences

Mark Grechanik

Abstract—Integration testing is vitally important for ensuring software quality, since many serious software defects are not isolated in single components. Unfortunately, creating integration tests is often a manual and laborious effort. A fundamental problem of software testing is how to automatically create effective integration tests with oracles that find bugs efficiently.

We created a novel approach for *Automatically Synthesizing Integration Software Tests (ASSIST)* that automatically obtains models that describe frequently interacting components in software applications, thus reducing the number of synthesized integration tests and increasing their bug-finding power. In ASSIST, static and dynamic analyses are used along with carving runtime states to obtain test input data as well as oracles for the synthesized integration tests. We experimented with three Java applications and show that integration tests that are synthesized using ASSIST have comparable bug finding power with manually created integration tests.

Index Terms—software testing, pattern mining, execution trace

I. INTRODUCTION

Many companies have adopted agile development [20], in particular continuous delivery where software is tested and released frequently, at the end of each delivery iteration. In continuous delivery, it is important to test integrated software components at the end of each short-term (i.e., ten day) iteration [21, pages 55-82]. In fact, integration testing has emerged as a major testing approach for agile and distributed software development [25], since the majority of serious software defects are no longer isolated in single components and many catastrophic problems occur in interactions among different components [23].

In *integration testing*, integrated software modules or components are evaluated as a whole to determine if they behave correctly [2, page 6] [4, page 21]. For object-oriented software, integration tests invoke methods that belong to different classes, which exchange data as a result of these invocations [11]. *Acceptance testing* is a kind of integration testing where many components of the application are integrated to implement some requirements [4]. At an extreme, *big bang testing* is an example of the coarsest granularity of the acceptance testing, where the entire application is assembled and tested in one step [33], however, its usefulness is limited, since a single debugging task is impractical [37, Section 7.2].

Executing acceptance and big-bang tests takes significant resources and time, since they require comprehensive and laborious installation and configuration of the *application under test (AUT)* on a testbed, and each run of these tests may take tens of minutes or hours, depending on the functionality of the AUT. Naturally, acceptance and big-bang tests are run on testbeds during major software releases, however, it is impractical to do so during and at the end of the short-term agile iterations. Clearly, finer granularity integration tests are required that are coarser than *unit tests*, where implementations of methods that belong to the same class are tested individually [4], [26]). Combining two or more methods that belong to different classes is an example of an integration test of a finer granularity that are needed for agile iterations [27]. Given that developers routinely make small incremental changes to applications to fix bugs and modify their functionalities, finer granularity tests are needed to verify that the AUT behaves as desired during and at the end of the agile iterations.

The larger the project, the more important integration testing is to find bugs efficiently in integrated components of an application [37]. Unfortunately, it is expensive, since the average cost per finding and fixing a defect is currently the highest for integration and acceptance testing [23]. This cost increases approximately by anywhere from five and up to twenty times if a defect is missed during integration testing and found at a later stage [15]. Creating effective integration tests requires significant time and effort, since it is not feasible to test all combinations of components in a software application, and the number of these combinations is enormous for nontrivial applications [5], [17]. Despite these difficulties, the demand for integration tests is high, since they are reported to have a higher defect removal efficiency when compared with other forms of testing (e.g., unit) [5], [23].

Our key idea is to use a stable release of the AUT to synthesize integration tests with oracles that will be used to test the subsequent releases of this AUT as part of agile iterative development. Creating integration tests be ASSISTed with automatically obtained models that describe frequently interacting components, and thus are viewed as strong candidates for containing integration bugs. ASSIST combines in a novel way static dataflow and dynamic analyses with pattern mining to guide the synthesis of integration tests. Our tool and experimental results are publicly available at <https://www.dropbox.com/s/k1mfuzfw6r7138a/assist-release.tar.gz?dl=0>.

DOI reference number: 10.18293/SEKE2019-001

II. THE PROBLEM

Making integration testing cheaper and more effective is very important and is equally very difficult. Constructing finely granular integration tests is a laborious effort that requires time and resources, which is difficult to justify especially in continuous delivery where software is released in short-term iterations. Combining different components blindly in integration tests reduces their effectiveness, since the total number of integration tests is exponential in the number of components in a software application and many components do not interact with one another. A fundamental problem of software testing is how to automatically create effective integration tests that have a high bug-finding power.

A main objective for software integration tests is to be effective in finding bugs. An equally important objective is to find bugs in a shorter time period without using significant amount of resources, i.e., software integration tests should also be efficient. A system that generates millions of random integration tests is unlikely to be effective and efficient, since running these tests will consume significant resources and time without any guarantees that integration bugs will be found. Thus, our main goal is to minimize the number of synthesized integration tests and their execution time and to increase their effectiveness of finding bugs at the same time.

III. OUR SOLUTION

The architecture and the workflow of ASSIST are shown in Figure 1. The input to ASSIST (1) is the *Application Test Suite (ATS)* that consists of the AUT, unit and acceptance tests and input test data for these tests. The AUT (2) is run using acceptance tests with the Profiler that collects Execution Traces that are (3) analyzed by the Frequent Pattern Miner that outputs (4) frequent patterns of method calls. The Model Learner (5) learns the model that correlates properties of test input data with frequently mined method calls and it produces (6) the Model that is used to prioritize the synthesis of integration tests, i.e., to produce more effective integration tests efficiently. An important contribution of ASSIST is that stakeholders concentrate on creating and improving unit and acceptance tests as they do it now, and effective integration tests will be synthesized automatically using models that are learned using these acceptance and unit tests.

To execute synthesized integration tests, input test data is required, i.e., all variables and fields of the objects should be initialized that are used in the methods of these integration tests. Moreover, since the first method of an integration test is the N^{th} method that is executed as part of some acceptance test, this method uses the values of different objects and their fields, which constitute the *state of the AUT*. Our idea is to generate test input data by carving the AUT state [39] before executing the N^{th} method in the acceptance test for the given integration test. In fact, since the sequence of methods in an integration test can be executed as part of two or more acceptance tests, the carved states for these acceptance tests will serve as the set of the input data for the same integration test. A rudimentary

state carving method is to traverse the heap starting from the objects that are created in the main method.

The Model is used (7) as the input to the Execution State Carver that reruns the AUT with specific acceptance tests in order to carve (8) AUT States for the frequent patterns of method calls. Independently from this step, (9) unit tests from the ATS are inputted to the Unit Test Analyzer that uses static analyses to obtain (10) complex Oracle Expressions that include variables and AUT classes that are eventually used in *assert* statements in these unit tests. Next, (11) specific Oracle Expressions are selected for carved AUT States and then these selected Oracle Expressions are projected (12) onto the carved AUT States using the State Projector to obtain (13) the values of the oracles. As we discussed, unit tests can contain complex expressions and control flows, and its assertion statements contain variables whose values are computed as results of executing these unit tests. To determine what objects and their fields from the AUT are used in these assertions, unit tests are analyzed using a combination of backward slicing [38] and symbolic execution to obtain all expressions that contribute to computing the values of oracle expressions in assert statements. Then, these expressions are re-evaluated given the carved states and new values for the oracles for these expressions are obtained. These obtained oracles, the source code of the AUT and the Model (14) are used by the Integration State Synthesizer that (15) outputs integration tests. This concludes the description of the ASSIST architecture.

IV. EXPERIMENTAL EVALUATION

In this section, we pose research questions (RQs), describe subject applications, explain our methodology and variables, and discuss threats to validity.

A. Research Questions

As part of evaluation, we will answer the following research questions (RQs) to assess how ASSIST meets the objectives of effectiveness and efficiency.

RQ1: How effective are synthesized integrations tests in finding bugs? The rationale for this research question is to determine whether ASSIST synthesizes integration tests that can locate more integration bugs in software when compared with certain baseline approaches, e.g., manually created integration tests and FUSION, an approach that composes integration tests from unit tests [29].

RQ2: How efficient is ASSIST in synthesizing integration tests that can help find bugs without a significant use of computing resources? The rationale for this research question is to determine if ASSIST produces fewer integration tests and their total execution time is not prohibitive, while measuring their effectiveness of finding bugs at the same time. Our goal is to show that ASSIST can synthesize a much smaller and manageable number of integration tests that have good bug-finding power.

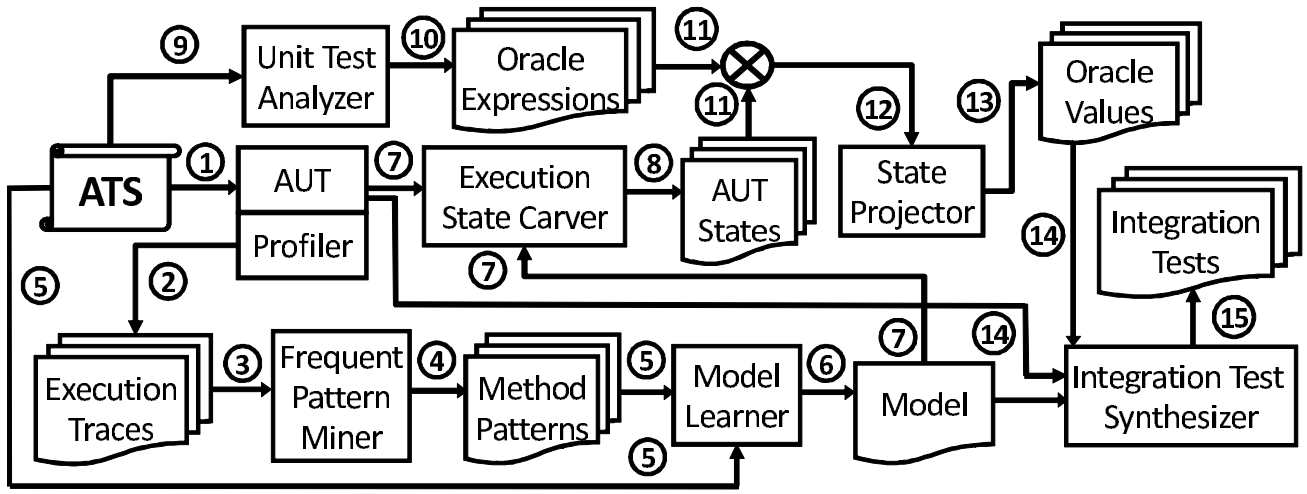

Fig. 1. The architecture and workflow of ASSIST.

TABLE I
CHARACTERISTICS OF SUBJECT APPLICATIONS.

AUT	Size, KLOC	Acc Tests	Unit Tests	Integration Tests	
				ASSIST	FUSION
NANOXML	7	36	92	48	75
SCRIBE	3.7	29	39	36	28
SHTUTXML	1.3	5	40	6	6

TABLE II
MAXIMUM VALUES OF ELAPSED EXECUTION TIME AND MEMORY
CONSUMPTION FOR ASSIST.

AUT	Instrum		Pattern Mining		Synthesis		State
	Test	Mem	Test	Mem	Test	Mem	
SCR	16s	55K	0.01s	2.3KB	18s	70K	0.2GB
NAN	17s	55K	0.04s	2.4KB	7s	60K	1.5GB
SHT	10s	57K	0.18s	2.4KB	7s	52K	0.95GB

B. Subject Applications And Their Test Suites

The subject applications for evaluating ASSIST are open-source Java applications that are widely used. Their characteristics are given in Table I. SCRIBE is one of the subject applications that serves as a OAuth module for Java applications. This application has close to 50 contributors and 22 releases. NanoXML is a Java-based non-validating parser. The third subject application is ShtutXML, an XML to text mapper. All subject applications have test suites that contain mixtures of unit and acceptance tests. In addition, we used several graduate students from UIC with prior software development experience to study these applications and create additional unit and acceptance tests.

C. Methodology And Variables

To address RQ1 and RQ2 we evaluate ASSIST using the following two dependent variables: the number of synthesized integration tests and their bug-finding power. The number of synthesized integration tests is a function of the threshold value for mining frequent method sequences. The smaller the value

is the more sequences can be mined, which is exponential in the limit. The larger the threshold value is, the fewer more frequent method sequences can be mined, however, the mining process may take a very long time. Unfortunately, frequent pattern mining algorithms are computationally intensive, and increasing the threshold value closer to one may take weeks or months even using powerful computers. Thus, as part of our experimentation we show the sizes of mined method sequences that we obtain for different threshold values and how they affect sizes of synthesized integration test suites.

We measure the bug-finding power of test suites using *mutation testing*, which is recognized as one of the strongest approaches for evaluating the effectiveness of test suites [14], [18]. The code of the *application under test* (AUT), P , is modified by applying *mutation operators* to the AUT's code to create a buggy but syntactically correct version of the AUT, P' , i.e., a *mutant*. Running the test suite for P on P' should fail some tests, i.e., the mutant is killed. Otherwise, the test suite is deemed not adequate to find bugs and it should be enhanced with new tests that can kill mutants that were not killed with the previous version of the test suite. A key measurement of the power of determining the adequacy of test suites is mutant killing ratio, i.e., the ratio of the number of mutants killed by a test suite to the total number of generated non-equivalent mutants. That is, our goal is to apply a mutation testing approach to the subject applications that generates mutants for determining the adequacy of integration test suites synthesized by ASSIST and the mutant killing ratio should be approximately the same when comparing to test suites that are manually created or generated using a competitive approach.

In our evaluation we compare the tests produced by our approach with FUSION [29], a state of the art tool for generating integration tests by combining unit tests using an object-relational model that it re-engineers from the source code of the application. The independent variables in our evaluation included the two mutation testing tools, jMINT [16] and JavaLanche [30], the set of subject applications, and the threshold values used in the pattern mining tool called BIDE

TABLE III
WE DESCRIBE SELECTED PARAMETERS FOR MINED FREQUENT
SEQUENCES FOR SYNTHESIZING INTEGRATION TESTS USING ASSIST.

AUT	Unq Mth	Max Len Seq	BIDE Inpt	Thresh	BIDE output	Seq Used In ASSIST
SCRIBE	81	60	134	0.01	129	87
NANOXML	101	602	121	0.05	180	42
SHTUTXML	28	48	298	0.002	27	15

to extract frequent method sequences from execution traces that are obtained from the subject applications. The number of integration tests that ASSIST synthesizes is also guided by the number of tests that contain oracles that come with the subject applications.

For frequent pattern mining, we use an closed sequence frequent pattern mining tool called BIDE [34]. This tool implements a very efficient algorithm for determining closed frequent sequences. We note that ASSIST is not tied to these specific tools. Any frequent pattern mining tool that identifies closed frequent sequences can be used in place of this tool.

D. Threats to Validity

One threat to external validity is the nature of applications that we used to evaluate ASSIST – they are small and may not be good representatives of the overall population of applications. We plan to conduct more experiments with many more applications to generalize these results. Subject applications were chosen based on the availability of large and diverse tests suites that we used as acceptance tests and to extract test oracles. In addition, we are also constrained by the limitations of FUSION, since it does not produce oracles. The counter argument to this threat to validity is that the subject applications are popular and have many tests and they may be viewed as good representative of the applications that are built in industry.

Another threat to validity is that we do not address the problem of storing transient state components, such as pointers to external resources (e.g., sockets and files). Since we show that our approach works for non-transient data structures, we hope to address the challenges with transient states as the next logical step in our future work. This technical challenge does not pose a threat to the core of ASSIST.

Finally, a threat to validity is that we evaluate the mutants against the integration tests generated by only one tool, namely, FUSION. Ideally, we need more tools on generating integration mutants that contain meaningful oracles, unfortunately, little research is done in this area that resulted in tools that can be used in our evaluation. The very purpose of our research is to address this limitation.

V. RESULTS

In this section, we report the results of the experiments and state how they address our RQs. We carried out experiments using Mac OS X 10.8, 64-bit CPU 2.4 GHz Intel Core i7, 8GB of RAM, 256KB L2 Cache(per core) and 6MB L3 Cache.

Performance-related measurements are shown in Table II. Clearly, the biggest space-related expense is the the carved state that requires approximately 1.5GB for NanoXML. Instrumenting the applications and synthesizing data takes less than 20 seconds, which is a reasonable expense. We can conclude that with respect to time and memory consumption, ASSIST is a practical approach that can be used for reasonably sized software applications to generate integration tests.

We evaluate the results of our approach and compare its effectiveness compared to manually generated tests and the tests generated by FUSION. Results of our experiments are shown in Table IV. For the AUT SCRIBE the strong mutant killing ratio is the same that is achieved with manually created tests. This result shows that it is possible to achieve the same result with ASSIST as it is achieved with manually created tests. Even though the ratio for SHTUTXML is smaller with ASSIST-based integration tests when compared to manually created tests, we view it as an impressive result, since ASSIST is fully automatic.

The application NANOXML is a source of concern, since its mutant killing ratio is very low with ASSIST-based integration tests. Our investigation revealed the following. When we run the acceptance tests, that are 101 unique methods in NANOXML that are invoked and are written in execution traces. Of these, there are 27 unique methods that are mined as frequent sequential patterns. Unfortunately, there are unit tests only for five methods. For the remaining methods there are no assertions in any of the manually created tests. Moreover, those methods that are used in unit tests and are part of the mined frequent sequences are loosely integrated with other methods in these sequences, so that the tightness of integration is very poor. ASSIST is based on the assumption, that unit tests and acceptance tests are adequate to produce integration tests that can be used as the software evolves. This also exposes the characteristics of the test suite and the lack of adequate tests for methods that were identified in the set of frequently used methods. As a result, ASSIST could not synthesize enough effective integration tests.

The case with NANOXML highlights the results of consequences of deficiencies that result in poorly built tests rather than limitations of ASSIST. Indeed, if acceptance and unit tests are abundant and if they are constructed properly, ASSIST automates a difficult and laborious tasks of creating effective integration tests. Moreover, for SCRIBE, ASSIST achieve the same mutant killing ratio with fewer synthesized tests, i.e., 36 when compared with 100 manually created tests. For SHTUTXML, the mutant killing ratio is achieved with only six synthesized tests.

We also see that using weak mutation ASSIST produces a weak mutation killing ratio that is equal to the manually created tests for two applications, SCRIBE and NANOXML. In addition, our approach performs equally well compared to FUSION for both these applications. In both these cases, our approach also provides mutant killing ratios that is at least 50% of mutant killing ratio of manually created tests.

The results of evaluating ASSIST with the mutation tool

TABLE IV
EVALUATING THE EFFECTIVENESS OF ASSIST BY COMPARING IT WITH FUSION. MUTANTS ARE GENERATED USING JMINT.

AUT Name	Type of tests	Tests Created	Mutants Generated	Mutants Triggered	Mutants Killed	Trigger Ratio	Killed Ratio
SCRIBE	DEFAULT	100	115	15	6	13.04	5.21
	ASSIST	36	115	15	6	13.04	5.21
	FUSION	28	115	15	-	13.04	
NANOXML	DEFAULT	116	104	95	34	91.34	32.69

	FUSION	6	12	2	-	16.66	

TABLE V
EVALUATING THE EFFECTIVENESS OF ASSIST BY COMPARING IT WITH FUSION. MUTANTS ARE GENERATED USING JAVALANCHE.

Description of the Step	SCRIBE				NANOXML				SHTUTXML			
	FUSION		ASSIST		FUSION		ASSIST		FUSION		ASSIST	
Total mutations	356		2634		1442		7330		193		719	
Covered Mutations in Scan Step	105	29.49%	2111	80.14%	731	50.69%	6957	94.91%	0	0	403	56.05%
Covered Mutations	100	28.09%	100	3.80%	99	6.87%	99	1.35%	0	0	100	13.91%
Not Covered Mutations	256	71.91%	2534	96.20%	1343	93.13%	7231	98.65%	193	0	619	86.09%
Killed Mutants	36	10.11%	80	3.04%	47	3.26%	66	0.90%	0	0	49	6.82%
Surviving Mutants	320	89.89%	2554	96.96%	1395	96.74%	7264	99.10%	193	0	670	93.18%
Mutations Score	10.11%		3.04%		3.26%		0.90%		0.0%		6.82%	
Mutation Score for covered mutants	36.00%		80%		47.47%		66.67%		0		49%	

called Javalanche are shown in Table V. ASSIST-based synthesized integration tests are richer than ones created by FUSION, resulting in more mutants generated by Javalanche for ASSIST. As a result, ASSIST-based tests cover more mutated statements when compared to ones generated by FUSION. ASSIST-based tests kill many more mutants when compared with FUSION-generated tests. The mutation score for covered mutants is much higher for all applications for ASSIST. Based on this evidence we can conclude that **we positively answer RQ1, i.e., synthesized integrations tests are effective in finding bugs.**

To address RQ2, we will need to evaluate the results of our approach in terms of performance of the frequent mining algorithm which is dependent on the initial sequences generated during the execution of acceptance tests and the number of tests ASSIST generates. Table III provides information on the number of unique methods for each subject application, maximal sequence of method calls that was traced during execution of acceptance tests. The last three columns state the threshold values that were used to identify the frequent sequences, and the actual number of sequences that were used by ASSIST. For each of the subject applications, we note that it did not take more than a couple of seconds to identify these frequent sequences. The other result we need to evaluate to address RQ2 would be the number of integration tests ASSIST produces. Table I provides details on the number of tests we produce. It can be observed that the number of tests generated by ASSIST is close to the number of tests that were created manually or by FUSION. This shows that even though there is a potential of execution trace producing a large number of sequences, using a combination frequent mining and static analysis techniques ASSIST is able to produce tests that can

be executed as efficiently as manually produced tests and the tests produced by FUSION. Based on this evidence we can conclude that **we positively answer RQ2, i.e., ASSIST is efficient in synthesizing integration tests that can help find bugs without a significant use of computing resources.**

VI. RELATED WORK

Related work on automatic generation of integration tests has many branches. Different model-based approaches exist for generating integration tests using different types of formal models [9], [19], [28] and using modeling approaches for creating integration tests for distributed applications [6], [35]. Some approaches learn models and class dependencies for integration testing from application code and behavior [3] or from previous versions of the same application [7], [8]. Opposite to these approaches, ASSIST does not require models for generating integration tests, since models may be outdated, incomplete, or they may not exist at all. In addition, it is not clear how oracles are defined for these approaches. ASSIST is different from these approaches and complementary to them in that ASSIST synthesizes integration tests using models of method invocations. Unlike ASSIST, these approaches do not have explicit mechanisms to control the number of generated tests while increasing their effectiveness, and it is a question how efficiently it is achieved.

Class Integration and Test Order (CITO) approaches determine orders in which classes are composed in integration tests using graph-based and search-based solutions [1], [10], [12], [13], [22], [36]. However, the determination of a cost function, which is able to generate the best solutions, is not always a trivial task. In contrast, ASSIST does not require cost functions, and it extracts oracles from tests, while CITO

does not address the oracle problem. Unlike ASSIST, CITO approaches do not reflect the frequency of executions of integrated components, and therefore it is not clear how it can increase the effectiveness of the composed integration tests.

Approaches that compose integration tests from unit tests and some software modules [24], [29], [31], [32] address a different angle of the problem than ASSIST – the latter concentrate on producing effective integration tests efficiently, while it is unclear how the former approach addresses a problem of reducing the large number of combinations of unit tests into integration tests.

VII. CONCLUSION

We created a novel approach for *Automatically Synthesizing Integration Software Tests (ASSIST)* that automatically obtains models that describe frequently interacting components in software applications, thus reducing the number of synthesized integration tests and increasing their bug-finding power. In ASSIST, static and dynamic analyses are used along with carving runtime states to obtain test input data as well as oracles for the synthesized integration tests. We experimented with three Java applications and show that integration tests that are synthesized using ASSIST have comparable bug finding power with manually created integration tests.

Abstract—Exception handling mechanisms are a common feature of mainstream programming languages to deal with exceptional conditions. If on the one hand they allow the programmer to prepare the code to deal with exceptional conditions, on the other hand they can become a source of bugs that threatens the application robustness – studies have shown that uncaught exceptions are the main cause of application crashes. To keep track of crashes and enable an easier fault localization, several applications, nowadays, use crash reporting tools. In this work, we propose a tool named CrashAwareDev, integrated with the Eclipse IDE, which mines the information available in crash reporting tools to support programmers in their day-to-day activities. The proposed tool alerts developers about the classes related to recent crashes and warns about source code characteristics (bug patterns) that can be related to future crashes (similar to the ones that have happened). Doing so the tool aims at bringing the development environment closer to crash reporting tools, that are usually only used for bug fixing or for extracting robustness metrics. A case study was conducted and showed that the tool can support software development by displaying bug pattern alerts directly in the source code, signaling the classes involved in recent faults, and speeding up the crash’s fault localization within the development environment itself.

Index Terms—Exception handling, crash report, Eclipse plug-in, uncaught exceptions

I. INTRODUCTION

Exception handling mechanisms [1] are a common feature of modern programming languages. Exception handling structures are used to deal with unexpected events that occur during the execution

of a program [2], allowing exceptions to be thrown, captured, and handled at different points in the system. However, the exception handling code designed to make a system more robust often works the other way around and become a burden programmers has to cope with, leading to bugs such as the uncaught exceptions. The uncaught exceptions are the main cause of crashes in Java software systems [3]. A crash is an abnormal behavior of a system that leads to the interruption of its execution.

After a crash occurs, systems typically store information related to the crash on crash report systems. Such information usually contains the uncaught exception that caused the crash and its stack trace. The exception stack trace is a representation of the method call stack and contains information about classes and methods by which an exception was propagated. Since the exception stack trace is a source of information widely used by programmers while debugging they are often added on crash reports [4]. Moreover, these reports may contain other information such as the operating system used at the time of the crash, the user login, the browser/system version, the user’s IP address, and other request parameters. In addition to facilitating the fault localization, the information available on crash report tools can assist in prioritizing bug corrections (depending on the number of users affected, for example) or understanding the impact of system crashes [5]. The utility of crash report systems may go beyond recording crash data and supporting debugging. Some studies have shown

that such information can be used for various purposes such as fault classification [6][7] and fault localization [8][9][10]. None of the existing works, however, extract data from crash reports to support programmers during system coding.

In this paper, we propose a way to mine information stored in crash reports and provide useful information to the programmer within his/her programming environment. We present a tool called CrashAwareDev, an Eclipse¹ IDE plug-in, which supports the developer in coding time by (i) alerting him/her about the classes related to recent crashes; (ii) warning about source code characteristics (bug patterns) that can be related to future crashes (similar to the ones that have happened); and (iii) providing direct access to crash reports within the IDE. A case study was conducted on an industrial web-based software system comprising of 1300 KLOC of Java source code. Along the evaluation period, a group of 5 developers used the tool on a daily basis (during 4 days). Overall the tool presented 95 warnings (i.e., 17 class alerts and 78 bug pattern warnings).

II. BACKGROUND

The Java programming language provides an exception handling mechanism to support error handling [12]. When an error occurs during execution of code in a try block, the error is caught and handled by an exception handler in one of the subsequent catch blocks associated with it. If no catch block can handle the error, the method is terminated abnormally and the Java virtual machine (JVM) searches backward through the call stack to find an exception handler that can handle the error [15].

In Java, exceptions are represented according to a class hierarchy, on which every exception is an instance of the Throwable class, and can be of three kinds: the checked exceptions (extends Exception), the runtime exceptions (extends RuntimeException) and errors (extends Error) [12].

Checked exceptions represent conditions that, although exceptional, can reasonably be expected to occur, and if they do occur must be dealt with in some way. Unchecked runtime exceptions

represent conditions that, generally speaking, reflect errors in your program's logic and cannot be reasonably recovered from at run time [13]. By convention, instances of Error represent unrecoverable conditions which usually result from failures detected by the Java Virtual Machine due to resource limitations, such as OutOfMemoryError. Normally these cannot be handled inside the application [13].

III. ANALYZING CRASH REPORTS

A. Methodology

Before implementing the CrashAwareDev tool, we conducted a study whose goal was to identify the characteristics of most frequent crashes of an industrial Web-based system, and based on such characteristics, check whether or not existing static analysis tools could alert about them. Figure 1 illustrates the main steps taken in this study. The target system used in this study was an industrial Web-based system, named SIPAC, comprising of 1300 KLOC of Java source code and designed to automate business processes for universities focusing on different and complementary aspects, such as administration, planning and management – SIPAC is used in approximately 55 Brazilian universities.

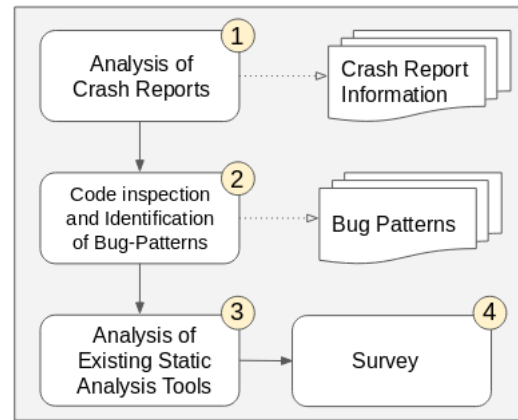

Fig. 1. Methodology overview.

Step 1: Analysis of Crash Reports. We analyzed the most frequent exceptions that caused crashes over a period of one month.

Step 2: Code Inspection and Identification of Bug Patterns. We manually inspected the code related to the most frequent kinds system crashes to identify common characteristics among them.

¹<https://www.eclipse.org/>

Step 3: Analysis of Existing Static Analysis Tools. We analyzed whether or not existing static analysis tools could be able to detect and therefore prevent such causes of crashes identified on the previous step.

Step 4: Survey. Finally, we conducted a study on which we surveyed a group of developers (working on the target system) to evaluate how they used.

B. Crash Analysis

In order to investigate the main causes of crashes reported for the target system, we analyzed the crash reports of one month (June 2018). In this period (2018-06-01 to 2018-06-30), approximately 1933617 accesses were made to the system, from this set 680 accesses were faulty (0.0035% of the accesses) - on which the user faced one or more crashes. We observed that approximately 1966 crashes were recorded in the period, affecting 347 distinct users.

We extracted the types of most frequent uncaught exceptions (leading to crashes). The top 5 types of uncaught exceptions raised shown in Table I. We can observe that approximately 63.9% (1241 errors of 1966) of the crashes of the analyzed period was caused by five types of exceptions.

Root Cause	Ocurr.	%	Analyzed
NullPointerException	749	38,09	10
LazyInitializationException	171	8,69	2
JspException	166	8,44	21
IllegalArgumentException	102	5,18	1
SQLException	53	2,69	5
Total	1241	63,9	39

TABLE I

THE TOP 5 TYPES OF UNCAUGHT EXCEPTIONS RAISED IN JUNE/2018.

We then manually inspected the source code related to a subset of such crashes (we randomly selected a subset of each of the top 5 uncaught exceptions – as shown in the last column of Table I). The purpose of this analysis was to identify common characteristics related to the causes of the most frequent uncaught exceptions.

Overall we inspected the source code related to 39 crashes. We could observe common characteristics among some of them, which led to the

definition of four specific bug patterns listed in Table II.

Tag	Description	Ocurr.
BP01	Unchecked database query return	3
BP02	Unchecked classes methods parameters	2
BP03	Unchecked request parameters	2
BP04	Controllers do not implement get/set methods	4

TABLE II

BUG PATTERNS DETECTED DURING ANALYSIS.

Each bug pattern found in this study is described as follows:

- **BP01:** When querying any data in a database, it is recommended to check if the value is not null, to prevent a possible null pointer exception.
- **BP02:** Static methods of utility classes should check if their arguments are not null.
- **BP03:** Like BP01, objects retrieved from the HTTP session must be checked.
- **BP04:** Private attributes of view controllers must most often have the get and set methods implemented. Otherwise, a JspException may be thrown while rendering the Web page.

C. Analysis of Existing Static Analysis Tools

We then investigated whether some of the existing static analysis tools could alert about some of the 39 crash causes identified during the manual inspection. We used SonarLint² and SpotBugs³, both in its Eclipse's plug-in version and observed that none of the 39 defects were detected by the tools.

D. Survey

We applied a survey the developers working on the target system to investigate how they use the crash report information during development. The survey was sent to 25 developers, and we obtained 14 responses, from which: 5 respondents mentioned that never used the crash report; 8 respondents mentioned that only used for debugging purposes; and only one mentioned that used the crash report on a daily basis for monitoring of errors. Moreover,

²<https://www.sonarlint.org/>

³<https://spotbugs.github.io>

7 respondents mentioned that they had difficulties in using the features of the crash report system used.

IV. THE CRASHAWAREDEV TOOL

Based on the steps described previously we implemented a tool – called CrashAwareDev. CrashAwareDev’s main purpose is to present information mined from crash reports and identified bug patterns on the developer’s IDE, at coding time. One of the motivations of this research was the perception that, in the context of target system development (SIPAC), crash report information is basically used for debugging failures and was not used to alert the developer of potential crash causes or classes frequently related to crashes. Figure 2 represents an overview of the main features of CrashAwareDev and described next.

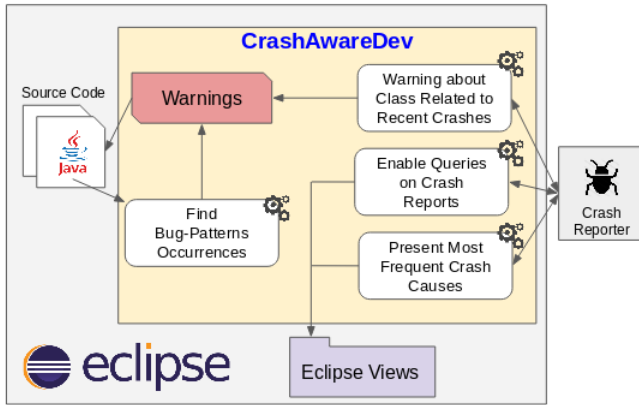

Fig. 2. CrashAwareDev’s Components diagram.

Warning about Classes related to Recent Crashes. The tool alerts whether the class being changed was associated with at least one recent system crash (i.e., the period considered is configurable). We have adopted the following heuristic: if the class appears in the exception stack trace of one crash, then it will be associated with the crash, as this means that the exception at some point was propagated within a method of this class. However, this is not to say that the defect is located in that class, but can information help to identify the fault’s origin. The tool generates warnings that are displayed in source code during development as illustrated in Figure 3.

Find Bug-Patterns Occurrences. On the study described previously, we identified source code

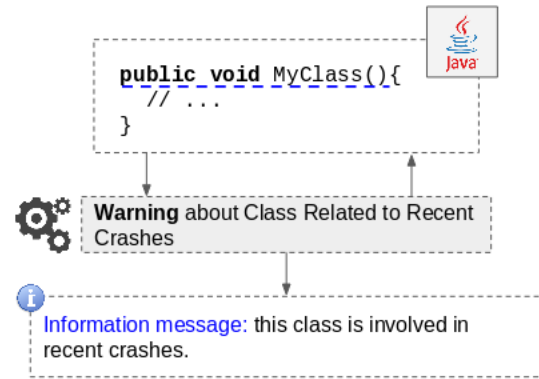

Fig. 3. Warning about classes related to recent crashes.

characteristics (bug patterns) that lead to crashes in SIPAC. Hence, at each compilation, the tool statically analyzes of the changed artifacts looking for bug patterns (described in Table II) and warnings that are displayed directly in IDE as illustrated in Figure 4.

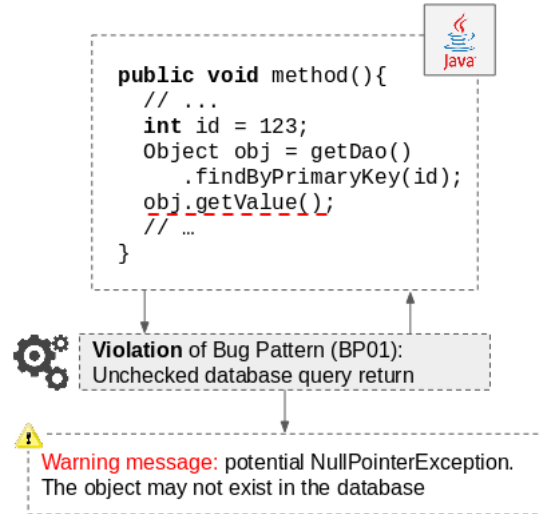

Fig. 4. Bug-Pattern Violation Alert.

Enable Queries on Crash Reports. This feature aims to bring the programmer closer to the crash report during coding. The goal is to enable the developer to query for recent system crashes, filtering them by class name. Summarized crash information is displayed in an Eclipse view with a link to display the complete information directly in the crash reporter (in an external browser).

Present Most Frequent Crash Causes. This feature basically displays the most common types of uncaught exceptions that have occurred in a

given period of time (e.g., one month). The data displayed are similar to those shown in Table I.

V. EVALUATION

To evaluate CrashAwareDev tool we performed a case study on which a group of developers used the tool for a given period of time and quantitative and qualitative data regarding the tool usage was collected. We invited SIPAC developers to participate in the study and a group of 5 developers volunteered to participate. They received brief training on the features of CrashAwareDev, and used the tool for 4 consecutive days, for approximately 8 hours daily. Table III presents the metrics collected in this study.

Metric	Count
M1: Number of classes changed	105
M2: Number of classes with some alert	61
M3: Number of alerts per bug pattern	78
BP01 - Check values when querying in a database	47
BP02 - Check auxiliary methods arguments	15
BP03 - Check values carried by request	16
BP04 - Implement private attributes' get/set	N/A
M4: Class alerts associated with a crash	17

TABLE III
METRICS COLLECTED DURING EVALUATION

During the execution period, we collected in the logs that 105 different classes were changed (M1). In 61 of these, some problem was detected by the tool and at least one warning was shown to the developer (M2). A total of 78 bug pattern alerts were displayed. They were distributed among the patterns listed in Table III (M3).

The BP04 pattern was removed during the execution of the study because the participants reported that most warnings would be false positives, as not every private method of controllers should necessarily be referenced in JSP pages. Therefore, we disabled the checking of this pattern during the study. As described earlier, the *Class Checker* feature analyzes whether the changed class is present in some recent crash stack trace. We collected 17 warnings on this check (M4).

Moreover, we also counted how many times each CrashAwareDev feature was used during the study (Q5). The *Query Crashes from Crash Reporter* function was used four times by the participants. We observed that this query was performed

after an alert was displayed in the class (during the *Class Checker* execution) and the developer was interested in checking the crashes in which the class was involved. Of these four queries, in two times the participant used the link to see the complete information of the crash. The *Query Top Root Causes* feature was not used during this study. This information did not prove useful to programmers during the study, but we believe that it is of greater interest to leader developers (who did not participate in the study).

We also questioned participants about the usefulness of the tool. All of them mentioned that the tool warnings were useful. One of the participants also mentioned that more bug-checking rules could have been implemented as they could indeed help in preventing crashes in the long run. Two other developers also suggested that in some cases the tool might also support the fault localization in the production environment in a future version.

VI. RELATED WORK

Information mining on crash reporters and/or stack traces. Some studies were carried out with the objective of extracting data from crash reports and using them for various purposes. Among them are those who used the data to find bug hazards in exception handling code [14], to classify the types of failures [6][7] and to facilitate their location [8][9][10]. In this article, we use a grouping of crashes per type of exception. We sought to identify error patterns associated with these types through manual analysis of crashes. Our research did not propose any mechanism for locating defects, but we tried to approach the programmer's development environment to the crash reporter, which may help at coding time the identification of classes associated to recent faults.

Bug Detection Tools. Several static analysis tools have been proposed to detect bug patterns in the source code from predefined rules. These patterns are categorized into various types such as correctness, code smells, vulnerability, security, performance, etc. PMD [17] is an open-source application and is based on bug patterns to find errors in the Java source code. It allows new patterns to be written in Java or XPath. Another tool proposed was the FindBugs [18] which also

examines the source code and bytecode of Java programs. In this paper a subset of the FindBugs rules was described and compared to the PMD with respect to the number of alerts generated, showing that the number of FindBugs alerts is lower in all experiments done. In 2016 FindBugs was discontinued and succeeded by SpotBugs, which we use in this work. Another existing static analysis tool is SonarQube [19] which presented a proposal for analysis along with continuous integration systems. We used in this work your Eclipse version, called SonarLint. CrashAwareDev has a static analysis feature, as well as the tools mentioned. However, we seek to define rules based on real crashes, in order to reduce the known false positives in the existing tools.

VII. CONCLUDING REMARKS

In this work, we presented a way to use data from crash reports to support programmers during software development. To promote this support, we have developed a plug-in tool for the Eclipse IDE, CrashAwareDev. Before proposing the tool, we performed a detailed study of crashes stored in a real crash reporter in order to identify the main causes of crashes. A set of common causes of crashes were defined as bug patterns which could be identified in the static analysis performed by CrashAwareDev. Moreover, the tool also alerts the developer about classes frequently involved in crashes and enabled them to access information of crash reports within the IDE. A case study in a real development context was performed and the results revealed that the tool could indeed alert the developers about several application-specific bug patterns.

Acknowledgments. This research has been supported by CAPES-BRAZIL.

Abstract

The development of tools and smart devices has grown exponentially over the past few years, most due to the appearance of the Internet of Things (IoT). The large number of different connected devices highlighted challenges such as interoperability, scalability and reliability. In this scenario, for the development of new services and applications, it is necessary to use software platforms that ease the deployment and validation based on those challenges. With this, arises the need for middlewares, platforms that provide an environment for the development of such applications. In this way, in order to provide a simple, lightweight and dynamic approach, this article presents a study and development of an architecture that allows the communication, control and monitoring of IoT devices using an intuitive manner through an actor model. This is possible through the integration of the Calvin framework, the MQTT protocol and the OCF data model, providing an interoperable, reliable, dynamic and remote communication. A smart home environment was used for validation showing the relevance of the proposal.

Actor model; dynamic control; interoperability; IoT; MQTT; OCF; smart home

1 Introduction

Internet of Things (IoT) is described as a network infrastructure with interoperable communication standards and protocols where physical or virtual “things” share information in real time [22]. Aiming to make the Internet more comprehensive and immersive, IoT enables access to a wide range of devices. Those devices are used to build applications in many domains, including industrial and home automation, intelligent cities and healthcare [24].

Due to the increasing interest in IoT application, a wide variety of devices and objects that aims to provide utilities and services through the Internet are under development. This variety of devices and services creates new challenges, which demands the use of different architecture models in terms of Software Engineering.

The main challenges to achieve the maximum potential of IoT are interoperability, mobility, scalability, performance, security and privacy. Because of the heterogeneity of devices and platforms, interoperability is a major obstacle to be overcome. Standardization of protocols and pattern interpretations are important to make all devices accessible and interoperable. Therefore, data exchange between a large number of devices must be managed so that sensitive data is not compromised [1, 10].

Middlewares are used to allow the usage of heterogeneous components and to abstract implementation details of network protocols and communication resources. A middleware works as a communication link between devices and applications for IoT. It should provide interoperability, device discovery and management, security, privacy, and also high-volume data management [2, 15].

In this paper, we propose a new IoT System architecture model, based on an actor-based middleware, that is interoperable, dynamically controllable and manageable. This new system is built on top of Calvin [21] middleware, MQTT communication protocol, and oneIoTa models based on the OpenConnectivity Foundation (OCF)¹ specifications. While Calvin was used for the development, deployment and execution of an IoT smart home application, MQTT and oneIoTa provided interoperability and standardization between different devices. As a validation scenario, we built a smart-home application, which, based on the user behaviour, demands ways to dynamic control remote devices in a interoperable way.

The paper is structured as follows. Section 2 discusses the related work. Section 3 introduces the tools used for

DOI reference number:10.18293/SEKE2019-177

¹<http://www.openconnectivity.org>

the IoT application. Specifically, the Calvin framework that supported the entire implementation, the MQTT protocol and the OCF “consortium” are described. Section 4 details the proposed architecture and the dynamically controlled smart home application. The implementation and validation of the proposed system are presented in Section 4. Finally, conclusions and future works are presented in Section 5.

2. Related Work

Several studies were executed to design, implement and control IoT systems. Konduru et al [11] presents a study that identifies challenges and solutions considering interoperability of devices. Tools such as Google Weaver, IoTivity, AllJoyn and Apple Home Kit are analysed. Google Weaver and the Apple Home Kit are focused on solving interoperability only for pre-defined devices. While AllJoyn is a framework that together with IoTivity are part of the Open Connectivity Foundation (OCF).

Belsa et al [3] also address the interoperability problem, but with a different approach. IoT platforms are integrated through a flow-based model. The proposed architecture is based on the Node-RED² middleware. However, unlike Calvin, that uses a distributed hash table (DHTs), it does not support the development of applications with distributed systems. [20], also uses Node-RED to design, deploy and control devices remotely in a smart laboratory.

Finally, [12] implements a Healthcare resource model using OCF and IoTivity platform. In this work, two OCF standards are used, the OIC Healthcare Resource and the OIC Healthcare Device. Some of these resource are blood glucose, body metrics, heart rate and oxygen saturation sensors. In which, each resource has a schema and RAML.

3 Basic Concepts

In this section we present the main technologies used in this work.

3.1 Calvin

Calvin is an open source framework aiming to ease the development of IoT applications in distributed systems. It is based on a data flow programming methodology through an actor model [14, 16]. The paradigm of data flow programming is present as an actor model. An actor is a software component that models functions, devices, services or some type of computing in the form of an object. In Calvin, tokens are used to establish communication between actors. These tokens are created when the input actors captures and processes data. Data is then transformed into resources, which in this environment are considered tokens, that will be consumed by other actors [18].

²Node-RED: <https://nodered.org/>

The framework has several standard actors and sensors responsible for input/output of data, media and network access (including HTTP, TCP and MQTT), among others [21]. New actors can be implemented in Python and the dataflow between them is expressed using a declarative language called CalvinScript [19]. Because of the ease of developing actors, Calvin simplifies the implementation of several new services based on this type of model.

To develop an application in Calvin it is necessary to follow a cycle consisting of four phases: describe, connect, deploy and manage. Firstly, the developer will describe how a task is executed by each actor. Secondly, it is necessary to make the connections between them. This can be done using the Calvin GUI. This tool lists the available actors and allows to connect them through their inputs and outputs. When performing this, the CalvinScript is automatically generated. Figure 1 shows a detail of Calvin’s graphical interface. After creating connections, the application is already ready to deploy. Finally, during the management phase, modifications can be made in the application and Calvin executes the deployment [14, 16].

Figure 1. Calvin GUI.

In Calvin’s architecture there is a layer called runtime where actors are executed. It has two sub-layers, platform dependent and platform independent. The first allows communication between several runtimes through the most varied communication protocols, such as WiFi and Bluetooth. The second, allows the execution of several actors at one runtime only. Calvin GUI works on that layer.

3.2 MQTT

Message Queue Telemetry Transport (MQTT) is an application layer protocol that centralizes the sending and receiving of data from applications using a wireless sensor network, enabling the communication between devices with limited power source. This architecture is based on a Publisher/Subscriber system. Publishers are responsible for sending data collected through sensors, while subscribers consumes the data that was collected [9].

A Broker is used to coordinate the sending and receiving of data in order to ensure that the communication will be reliably. The Broker receives the data collected and classifies the data as topics. The data is then sent to devices interested in a specific topic. The broker also ensures that the data will be received only by the subscribers who will consume them. To provide safety and quality of data com-

munication, MQTT uses encryption and login to guarantee a minimum level of quality of service (QoS) [13].

The MQTT also allows the creation of a development environment for IoT applications. This is due to its high integration capability with several IoT development platforms, as it enables the development of services using various programming languages, such as Python, Java, JavaScript, PHP, Ruby and C. Also, MQTT allows extending these services to mobile platform such iOS and Android [6].

3.3 OCF and oneIoTa

Open Connectivity Foundation³ (OCF), is an IoT consortium that aims the specifications, open source and certifications needed for the development of an IoT environment with interoperability between devices that acts as OCF Clients and Servers [4, 17]. The exchange of information between devices uses the JSON format, following the specifications for identifying them and their connected resource, which makes it easier to validate the data structure [5]. To describe OCF services the specifications of the resources are made using a descriptive language of RESTful APIs, the RAML. To ease the implementation of the OCF data model, the consortium has developed the open tool oneIoTa⁴ that has several examples of type RAML, Swagger and JSON Schema models. Users can also create their own templates that, if approved, are stored in a GitHub repository.

4 Proposed Solution

As stated before, we are motivated by the following aspects: interoperability; remote access and dynamic configurations. Interoperability is a critical problem in IoT. Application developers should consider providing services to all clients regardless of the hardware platform specifications they use. Integration with different communication devices is necessary so that new functions can be added to the application without compromising existing functions or even losing them [1].

Devices and appliances must also allow remote access in order to be monitored and controlled through a computer or a smartphone [23]. In security applications remote access is indispensable because it allows the user to monitor their home when they are traveling for example.

Finally, IoT applications must allow dynamic configuration. Most of IoT applications developed today were created to perform pre-defined tasks, for that reason they are static systems limited to certain actions. Dynamic configuration makes the system more elastic and comprehensive because the user can configure the applications to handle devices and sensors that will be added later. In addition,

new monitoring and control applications can be created and modified at the users discretion.

To achieve the above goals and to facilitate the implementation of the system, we are looking for an IoT middleware that provides the best possible solution. The existing IoT architectures are divided into three types of classes: service-based; cloud-based; and actor-based. Service-based architectures and actors provide interoperability, they support a specific programming model or device abstraction. However, the service-based model provides limited functionality for the user when it comes to integrating with other applications or even interpreting data. The cloud-based model provides interoperability through specific standards, which is not desired, and the middleware can stop if the cloud provider terminates the service [15]. For these reasons, the actor-based model is the best solution for the smart home system we propose.

An actor-based architecture provides a better way of dealing with large-scale IoT devices, since middleware can be deployed across all layers of the architecture, so devices can perform actions where it is more adequate. Therefore, an actor-based middleware, such as Calvin and Node-RED, is a good choice in applications involving a large number of “things”. In addition to having features such as interoperability, security, and privacy, where users can choose the form and location where the data will be stored [15].

The proposed architecture involves a variety of devices and technologies. The first part consists of sensors, for example temperature sensors, present in wireless nodes. These nodes are connected to a gateway unit which, in turn, is responsible for sending the sensor data, through messages, to the MQTT Broker. The gateway must then be equipped with the Calvin framework with a Publish application that sends the messages with a specific topic for the sensor identification. Calvin Constrained is a good choice in this case due to the limitation of some devices.

In Figure 2 a representation of the logical diagram of the proposed system can be seen. This diagram provides a view of the connection and communication between the architecture elements. Each component behaves as follows:

1. The Middleware receives the data sent by the sensors with its information, and modifies that data and transforms it into a JSON object. This object is a sequence of key/value pairs. A key must be a string, and the value must be a JSON base type;
2. The Gateway is a MQTT client that connects to the cloud server through a TCP/IP connection. Once connected the gateway can publish the data of sensors and devices for the broker to distribute to the controller and also subscribe to the data published by the broker to the devices. The broker acts as an intermediary between the gateway and the controller.
3. The Controller application subscribes to the sensors

³OCF: <https://openconnectivity.org/>

⁴oneIoTa: <https://oneiota.org/>

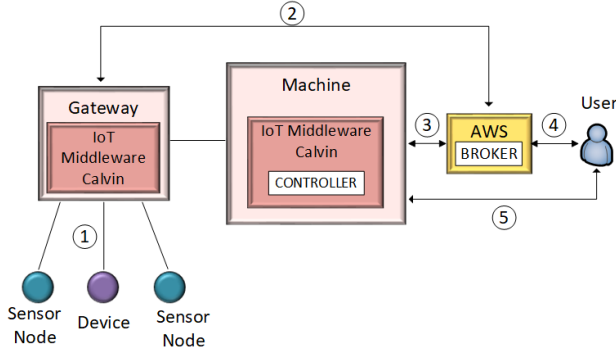

Figure 2. Architecture of the proposed system.

and devices data coming from the Gateway through the cloud, performs the control action and publishes the new data to the device;

4. The user has direct access to the cloud server through the platform on the Internet, and can manage the Broker data;
5. The user can access the application controller directly from the local machine or via remote access.

In order to exchange MQTT messages, a Broker, which is implemented on a cloud platform, is required. There are several free and paid cloud platforms available with support for gateways, services, and application protocols such as REST, COAP, XMPP, and MQTT [1]. Eclipse Mosquitto was chosen for the application because it is a Broker that provides a lightweight server implementation of the MQTT protocol and, moreover, it is open source (EPL/EDL licensed) [7, 8].

Finally, the control module provides the system-wide management through dynamic configuration. The application is implemented in Calvin GUI, which is a web-based GUI for Calvin application development. To access the GUI platform the user must have the Calvin runtime running on a local machine or on a machine on the same network. The dynamic configuration of this application is done in a simple way, given the ease in changing the actors and their data flows in the GUI platform. Therefore, you can at any time interrupt the application's data flow and modify it according to your needs.

4.1 Validation

A smart home application was implemented using the proposed architecture to validate the proposed solution. Figure 3 provides a visual illustration of the technologies and how they connect with each other. The application consists of a system that collects sensor data and transmits it to

the controller. This data is used to monitor and to control the actuator device dynamically and remotely. The use case consists of performing the temperature control of environments by means of an air conditioning device and sensor nodes.

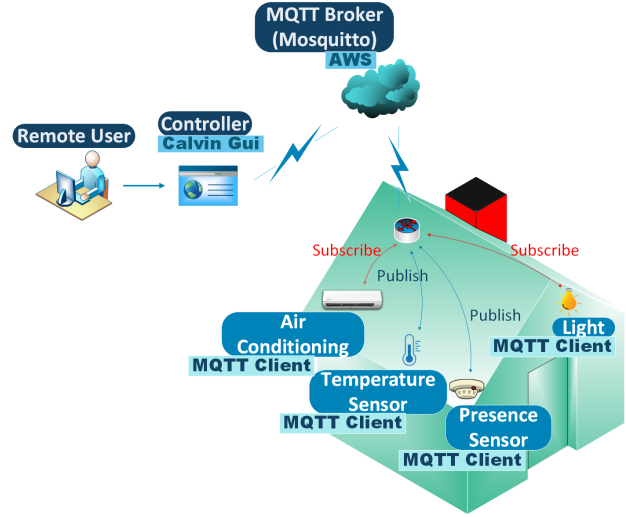

Figure 3. Smart home system overview.

A test environment consisting of four (4) Linux based Virtual Machines running Calvin the framework. Two of these machines were used to simulate an environment of a residence with their devices, i.e. the air conditioners. The other two machines were used to simulate the temperature sensors distributed in the environments. In Figure 4 the sequence of messages of two different simulated environments, living room and room, can be observed.

```

{'topic': 'u/ocf/rt/sala/ar/oic.r.TemperaturaArCondicionado', 'payload': '{
```

Figure 4. Sequence of messages between entities.

To validate the interoperable feature, it was used the oneIoTa specification for OCF devices⁵. Table 1 details the specifications of air conditioner devices. As can be observed in Figure 4, the payload of the devices are in accordance with the recommendations of the OCF, but as a

⁵OCF Device Specification: https://openconnectivity.org/specs/OCF_Device_Specification_v2.0.0.pdf

differentiation between the requirements of the sensor and the air conditioner, the air conditioner was modified to facilitate the understanding of reader. These specifications, as mentioned in 3.3, enables interoperability between devices. OCF defines the resource model that provides consistency among the devices in the home. This model uses the system of resources and devices, whose features exchanged are of various types, in the case of air conditioner has the type binary and the temperature. Each resource type defines a set of properties that are defined using the JSON format.

Table 1. OCF Device Resources.

Device Name	Required Resource name	Required Resource Type	RAML/JSON example
Air Conditioner	Binary Switch	oic.r.switch.binary	{ "rt": ["oic.r.switch.binary"], "id": "unique.example.id", "value": false }
	Temperature	oic.r.temperature	{ "rt": ["oic.r.temperature"], "id": "unique.example.id", "temperature": 20.0, "units": "C", "range": [0.0,100.0] }

To fulfill the remote access feature, Calvin GUI was used to perform updates remotely. The framework allows the control to be remotely carried out on the machine where Calvin is installed or on another machine on same network. In addition, the inclusion of a virtual machine in the cloud, used as a broker running the MQTT server, allows the user to subscribe to a topic of interest. The data published in this topic is sent to those who requested it. In Figure 4 it is possible to identify 3 different topics that the user can sign in. Figure 5 shows more clearly how the message exchange occurred in the application.

Figure 5. Subscriber topics in JSON format.

The user must initiate the process so that the controller requests the room temperature to the broker. The broker acquires this data from the sensor temperature and sends this value to the controller. The same occurs with the air conditioner. The control will determine whether the air condi-

tioner stays on/off or modifies its state according to the data available and the user specification.

To achieve dynamic configuration, the user must be able to add new devices, modify the control model, and its parameters. Figure 6 shows a small part of the control implemented. Figure 6(a) shows a specific setpoint for the control of the switch of the air conditioner. In Figure 6(b) this setpoint was removed from the control and replaced in the Figure 6(c) (setpoint2). This sequence was executed in runtime, where the controller device was kept running during the changing of setpoints. Also, by the use of a standardized data model (oneIoTa), all remote clients were able to keep receiving updates without any interruption.

5. Conclusions and future work

This article presented an architecture that integrates several technologies, such as IoT protocols and frameworks, to provide a scalable and dynamic environment for the development of services to remotely control and monitoring devices such as, sensors and actuators. The whole architecture was developed following a model based on actors, which enabled a dynamic manipulation of components for IoT applications. As also, using a widely-used protocol, it was possible to establish the communication in a practical and intuitive way through a MQTT broker integrating with cloud services. A JSON based data model (oneIoTa) was used to ensure interoperability between devices. The approach has been successfully developed, as can be verified in its validation procedure. This infrastructure can be adapted to other environments, such as industrial, hospital or business, according to each user's need. In the future, we should include several other devices, providing a means of remote monitoring of these devices and their location in application domains.

Abstract—This paper addresses the problem of recovering behavioural models from IoT devices in order to help engineers understand how they are functioning and audit them. We present a model learning approach called ASSESS, which takes as inputs execution traces collected from IoT devices and generates models called systems of Labelled Transition Systems (LTSs). ASSESS generates as many LTSs as components integrated and identified into a device. The approach is specialised to IoT devices as it takes into account two architectures often used to integrate components with this kind of system (cyclic functioning, loosely-coupled or decoupled architectures). We experimented the approach on two IoT devices and an IoT gateway to evaluate the model conciseness and the approach efficiency.

Keywords—Reverse engineering; IoT; Model learning; Passive learning.

I. INTRODUCTION

Internet connected devices, and especially Internet of Things (IoT), belong to the digital transformation trends proposed by industrial experts or advisory firms for several years. The IoT, which we consider as a network of smart embedded devices connected to the Internet, is indeed a broad-based concept, transforming several uses from consumer devices to large-scale manufacturing. However, many customers and companies prefer staying away from the IoT hype because of the issues related to privacy and more generally to security. It is indeed manifest that IoT devices have to be audited before using them, in particular in the industry or in healthcare. Many companies chose to outsource the IoT development for saving costs, hence the IoT audit is rather done after the development. It is often carried out from the source code or from devices seen as black boxes. A common solution to help audit such devices is to apply a reverse engineering process, which is usually done by hands. From a black-box, this process is required to understand how devices are functioning. Besides, it helps document the behaviours of IoT devices or IoT networks, and may serve to detect bugs or security issues.

In the literature, some papers dealing with the reverse engineering of IoT devices have been published recently [1], [2]. These approaches recover critical information or detect privacy issues from source codes, firmwares or chips.

This paper proposes another approach called ASSESS (Analysis, Extraction, Separation, Synchronisation) to recover behavioural models from IoT devices. Our approach, which is based on the model learning concept, takes execution traces collected from IoT devices and generates models called systems of LTSs (Labelled Transition System). Model learning approaches [3], [4], [5], [6], [7], [8] have proven to be valuable for retro-engineering models that can be exploited in several software engineering steps. Our approach advances the state of the art in these two points.

- It is specialised to IoT devices in the sense that their general functioning is considered while the model generation. We define an IoT device as an embedded device integrating several components and running in a cyclic way [9]. Several works focused on the component architectures of embedded devices, i.e. on how to compose them efficiently. It is often advised to use a loosely-coupled architecture [10], where components remain autonomous and allow middleware software to manage internal communication between them. With this kind of architecture, components are synchronised together. However, we also observed that IoT devices may also have a decoupled architecture, where the components operate independently. We consider both architectures for the model generation.
- Most of the model learning algorithms build one big model for a given system. Such models may quickly become uninterpretable. We focused on this problem and laid the first stone of the approach in [11]. Our approach builds as many LTSs as components detected in logs collected from an IoT device. From these messages, our approach is able to build traces and infer systems of LTSs. Two strategies, which refer to the previous IoT device architectures, are proposed to synchronise LTSs together to form a complete model. The present approach target specific system, IoT devices, and relax some assumption with the modification of algorithms.

We have implemented a prototype tool to experiment our algorithms and appraise their benefits. We provide a preliminary evaluation in the paper made on two IoT devices. Besides, this experimentation also shows that ASSESS may be applied on an IoT gateway to recover a model

expressing the behaviours of an IoT network, i.e. of the devices communicating with this gateway.

The paper is organized as follows: we recall some definitions about the LTS model in Section II. Our approach is presented in Section III. The next section shows some results of our experimentation. Section V summarises our contributions and draws some perspectives for future work.

II. THE LTS MODEL

We express the behaviours of components with Labelled Transition Systems (LTS) as defined in [12]. This model is defined in terms of states and transitions labelled by actions, taken from a general action set \mathcal{L} , which expresses what happens. τ is a special symbol encoding an internal (silent) action; it is common to denote the set $\mathcal{L} \cup \tau$ by \mathcal{L}_τ .

Definition 1 (LTS) A Labelled Transition System (LTS) is a 4-tuple $\langle Q, q_0, \Sigma, \rightarrow \rangle$ where:

- Q is a finite set of states; q_0 is the initial state;
- $\Sigma \cup \{\tau\} \subseteq \mathcal{L}_\tau$ is the finite set of actions, with τ the internal (unobservable) action;
- $\rightarrow \subseteq Q \times \Sigma \cup \{\tau\} \times Q$ is a finite set of transitions. A transition (q, a, q') is also denoted $q \xrightarrow{a} q'$.

We use the generalised transition relation \rightarrow to represent LTS paths: $q \xrightarrow{a_1 \dots a_n} q' =_{def} \exists q_0 \dots q_n, q = q_0 \xrightarrow{a_1} q_1 \dots q_{n-1} \xrightarrow{a_n} q_n = q'$. We also use the following notations on action sequences. The concatenation of two action sequences $seq_1, seq_2 \in \mathcal{L}_\tau^*$ is denoted $seq_1.seq_2$. ϵ denotes the empty sequence. A trace is a finite sequence of observable actions in \mathcal{L}^* .

To better match the functioning of IoT devices, we assume that an action has the form $a(\alpha)$ with a a label and α an assignment of parameters in P , with P the set of parameter assignments. For example, $switch(id := 115, cmd := on)$ is made up of the label "switch" followed by the assignment $(id := 115, cmd := on)$ of two parameters.

The use of LTSs allows to exploit the definitions related to the LTS composition. The integration of two components C_1 and C_2 , modelled with LTSs, is often defined by two operations in the literature. The first one is the parallel composition of C_1 and C_2 denoted $C_1 \parallel C_2$, which synchronises their shared actions, also called *synchronisation actions* (the rest must happen independently). This composition is often followed by the hiding of the communications between C_1 and C_2 to express that only the communications with the environment are observable. This operation is defined by the relation $hide\ S\ in\ C_1 \parallel C_2$ with S a set of actions. We refer to [13] for the definitions of these two LTS operators.

This principle of LTS composition leads to a model called system of LTSs, which describes a component-based system:

Definition 2 (System of LTSs) A system of LTSs SC is the couple $\langle S, C \rangle$ with $C = \{C_1, \dots, C_n\}$ a non empty set of LTSs, and S a set of synchronisation actions.

III. THE ASSESS APPROACH

This section presents our model learning approach, which aims at inferring system of LTSs from messages given by an IoT device. The later is seen as a black box and integrates components by means of a loosely coupled or a decoupled architecture. We assume that the components produce messages or logs which include component identifiers, i.e. parameter assignments allowing to identify components. However we consider that the component calls are hidden. This is usually the case with IoT devices integrating several sensors. Furthermore, the messages have to include timestamps for ordering them. A logical clock mechanism may be required to add timestamps in logs.

The list of messages is initially translated into a set of execution traces with our tool TFormat¹. This one starts by filtering and formatting raw messages into actions by means of regular expressions. Then, the tool analyses the timestamps of every pair of successive actions and computes means of time intervals. It searches for gaps between actions (distinctive longer durations), which are usually observed when an execution trace ends and another one begins. The time gap detection is used for the trace extraction. We denote the trace set $Traces(SUL)$ and assume that a trace has the form $a_1(\alpha_1) \dots a_k(\alpha_k)$.

The model generation is performed by three steps called "Trace Extraction", "LTS Generation", and "LTS Synchronisation". The last step proposes two LTS generation strategies called "LTS Loose-coupling" and "LTS Decoupling". These steps are illustrated with the example of Figure 1. In the first step, the traces of $Traces(SUL)$ are analysed to detect component calls by covering the component identifiers found in actions. The example of Figure 1 lists 3 traces that capture the behaviours of two components ($id:=1, id:=3$), which call other components. The component calls are here detected whenever a new identifier is found ($id:=2, id:=3$). In a trace, the action sequences having different identifiers are extracted and replaced by synchronisation actions of the form $call(id)$ and $return(id)$ to express component calls, with id an identifier referring to a component. Next, the resulting traces are partitioned to gather the traces having the same identifier. We obtain 3 trace sets in our example of Figure 1.

The step "LTS Generation" transforms each previous trace set into a LTS. In this step, we take into account the general functioning of the IoT devices, which are usually designed to perform actions in a cyclic way. The traces are hence transformed into cyclic LTS paths, the later being joined on an initial state. Once every trace set is transformed into a LTS, we obtain a first system of LTSs $SC = \langle S, C \rangle$ with C the set of LTSs and S the set of synchronisation actions.

The last step transforms this system of LTSs to produce more general models with respect to the nature of the IoT devices. As stated earlier, we consider that these devices

¹<https://github.com/sasa27/TFormat>

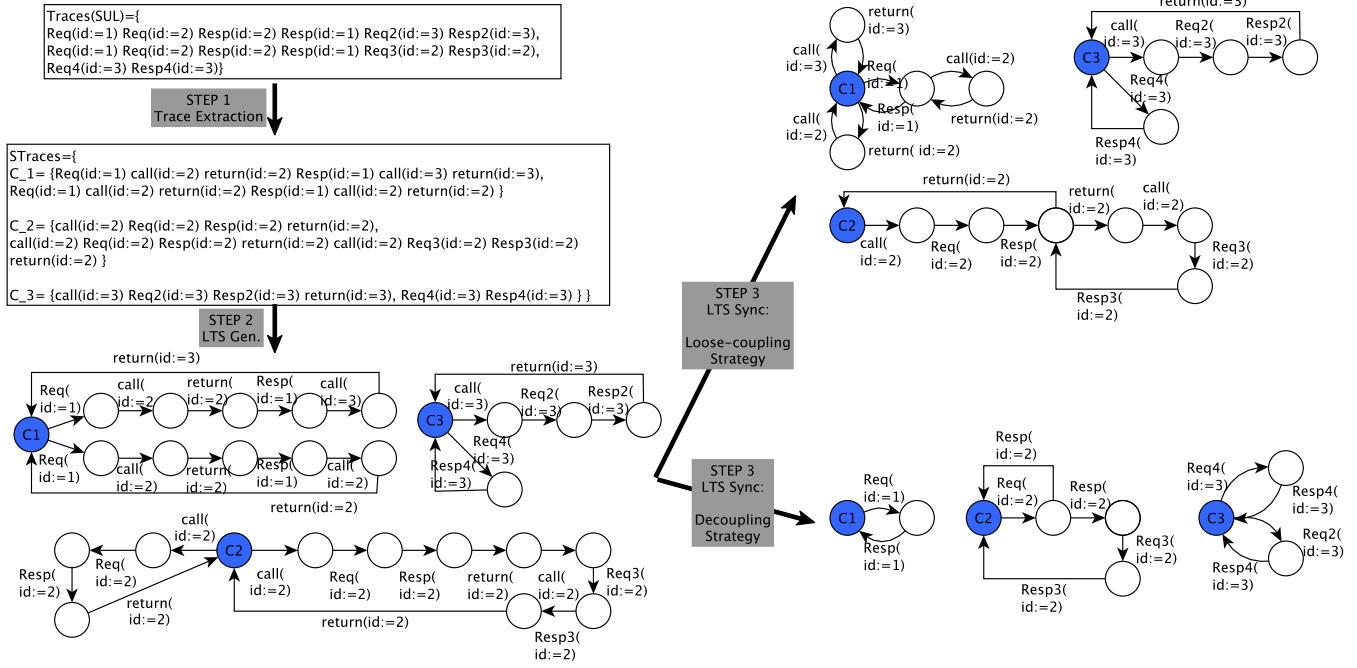

Figure 1: The ASSESS approach overview

may integrate loosely-coupled or decoupled components. The strategy “LTS Loose-coupling” builds a system of LTSs $SC1$ such that $SC1$ allows repetitive calls of components, which are synchronised together. This is materialised by replacing the sequences $q_1 \xrightarrow{call(id) \ return(id)} q_2$ with loops. Then, we apply the kTail algorithm [3]. kTail is a well-known approach that merges the (equivalent) states having the same k-future, i.e. the same event sequences having the maximum length k . We obtain three LTSs in Figure 1(right-top side) expressing components that call each other.

The strategy “LTS Decoupling” produces another system of LTSs $SC2$ from SC to express the behaviours of independent components. The synchronised actions are removed from the LTSs of SC . Then, the kTail algorithm is applied. We obtain three LTSs expressing autonomous components. Now, we detail these steps below.

A. Step 1: Trace Extraction

This step covers the traces of $Traces(SUL)$ and the identifiers included in actions to detect implicit component calls and to gather the traces related to each component in separate trace sets. The following definition formalises the notion of component identification:

Definition 3 (Component identification) Let $a_1(\alpha_1)$ be an action of \mathcal{L} . The component identifier of $a_1(\alpha_1)$ is given by the mapping $ID : \mathcal{L} \rightarrow P$, which gives the parameter assignment α' found in α_1 that identifies the component producing the action $a_1(\alpha_1)$.

The component identifier of a sequence $a_1(\alpha_1)a_2(\alpha_2) \dots a_k(\alpha_k)$ is given by the mapping $ID_s : \mathcal{L}^* \rightarrow P$. $ID_s(a_1(\alpha_1)a_2(\alpha_2) \dots a_k(\alpha_k)) =_{def} \begin{cases} \alpha' \text{ iff } \forall a_i \notin \{call, return\} : ID(a_i(\alpha_i)) = \alpha' (1 \leq i < k) \\ \{\} \text{ otherwise.} \end{cases}$

For simplicity, we denote the mapping ID_s by ID in the remainder of the paper.

Algorithm 1: Component Trace Detection

```

input :  $Traces(SUL)$ 
output :  $STraces$ 
1  $Traces := \{\}$ ;
2 foreach  $t = a_1(\alpha_1)a_2(\alpha_2) \dots a_k(\alpha_k) \in Traces(SUL)$  do
3    $id := ID(a_1(\alpha_1)); T := \{\}$ ;
4    $T := Extract(t, T, id)$ ;
5    $Traces := Traces \cup T$ ;
6  $STraces := GroupById(Traces)$ ;
7 return  $STraces$ ;

```

The Trace Extraction step is implemented with Algorithm 1, and its two procedures *Extract* and *GroupById*. The algorithm covers every trace t of $Traces(SUL)$, extracts the identifier id of the first running component found in the first action of t and calls the procedure *Extract*. The latter takes t , id and a set T used to store new traces. *Extract* potentially splits t into several traces, each having one non empty component identifier. Then, the procedure *GroupById* partitions all the traces given by *Extract* and returns the set $STraces = \{C_1, C_2, \dots, C_n\}$ such that the traces of a set C_i exhibit the behaviour of one component only. The procedure *Extract*($t = a_1(\alpha_1)a_2(\alpha_2) \dots a_k(\alpha_k)$, T, id) is given in Algorithm 2. It covers the component identifiers in the actions of t to detect component calls. While covering the actions of t , if an identifier n different from *newid* (first identifier of the current trace) is found (line 6), we assume that a new component has been called by the current one. In this case, the procedure searches for the sequence $a_{i+1}(\alpha_{i+1}) \dots a_{j-1}(\alpha_{j-1})$ composed of actions having identifiers different from *newid*. This sequence is extracted and replaced by the synchronisation actions

Algorithm 2: Procedure Extract

```

1 Procedure Extract( $t = a_1(\alpha_1)a_2(\alpha_2) \dots a_k(\alpha_k), T, id$ ):  $T$  is
2    $newid := Identifier(a_1(\alpha_1));$ 
3    $t' := a_1(\alpha_1); a_{k+1}(\alpha_{k+1}) = \epsilon; i := 1;$ 
4   while  $i < k$  do
5      $n := ID(a_{i+1}(\alpha_{i+1}));$ 
6     if  $n == newid$  then
7        $t' := t'.a_{i+1}(\alpha_{i+1});$ 
8        $j := i + 1;$ 
9     else
10      find smallest  $j > i$  such that  $ID(a_j(\alpha_j)) == newid$ 
11      or  $j := k + 1;$ 
12       $t' := t'.call(n).return(n).a_j(\alpha_j);$ 
13      if  $(j - i) > 2$  then
14         $Extract(a_{i+1}(\alpha_{i+1}) \dots a_{j-1}(\alpha_{j-1}), T, id);$ 
15      else
16         $t_n := call(n).a_{i+1}(\alpha_{i+1}).return(n);$ 
17        if  $\exists t_2 \in T : ID(t_2) == n$  then
18           $t_n := t_2.t_n; T := T \setminus \{t_2\};$ 
19         $T := T \cup \{t_n\};$ 
20       $i := j;$ 
21   if  $newid \neq id$  then
22      $t' := call(newid).t'.return(newid);$ 
23   if  $\exists t_2 \in T : ID(t_2) == newid$  then
24      $t' := t_2.t'; T := T \setminus \{t_2\};$ 
25    $T := T \cup \{t'\};$ 
26   return  $T;$ 

```

$call(n).return(n)$, which model the call of a component C_n . If the extracted sequence has more than one action, the procedure *Extract* is recursively called (line 13). Otherwise, it builds a trace t_n composed of the action $a_{i+1}(\alpha_{i+1})$ surrounded by synchronisation actions. If there exists a trace t_2 in T having the identifier n , t_n is concatenated to t_2 . t_n is added to the trace set T . Once the trace t is covered, we obtain a new trace t' including synchronisation actions. The procedure *Extract* eventually checks whether t' has to be completed to express that this trace was produced by a component called by another one: if the identifier of t' is different from the identifier id given as input (line 20) then the trace t' is surrounded with $call(idnew)$ and $return(idnew)$. Finally, if there exists a trace t_2 in T having the component identifier $idnew$, then t' is concatenated to t_2 . The final trace t' is added to T .

The procedure *GroupById(Traces) : STraces*, partitions the trace set *Traces* in such a way that every subset holds traces sharing the same non empty component identifier. We partition *Trace* by defining the trace equivalence relation \sim_{id} and by extracting the equivalences classes of *Trace* for \sim_{id} . Let \sim_{id} on \mathcal{L}^* be given by $\forall seq_1, seq_2 \in \mathcal{L}^*, seq_1 \sim_{id} seq_2$ iff $ID(seq_1) = ID(seq_2)$. The procedure *GroupById* returns the partition $STraces = Trace / \sim_{id}$.

B. Step 2: LTS Generation

At this stage, *STraces* gathers n subsets with n the number of component identifiers found in the traces of *Traces*(SUL). These subsets of traces are now transformed into LTSs. Intuitively, given T_1 in *STraces*, a trace of T_1 is

lifted to the level of a LTS cyclic path. The LTS is obtained after joining the paths by means of a disjoint union on the state q_0 :

Definition 4 (LTS inference) Let $T_1 \in STraces$ be a trace set. The LTS C_1 expressing the behaviours found in T_1 is the tuple $\langle Q, q_0, \Sigma, \rightarrow \rangle$ where q_0 is the initial state, and Q, Σ, \rightarrow are defined by the following rule:

$$\frac{t = a_1(\alpha_1) \dots a_k(\alpha_k), id = ID(t)}{q_0 \xrightarrow{a_1(\alpha_1)} q_{id1} \dots q_{idk-1} \xrightarrow{a_k(\alpha_k)} q_0}$$

Once the LTS generation is completed, we obtain a first system of LTSs $SC = \langle S, C \rangle$ with C the set of LTSs derived from *STraces* and S the set of synchronized actions.

C. Step 3: LTS Synchronization

Algorithm 3: LTS Synchronisation Strategies

```

1 Procedure Loose-coupling( $SC = \langle S, \{C_1, C_2, \dots, C_n\} \rangle$ ):  $SC_1$  is
2   foreach  $C_i = \langle Q, q_0, \Sigma, \rightarrow \rangle \in C$  do
3     foreach  $q_1 \xrightarrow{call(\sigma).return(\sigma)} q_2$  do
4       merge  $q_1$  and  $q_2$ ;
5        $C'_i := kTail(k = 2, C_i);$ 
6   return  $\langle S, \{C'_1, C'_2, \dots, C'_n\} \rangle$ 
7 Procedure Decoupling( $SC = \langle S, \{C_1, C_2, \dots, C_n\} \rangle$ ):  $SC_2$  is
8   foreach  $C_i = \langle Q, q_0, \Sigma, \rightarrow \rangle \in C$  do
9      $C_i := \text{hide } S \text{ in } C_i;$ 
10     $C_i := \tau\text{-reduce } C_i;$ 
11     $C'_i := kTail(k = 2, C_i);$ 
12  return  $\langle S, \{C'_1, C'_2, \dots, C'_n\} \rangle$ 

```

This last step proposes two strategies to synchronise the LTSs of SC with regard to the architecture considered to integrate components together. Both strategies are implemented in Algorithm 3 with two procedures.

The strategy “LTS Loose-coupling” builds a new system of LTSs SC_1 from SC and keeps the transitions carrying synchronised actions. This strategy allows repetitive calls of components but also makes these calls optional by replacing the transition sequences of the form $q \xrightarrow{call(\sigma).return(\sigma)} q'$ by loops (lines 3,4).

The strategy “LTS Decoupling” gives another system of LTSs SC_2 from SC by firstly hiding the synchronisation actions. The operator $\text{hide } S \text{ in } C_i$ transforms the transitions of C_i by replacing the actions of S with the non observable action τ . We then reduce C_i by removing the transition labelled by τ . Several algorithms are proposed in the literature to perform this LTS reduction with respect to a given LTS equivalence relation. However, as the LTSs generated by Step 2 have a simple structure (only one outgoing transition per state), we propose a lightweight LTS reduction operation denoted τ -reduction:

Definition 5 (τ -reduction) Let $C_1 = \langle Q_1, q_{01}, \Sigma, \rightarrow_1 \rangle$ be a LTS. τ -reduction $C_1 =_{def} \langle Q_2, q_{02}, \Sigma, \rightarrow_2 \rangle$ where $Q_2, q_{02}, \rightarrow_2$ are the minimal sets satisfying the following inference rules:

$$\begin{array}{ccc} \frac{q_1 \xrightarrow{a(\alpha)} q_2}{q_1 \xrightarrow{a(\alpha)}_2 q_2} & \frac{q_1 \xrightarrow{a(\alpha)} q_2 \xrightarrow{\tau \dots \tau} q_3}{q_1 \xrightarrow{a(\alpha)}_2 (q_2 q_3)} & \frac{q_1 \xrightarrow{\tau \dots \tau} q_2 \xrightarrow{a(\alpha)} q_3}{(q_1 q_2) \xrightarrow{a(\alpha)}_2 q_2} \end{array}$$

kTail is finally applied on the LTSs achieved by both strategies. We use $k = 2$ as recommended in [6].

Both systems of LTSs SC_1 and SC_2 offer different points of view. With SC_1 , the component calls are explicitly given, which offers the possibility of extracting a dependency graph of components showing how the components are hierarchically organised. With the system of LTSs SC_2 , as the transitions carrying synchronised actions are removed, the parallel composition of the LTSs expresses the behaviours of asynchronous and autonomous components, which hence produce actions independently of the others. As it is illustrated in Figure 1, the second strategy returns more compact and general models.

IV. PRELIMINARY EVALUATION

We have implemented our approach in a tool, with which we began a first evaluation to answer to these two questions:

- RQ₁: can ASSESS extract more concise and readable models than the ones generated by kTail?
- RQ₂: how long does ASSESS take to generate models?

Setup: we applied ASSESS on two IoT devices and one IoT gateway. The first device (*exp.1*) is a smart thermostat controlling heat-pumps via infra-red, composed of 4 components (a Web server, two sensors, and a component that manages the heating mode). The second device (*exp.2*) is a Wifi IP camera that integrates 5 components. The IoT gateway (*exp.3*) was interconnected to 8 autonomous devices, which we consider as components for the experimentation. We collected HTTP messages from these systems and formatted them with our tool TFormat. The results and the tool are available here².

A. Question RQ₁

Procedure: we collected traces for every setup and ran ASSESS with its two strategies. We also ran kTail on the same trace sets for comparison purposes. Then, we measured the sizes of the generated models. These are given in Table I. Furthermore, with large trace sets, model learning might return spaghetti-like models, containing an uninterpretable mess of transitions. We compared the generated models to deduce whether ASSESS can significantly help reduce this spaghetti model problem by inferring one model per component.

Exp.	kTail		Loosely-coupled		Loosely-coupled without <i>call</i> and <i>return</i>		Decoupled	
	#states	#trans	#states	#trans	#states	#trans	#states	#trans
<i>exp.1</i>	52	90	116	208	61	118	31	54
<i>exp.2</i>	92	186	172	346	80	193	36	76
<i>exp.3</i>	349	419	426	552	362	439	310	339

Table I: Size of the LTSs obtained with kTail and ASSESS.

Figure 2: Overview of the models generated with kTail (*exp.3*)

Figure 3: Overview of the models generated with ASSESS (*exp.3*)

Results: Table I shows that we obtain larger transition sets with the "LTS Loose-coupling" strategy. In average, the state number is increased by 77.33% in comparison to the results of kTail. This is due to the addition of transitions labelled by synchronisation actions, which show how components interact with one another. If we do not take into account these transitions, we obtain models whose sizes are close to the sizes of the models generated by kTail. With the "LTS Decoupling" strategy, we always obtain more concise models. The state number is reduced on average by 37.33% with this strategy. The state reduction is a consequence of the segmentation of the traces by our algorithm. We infer one LTS for each component, which is easier to reduce with kTail than one big model. Afterwards, we compared the models generated by kTail and ASSESS and manifestly concluded on these experimentations that the systems of LTSs are significantly more interpretable. Figure 2 shows an overview of the "spaghetti"-like model generated by kTail for *exp.3*. This model (even zoomed) is difficult to understand. Figure 3 illustrates the system of LTSs generated by ASSESS (second strategy). We believe that the later is more readable since every component is represented by its own model whose transition set is smaller. Besides, a system of LTSs sounds more adaptable to the user needs. For instance, an undesired component may be concealed to help focus on the others.

²<https://github.com/Elblot/ASSESS>

B. Question RQ₂

Procedure: to investigate RQ₂, we measured the execution times of ASSESS with several trace sets containing 10 to 35000 traces of around 150 events collected from *exp.3*. Experimentations were done on a computer with 1 Intel(R) CPU i5-6500 @ 3.2GHz and 16GB RAM. Figure 4 draws two curves showing the execution times measured with both strategies.

Figure 4: Executions times of ASSESS

Results: Figure 4 shows that ASSESS requires less than 60 seconds to build models with the largest trace set. The tendency curves also confirm that the time complexity of both strategies is linear. Regarding the memory space complexity, we also observed a linear curve; we reached a memory limit between 25000 and 30000 traces (more than 3.5 millions of events) with the Loose-coupling strategy, and between 35000 and 40000 traces (more than 5 millions of events) with the Decoupled strategy. We hence believe that our tool can be used with systems producing a huge amount of messages.

V. CONCLUSION

The increase in IoT technologies popularity holds many benefits, but it is also accompanied by many concerns related to the IoT device reliability and security. Learning models from these devices may serve to audit them. However recovering models usable for inspection is still challenging. So far, most of the learning algorithms build big models and do not take into consideration the IoT device architectures. In this paper, we have presented ASSESS, a model learning method dedicated to IoT devices that recovers systems of LTSs. The method constructs execution traces from messages or logs, and generates LTSs that capture the behaviours of all the components of an IoT device and their synchronisations. Two strategies are proposed to adapt the model generation with regard to the loosely-coupled or decoupled architecture usually used to design embedded devices.

Our future work includes further evaluating ASSESS on other kinds of IoT devices, improving its effectiveness by devising parallel algorithms, and proposing other strategies to better match the available IoT architectures and frameworks.

Abstract—This work proposes an architecture for sharing devices' resources in the Internet of Things providing real sensor data for its users. The main idea is based on the fact that users such as developers and researchers do not always have access to the necessary hardware and resource sharing should impact these persons activities. Taking advantage of the Sensors as a Service model, we propose an architecture where several sensors and actuators can be coupled to environments and they also are represented virtually in a web system becoming available to be consumed by users and platforms. The architecture is composed of three layers and a model representing devices, the cloud, and clients, and how they interact with each other. A study case for testing the whole approach is also presented.

Index Terms—Internet of Things, Embedded Systems, Ubiquitous Computing

I. INTRODUCTION

The number of computing devices used in daily tasks, the internet coverage as well as how to handle data, are increasingly being used to improve people's lives and together with the Internet of Things (IoT), they are the key to the development of a wide range of applications [1]. These large number of components open up relevant issues, such as sharing data in heterogeneous environments once sensors deployment often employs high costs. Then, mechanisms for resource sharing should play a major role in this scenario.

These applications gather data from several sensors and the number of devices can make the project unfeasible. There is an emerging cloud computing model named Sensors-as-a-Service, where users can make public their own sensors' data to be consumed by other clients [2]. However, it is difficult to integrate and deploy such systems due to the heterogeneity of devices and communication technologies [3], [4]. Considering this, middleware for IoT play an important role in these systems since they can deal with the heterogeneity of hardware, data distribution, and communication protocols.

So, the objective of this paper is to propose an architecture for the management of resources and to expose them as a service in an IoT network. This Resource Management Architecture (RMA) is divided into three layers of abstractions where devices are responsible for keeping the real resources independently from the core of RMA, which deals with the virtualization, registering and updating of data from devices.

Then, clients can consume this data as a service using exposed web services that access the virtualization layer. The aim of RMA is to provide an integrated solution to be used in any domain since its general architecture is not bounded to any application provided and to work as a repository of devices where researchers can make their data consumable to other persons who might be interested in them.

The RMA is built over instances of a robust middleware for IoT in its layers, which treats the connectivity and scalability of devices [5]. Besides, we also propose a structure for the development of devices able to self-configuration in the RMA. Finally, the RMA can be accessed by web services or other web solutions. The rest of this paper is structured as follows: in section II, we present the related works; section III presents our proposed architecture and their components; in section IV, it is described the implementation of RMA; section V the RMA is evaluated based on software engineering methods. Finally, conclusions are discussed in section VI.

II. RELATED WORKS

During the last years, several approaches try to deal with shareable resources in different domains. For example, the research in Ambient Intelligent has been searching for technological strategies to improve the people life quality and solve problems caused by population growth in urban areas. A lot of papers explore technologies for improving citizen services and how to add value to public administration in Smart Cities [6]. In these cases, there are data coming from people, social networks, household, organizations (public and privates), and so on. Devices are often used in such approaches however, issues as interoperability, communicability, and how to turn data public and consumable are not in their scope. In this paper, we present an architecture that can be used to provide a layer of consumable devices that can be applied in any domain and deal with those issues.

When considering systems that use sensors as a service, there is an interoperable system [7] that offers a web service description language interface designed for users to access sensors. However, its main focus is on low-power wireless sensor nodes and energy profile. The SOCRADES middleware [8] is a solution for business integration that offers a web service-oriented architecture that integrates different types of intelligent objects. It uses an enterprise business solution

system to provide the ability of users to construct services based on physical objects using the Web of Things [9] and using REST applications [10]. These approaches tie the design of the device to the web system restraining new devices to be added at runtime. In our proposed approach, devices have their own mechanism for dealing with the core system at runtime.

III. THE RESOURCE MANAGEMENT ARCHITECTURE

In this section, we present the Research Management Architecture (RMA), an architecture responsible for the virtualization of devices that act as IoT objects, exposing their sensors and actuators to be accessed and consumed by who might be interested in their functionalities. These resources' data are maintained at runtime in a model that can be publicly visualized and subscribed for several purposes. Exposing devices as a service that can be virtually consumed brings some advantages since users do not need to have their own devices, reducing eventual costs in creating new ones. In this way, users can provide a shareable resource component that can be exploited for several purposes. The proposed architecture (Figure 1) is composed of three different layers:

- 1) **Device:** in this layer, the devices have an embedded system enhanced with a processing cycle where (i) it connects and registers in the Cloud layer at the very first time; (ii) it gathers data from all its sensors to be sent to the cloud layer and; (iii) it receives from the Cloud layer actions that must be executed by the device's actuators.
- 2) **Cloud:** it is capable of maintaining updated information from devices hosted in environments and running over an IoT middleware. The Resource Management Component (RMC) manages (i) the registering process of devices; (ii) the sensors' data updating process, and; (iii) the actions that must be executed by devices. Besides, it also capable of exposing RESTful web services for several purposes.
- 3) **Client:** it is responsible for the visualization of devices and environments. In this paper, it is represented as a web solution. It implements a publish and subscribe mechanism for allowing developers and researchers in obtaining data from real sensors without possessing them and it offers an infrastructure for those who want to provide sensors as a service.

In the RMA, a device is an IoT object equipped with a micro-controller (hardware) where sensors and actuators are plugged in. The devices host an embedded system capable of connecting and registering to the Cloud layer for providing current data to be consumed by users. The embedded system dynamically registers itself in the RMC by sending all its functionalities (available resources, data and action commands) and the environment it is situated. Once connected, the device receives a confirmation and it starts to send data gathered from its sensors directly to the RMC, which keeps the most recent value available to be consumed or visualized in a web panel in the Visualization layer. Besides, the embedded system deals with the action commands coming from the RMC that need to be executed by the device's actuators.

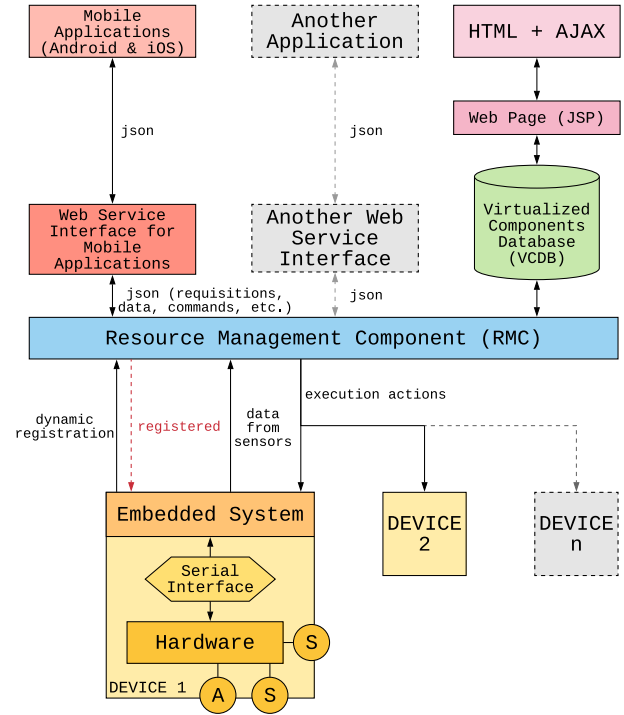

Fig. 1. The Resource Management Architecture's (RMA) components.

The RMC is the main component in the RMA and it maintains information about devices and environments to be consumed as a service by other layers. It has a mechanism for registering devices in given environments, storing their information in the Virtualized Components Database (VCDB). The VCDB keeps updated the data coming from devices by considering only the new values that have changed since the last data message was received. In addition, this layer exposes web services for providing different services such as visualization layers for mobile applications or allowing new technologies to interact and access the VCDB. Web services use a RESTful architecture for system interoperability and it uses Json files for exchanging information (data, requisitions, and execution commands) between the Cloud and Client layers.

The actions that need to be executed by devices are managed by the RMC. Any user that desire to perform an action in any available actuator must send an action command by accessing one of the provided services. The RMC redirects the action directly to the specific device. The technical information about hardware and actuators is transparent to the end user, that just need to know the available commands of the device he or she wants to interact. While one device is being used, the RMC blocks the specific actuator or the entire device for avoiding conflicts in the lower layer. The respective resource is unlocked after the execution or after a timeout boundary.

The RMC is a server-side solution running an IoT middleware instance where the devices must connect to. The middleware provides the connectivity and communicability necessary for devices to interact with the RMC layer and it

should guarantee the scalability of the system. These issues are not the focus of this work, however more technical details about the chosen middleware are provided later in Section IV.

For facilitating the environments managing, this layer provides a web page where all the environments can be accessed at real-time and users can create their own public or private environments. This web system shows all the public environments allowing users to select and see their available information and subscribe to have access to a specific and personalized group of information. In this work, an environment is defined by a logical representation of a physical space where several devices can co-exist sharing information in an IoT network.

IV. IMPLEMENTING THE RMA'S LAYERS

In this section, it is presented the implementation of the Device, Cloud and Client layers considering technological components and how these layers communicate with each other. For both Device and Cloud layers, we employ the ContextNet middleware [5], which is an IoT middleware for context reasoning and data sharing in a large scale environment. It is a context-providing service for stationary and mobile networks, which already addresses data communication issues such as fault tolerance, load balancing, node disconnect support (handover), and security. It uses the OMG DDS [11] protocol for handling messages between clients.

The Device layer uses a low coupled serial interface [12] for communicating with the micro-controllers that hosts the sensors and actuators. This interface isolates the high-level programming from the low-level using serial commands for activating users' pre-defined functions, which controls actuators or gathers data from sensors. The Client layer employs a web system capable of managing environments, showing their available resources, and it has a publish and subscribe mechanism for users interested in specific resources. All layers consider a model where these resources are part of devices situated in pre-existing environments in the architecture. For instance, the environments have to be manually registered by the user to facilitate their management and for security issues. This model is represented as a class diagram (Figure 2) shared between the three layers. The classes that can be found in our solution are described as follows:

- **Action:** the action that is executed at the low-level hardware in a device. Every command sent by the the Client and Cloud layers becomes an action in the Device layer.
- **Command:** it is the representation of commands available to be executed if the resource is an actuator. Sensors do not have commands because they are data providers.
- **Cycle:** it is the functioning cycle of the embedded system hosted in devices. It is responsible for synchronizing the device activities of sending data and executing actions.
- **Device:** it is the device representation used in the Client, Cloud and Device layers. It keeps the identification, name and description of a device and it is composed resources.
- **Embedded Client:** it is the ContextNet client instance responsible for receiving messages from the Cloud layer and other clients, and sending the data from sensors to

the Cloud layer. It also maps the components of the configuration file into its respective components.

- **Environment:** the virtual representation of environments in all layers. Each environment is composed of devices.
- **Main:** the main class that starts a device.
- **Resource:** it represents both sensors and actuators in all layers. The resources keep information about the serial port where the resource is connected, the available commands to be executed, and the availability of the resource.
- **Resource Management:** it is the main class of the cloud layer and it is a server instance of the ContextNet. It keeps a list of environments mapped and the devices registered for each one. It is responsible for the process of registering and updating devices and resources. It also exposes the web servers and the interfaces to the database.
- **Serial Communication:** the serial interface between the micro-controller and the system hosted at devices.

A. The Device Layer

The Device layer comprises devices running an embedded system with enough processing power interfacing sensors and actuators. There is a physical and logical architecture for clients where the first one uses hardware technologies and it is composed of a tiny mobile board with Bluetooth and WiFi connections (e.g. Raspberry Pi) connected to one or more micro-controllers using serial communication for accessing sensors and actuators. The logical architecture of the Device layer comprises both micro-controllers' programming and the embedded system. They are able of gathering the raw data from the sensors and then send it to the embedded system. After that, the embedded system sends the data to the Cloud layer or receive commands to be executed by actuators.

The micro-controller is programmed in a loop for verifying if there are messages coming from other layers. So, it accesses all the sensors and mounts a string to be sent by serial communication to the embedded system. Otherwise, the execution action is verified and if exists an equivalent programmed, an action is executed in the respective actuator.

Algorithm 1 Device's Processing Cycle

```

1: procedure CYCLE(configurationFile)
2:   mountDevice(configurationFile)
3:   intervalTime ← getIntervalTime()
4:   loop
5:     if isRegistered() then
6:       gatheredData ← dataFromSensors()
7:       sendToCloud(gatheredData)
8:       wait(intervalTime)
9:       actions[] ← getReceivedActions()
10:      executeNextActions(actions[])
11:     else
12:       registerDevice()

```

The embedded system controls the microcontroller and it uses a ContextNet client able to communicate with the Cloud layer. For this, there is a cycle (Algorithm 1) for synchronizing

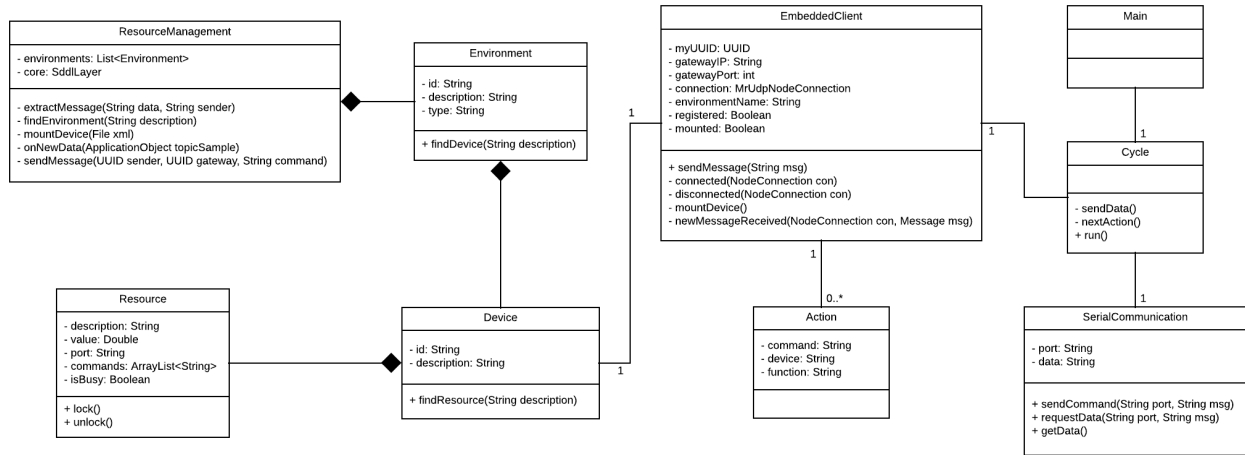

Fig. 2. The class diagram of the overall architecture comprising the Client, Cloud and Device layers.

the reception of data coming from sensors to be sent to the Cloud layer and the actions that need to be sent and executed in the micro-controller because both cannot execute at the same time for avoiding undesired conflicts. So, the actions received from the Cloud layer are put in a queue of actions to be executed one step after the data from sensors are collected through serial ports. It is also capable of performing a self-configuration and registration at the Cloud layer when it starts running and there is a cloud server available. For this, the device keeps an XML file describing all the available resources, commands, and the server configuration information. Once the file is correctly filled, the system performs everything automatically. The following information must be provided:

- (i) **Server:** the gateway of the server and the port must be provided in order to connect to the Cloud layer where the server instance of the ContextNet is installed. Besides, the time interval of sending data to the server must be set.
- (ii) **Environment:** for instance, it is necessary to inform in which environment the device is inserted into. For this, the identification number of the environment must be declared in the configuration file. The environment's identification is generated when users register an environment in the web system.
- (iii) **Resources:** all the resources available must be mapped in the configuration file. All the resources have the serial port where it is connected, its name, and a non-mandatory description. If the resource is an actuator, it also has the available execution commands.

The embedded system architecture is composed by the *Cycle* class, which instantiates an instance of ContextNet client (represented by the *EmbeddedClient* class) capable of exchanging message with other clients and the cloud server. Besides, the *EmbeddedClient* is responsible for the serial interface and it deals with a queue of actions received from the Cloud layer that has to be executed. The *SerialCommunication* and *Action* are the classes responsible for these behaviors.

B. The Cloud Layer

The cloud layer is a server instance of the ContextNet running a core system responsible for the virtualization of environments, devices and available resources. The devices register at the cloud informing their resources and environment where they are situated. This process starts when the core receives the file containing all the information of the device. Then, the system extracts the necessary information from the file and it registers the device at the system in the informed environment. Afterward, it sends back a message to the device authorizing the beginning of sending data from sensors.

Once the devices start sending data, the core system registers the new values and updates the old ones in VCDB (Figure 1). For every device, there are resources that can be sensors or actuators. In the case of sensors, if it is the first time that a new value of a resource is received, the system inserts this new value at the VCDB. Otherwise, if the value has changed since the last data reception, this new value is updated in VCDB. In the case of actuators, there is no data to be stored but it is kept the information about the availability of the resource. For example, the system informs if a certain actuator is being used or it is free for executing commands.

The core system deals with commands requisitions coming from the Client layer (a web system or by exposed web services) to be sent and executed at devices. The Client layer does not need to know technical details of hardware or even in which device the command will be executed. The commands are specific for a resource and the core system avoids duplicated resources and commands. Besides, it also redirects a received command to the respective device registered at the system by sending a message using ContextNet.

In the Cloud layer, there is also a locking process for avoiding conflicts in executing actions when two or more clients try to execute commands in the same actuator. For this, every time that a client needs to use a specific actuator, the core system locks this resource until the client informs that

is no longer using it, the action was performed, or a timeout boundary is reached. During this process, the locked resource is unavailable for all clients. It is important to remark that sensors are not part of the locking process because the nature of sensors is to provide data to be consumed. If the data is considered confidential, the environment can be set as private.

As stated before, web services can be exposed for extending the functionalities of the RMA in the Cloud layer. For creating RESTful web services it is used as an embedded servlet container and web server named Jetty. The available web services are a requisition service for agents applications for using resources with contextual planning; an execution service for activating or deactivating the actuators based on available commands; and a web service for providing data access to mobile applications.

The Cloud layer's model is composed of the *ResourceManagement* class where the ContextNet server is instantiated. Besides, it hosts a list of *Environments* with their *Devices*, *Resources*, and *Commands* classes.

C. The Client Layer

The idea behind the Client layer is to provide a layer capable of showing environments' resources in any kind of platform such as web pages, web services or mobile applications. Besides, it is responsible for providing some basic mechanisms that are not available in previous layers such as environments creation and, publish and subscriber mechanisms for example. The Client layer is represented as a web page for showing all the resources of environments and some basic functions for interacting with the resources. The user is able of creating environments to virtually host his devices and to expose them to be consumed by other users. Besides, the actuators have commands that users can activate by interacting with the Client layer's web system. The technologies employed are relational databases, Java web pages and Ajax.

Besides that, users can choose to follow some of the resources without the need to access the environments every time that he needs to get those values. The publish and subscriber mechanism allows users to access values always that a change is perceived by the core system in the Cloud layer. It allows the user to set basic rules such as defining a desired value to be announced when reached. All existing modules can co-exist without interfering in each other since all functions are managed by the Cloud layer. They all have to connect to the Cloud layer's database or use an exposed web service to access information.

V. EVALUATION

In this section, it is presented an initial case study evaluation in the assisted environment domain using the proposed RMA using a software engineering based approach. Case studies are employed because they are suitable for evaluation of software engineering methods involving development, operation, and its maintenance and artifacts [13].

The scenario will be held in a hypothetical Smart City where the government has access to a hospital where the

RMA is implanted. Some rooms in the hospital building have devices for controlling the temperature and luminosity (as sensors), and light lamps of the room (as actuators), and other devices for measuring some of the patients' information such as heartbeat frequency. Therefore, every room in the hospital endowed with devices is considered an environment in the RMA and its devices' resources are exposed as a service for the board of directors, government and everyone interested in them. It is important to remark that, even in this hypothetical scenario, there is no real personal contact of patients available.

Based on this, two devices were prepared for a room, named Room 403. Both devices use a Raspberry Pi Zero connected to an Arduino board. The first device is connected to a temperature and a luminosity sensor for the basic sensing of the room. The second one is a device with a light lamp connected to the Arduino working as an actuator and informing if the lamps are on or off. Besides, virtual devices were simulated in order to stress the RMC functioning. For this, the serial interface between the embedded system and the hardware were disabled, and several resources were simulated for each virtual device, which sends random data to the Cloud layer. So, one device for monitoring the heartbeat frequency of a patient and devices identical to the real ones above were simulated in each room. In general, 20 environments were prepared where the environment Room 403 has two real devices and one simulated, and the other 19 have three simulated resources.

The case study approach is divided into four steps: case study design, preparation for data collecting, the data collecting and data analysis. The following Table I shows the details and aim of the descriptive case study.

TABLE I
THE CASE STUDY DESIGN

Design	Description
Objective	A descriptive analysis of the behavior of the RMA functioning.
Case	The asynchronous process of transferring information from devices to the Cloud layer to be consumed by clients using web solutions.
Questions	Is the device connects correctly to the Cloud layer? Is the communication process between all layers works? Is the Client layer showing the correct data?
Method	Qualitative data analysis using negative case analysis and observation method.

Some tests were conducted trying to deny the research questions above. The preparation for the data collecting consisted in store both dynamic registration at the RMC and the answer that devices receive before starting sending data from sensors. Afterward, it is verified if these data arrives at all layers properly by analyzing the transferring process between hardware and device, device and cloud, and cloud and client. A string of data that comes out from the hardware is collected and compared if the data read arrived correctly at the embedded system. Between Devices and the Cloud layer, all devices should keep sending data to be stored at the VCDB in the RMC. Finally, between Cloud and Clients, these same

data should be read by clients when data update occurs.

The data collecting and analysis were performed in an arithmetic progression from 1 to 20 devices. Firstly, the server instance was running properly to verify the effectiveness of RMA and then it was disabled. Once there is no server instance available, they should not send data. Then, the data should be properly stored and read by Cloud and Client layers. Table II shows the resumed results from tests.

TABLE II
DATA COLLECTION AND ANALYSIS

Test	Description	Hit (%)
Hardware	Data is correctly transferred to the embedded system.	100
Connection with Server	Device registered at RMC and registered message received.	100
Connection without Server	Device registered at RMC and registered message received.	0
Data Updated and Stored	Data correctly stored at VCDB.	100
Data Read	Data correctly read by clients.	100

The communication between hardware and the embedded system is done using a serial interface, which guarantees no losses in the data transferring. None errors were observed in this process. As expected, when the server instance is disabled, it is observed that devices try to connect to the Cloud layer but there is no response from the server and no data is sent from any device. Otherwise, the device is registered and receives a confirmation to start sending data to the Cloud. All devices work properly considering an available server instance.

The most recent information available coming from devices is updated in the VCDB. Considering that the VCDB is implemented as a relational database, there are no big deals in this process not even in the visualization of the devices by the Client layer. This case study focused on observing the communication and the correctness of data flowing through the architecture. More experiments focusing on performance and a proper formalization were left for future efforts.

VI. CONCLUSION

In this work, it was presented a low-coupled three-layer architecture for exposing devices as a service to be consumed by clients. The devices are able of connecting to an IoT server, registering their resources (sensors and actuators) in a core system, which turns all the public data available that can be accessed by clients using web services and a web platform. A case study was proposed and evaluated integrating the Device, Cloud and Client layers for monitoring an environment.

RMA architecture employs different technologies in its layers. Devices are autonomous and uncoupled from the Cloud layer because they are built using hardware platforms enhanced with wi-fi connections and it uses a serial interface for communicating with micro-controllers. These technologies provide the necessary autonomy, heterogeneity of hardware employed, and communicability to the Cloud layer. The ContextNet middleware provides client and server instances and it

is used in the architecture because of the middleware guarantees connectivity, communicability, reliability, and scalability, in addition to using an industrial market standard protocol.

The Client layer offers web solutions for managing environments and for the visualization of their respective resources. Besides, it is possible to subscribe specifically to resources that one might be interested in. Moreover, the RMA aims to provide an architecture for exposing devices as a service to be consumed by persons that do not have access to these kinds of resources either for the cost or complexity of creating from scratch an architecture for that purpose.

Nowadays, the designer of the device should program how data is mounted and captured by the micro-controller and sent to the embedded system. As future works, it is important to create an automatized plug-and-play way of configuring the device in low-level. Besides, as micro-controllers are connected to the serial port of the tiny computer of the device, a similar process for the identification of serial ports by the embedded system is also interesting. The environment has to be set manually at the device's configuration file for security and control reasons, nevertheless, it is possible to identify and register autonomously the environment based on access points.

Abstract— Secure software implies that the process used in its development includes activities to insert, monitor and ensure security from the early stages of the software process. This article proposes the Security Process Framework that aims to facilitate the task of creating secure processes through the reuse of process components developed from security patterns. The components are recovered and prioritized from a repository through multicriteria techniques that consider security requirements and characteristics related to the project context. Software process lines are used to organize the selected components and to assemble the secure software process. Furthermore, a tool called SPro System was developed to support the use of the framework. Case studies were used to verify the applicability of the proposal, which showed that the framework and SPro System facilitated the tailoring and decreased the time spent in the definition of security processes.

Keywords - security patterns, security process, software process lines, process tailoring

I. INTRODUCTION

Nowadays, software are becoming increasingly complex, requiring high levels of security to prevent the occurrence of failures and data loss. Several authors propose that methodologies and processes for software development should be concerned with the security from the early stages of projects life cycle [8][9].

Nevertheless, to create software processes aimed at a secure software development is a long process, time consuming and that requires many resources. In addition, the processes must be suited to the needs of each project, which requires defining activities and security practices appropriate to the context and that includes the security requirements defined for the project [3][4][18]. This task is not trivial and it requires experts in security and in software processes, which are not always available in the team.

In the literature, numerous security standards and models are presented which describe best practices and security requirements, such as: ISO/IEC 27001 [1], ISO/IEC 27002 [2] and ISO/IEC 21827 [10]. However, these standards, as any other standard, do not detail the processes that need to be followed to implement security in its projects.

To facilitate the task of setting secure software processes, this paper proposes a framework consisting of: (1) a repository of process components defined from the security patterns; (2) techniques for prioritization and selection of these components from context information; (3) process lines that organize

process components contributing to their reuse and (4) a tool to support the use of the framework.

The components stored in the repository were defined from security patterns catalogs [15], security standards [1], [10] and scientific literature. Security patterns provide solutions already established to recurring security problems and serve as a reference for organizations that seek to meet security requirements [15]. Process components facilitate the development of new processes through the reuse of predefined components and enable the assessment and improvement of these through the use in different software projects. The components are associated with security requirements through rules and are prioritized from multicriteria techniques that consider the context of the project. The prioritized components are arranged using software process lines.

This article is organized as follows: in Section 2, related studies are discussed; in Section 3, concepts relevant to the understanding of the study are introduced; in Section 4, the proposed framework is described showing how the components of the processes and the prioritization methods were defined; in Section 5, the support tool is explained; and in Section 6, a case study is presented. Finally, in Section 7, the final considerations of the study are described.

II. RELATED WORK

In [11], a methodology for adapting software processes is presented, based on security requirements recommended by the security practices of the ISO/IEC 21827. The processes are compiled from components of the Rational Unified Process (RUP), Extreme Programming (XP) and on security patterns proposed in the literature. This study was developed in the same research group and the main differences is that it does not consider the context of the project, the use of prioritization techniques and software process lines.

Mellado, Medina and Piattini [6] propose to incorporate security requirements from the early stages of development using software product lines. Thus, the authors seek to facilitate the compliance with security standards and to manage potential variabilities that may happen among security requirements. The authors propose the use of security standards (ISO/IEC 27001 e ISO/IEC 15408) to manage security requirements. The focus of the work is on the product and our work focuses on the process.

In [7], the authors propose an extension of the Scrum software development framework with features focused on creating secure software.

Hamid and Weber [14] propose a model-driven engineering (MDE) methodological approach associated with a pattern-

based approach to support the development of secure software systems.

However, this study differs from the others due to the development of a secure processes tailoring framework using process components associated with the process area from ISO/IEC 21827. The process components are prioritized from multi-criteria decision techniques that consider context information. In addition, software process lines are used which organize the recovered components to form the process and a support tool is provided.

III. BACKGROUND

Security standards and models have key goals and practices so that organizations can define the expected level of security in their processes. In the literature, various standards of information security are described, among which we can highlight: ISO/IEC 27001, ISO/IEC 15408 and ISO/IEC 27002. ISO/IEC 27001 [1] describes a process for information security management in an organization that structures activities through a continuous improvement cycle. On the other hand, ISO/IEC 15408 provides a common set of requirements for security functions in products and systems and for assurance of measures applied to them during a security assessment [12]. The model SSE-CMM - Systems Security Engineering Capability Maturity Model, published as ISO/IEC 21827: 2008 [10], describes a set of process areas (PAs) that are required in a security engineering process. ISO/IEC 21827 proposes 22 process areas (PAs) that are organized into two groups: Security Base Practices and Project and Organizational Base Practices [10]. For each PA, it is presented a list of BPs (Base Practices) that assist in meeting the goals of the process areas (PA).

Security standards and models describe ways that are intended to assist in the development of security processes, providing practices to be implemented or guidelines to be followed by organizations. In this study, we chose to use the ISO/IEC 21827 [10] because this model defines a set of best practices that guide the organization in the implementation of effective security processes. In addition, this model is widely known and widespread.

Nevertheless, the ISO/IEC 21827, as well as other standards, does not detail the activities to be implemented by organizations. Therefore, it was decided to seek solutions in the literature used by other organizations that have been successful. Many of these solutions in the security area are documented as security patterns [15]. Even though many security patterns and techniques to use them are being proposed, it is complex to adapt and integrate them in every stage of the software development or in specific contexts.

In this study, the patterns are described as process components and associated with a specific use context. However, describe components and store them in a repository does not guarantee the proper selection and integration of these components to create a consistent software process. To solve this issue, the process components are selected through multi-criteria techniques and organized using software process lines (SPrL). SPrL are intended to represent the dynamic aspect of

the processes and a metamodel is used to describe the structural aspect of the components.

Software process lines emerged from software product lines and are aimed at the development of consistent processes, enabling the reuse of previously defined components. SPrL is a form of tailoring of processes that has the following objectives: i) increase the quality and adequacy of the processes; ii) representation of variabilities and similarities among processes to maximize reuse; and iii) reduce the risks of an inadequate tailoring of process [16].

The multi-criteria techniques help the decision making from the analysis of preferred criteria necessary for understanding the reality of the analyzed problem and the choice of the alternative that will allow the best decision to be made. These are examples of multi-criteria methods: AHP (Analytic Hierarchy Process) [19], TODIM (an acronym in Portuguese for Iterative and Multi-criteria Decision Making) [13], and TOPSIS (Technique for Order of Preference by Similarity to Ideal Solution) [5].

The theoretical foundation of the AHP is based on the decomposition and synthesis of the relations among the criteria until a prioritization of their indicators is reached, approaching a better response of single measurement of performance [19]. The TODIM is based on the Prospect Theory [13]. On the other hand, the TOPSIS is based on the calculation of the Euclidean distance between the most beneficial alternative and the costlier alternatives [5].

In our study, the prioritization methods are used to select the most appropriate process components for the project in question, using criteria that define the context. Several authors propose that the context should be considered for definition of software processes, such as: Boehm and Turner [4], Cockburn [3] and Kruchten [18]. In this study, we chose to use the context described by the Octopus Model, as proposed by Kruchten [18], which uses the following contextual factors: size, stable architecture, business model, team distribution, rate of change, system age, criticality and governance.

IV. SECURITY PROCESS FRAMEWORK

This section describes the Security Process Framework through detailing the process components repository and metamodel, the rules of components association to security requirements and the techniques used for the prioritization of the components.

A. Repository of Security Processes

The process components were defined from classes described in the metamodel (Figure 1), elaborated according to Software and Systems Process Engineering Metamodel Specification (SPeM) [17].

A process component is an aggregation of tasks that are performed by roles which have artifacts as input and output and are associated with a discipline. Furthermore, project processes are composed of process components and are associated with projects that use the process.

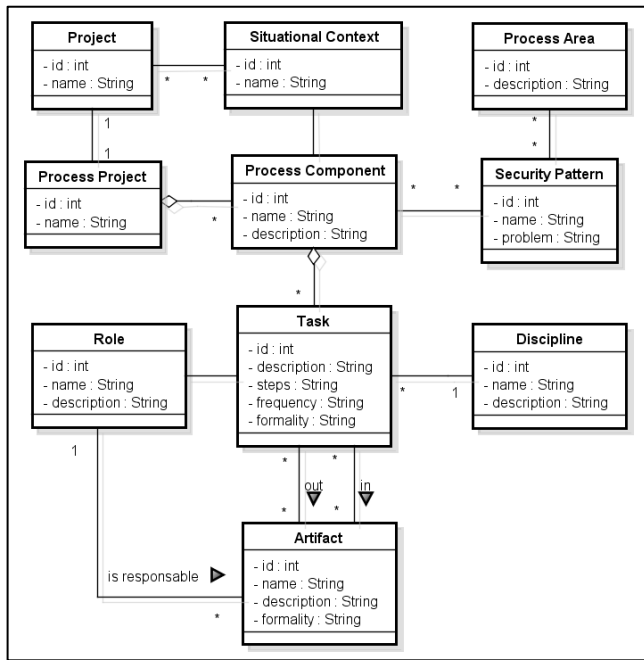

Figure 1. Security Process Metamodel

Process components and projects are associated with information of the situational context. Process components are associated with security patterns from which they were defined. Security patterns [15] are associated with process areas that they meet, extracted from the ISO/IEC 21827 [10].

To illustrate how the classes described in the metamodel are used to define the components, Figure 2 shows the process component Asset Valuation, described from the pattern of the same name [15]. This pattern aims at helping the organization to determine the overall importance of the assets under its control and ownership.

B. Security Components Association to PAs

The defined process components are associated with the goals of the 11 PAs - security base practices, found in the standard ISO/IEC 21827 [10]. For example, the component Asset Valuation (Figure 2) was associated with the process area PA 03 - Security Risks Assessment.

After the analysis of several catalogs of security patterns, each security pattern was described as a process component and associated with one or more process areas that it covers. These components were placed in a repository and are available for use in the development of processes that aim to meet security requirements. Thenceforth, it was possible to build a repository of software process components based on the ISO/IEC 21827 [10], with 50 process components, which have about 70 artifacts and 60 tasks.

C. Determination of the Prioritization Methods

The multi-criteria methods are used to select process components that have a context of use similar to the project context. These contexts are described using the attributes proposed by the Octopus Model.

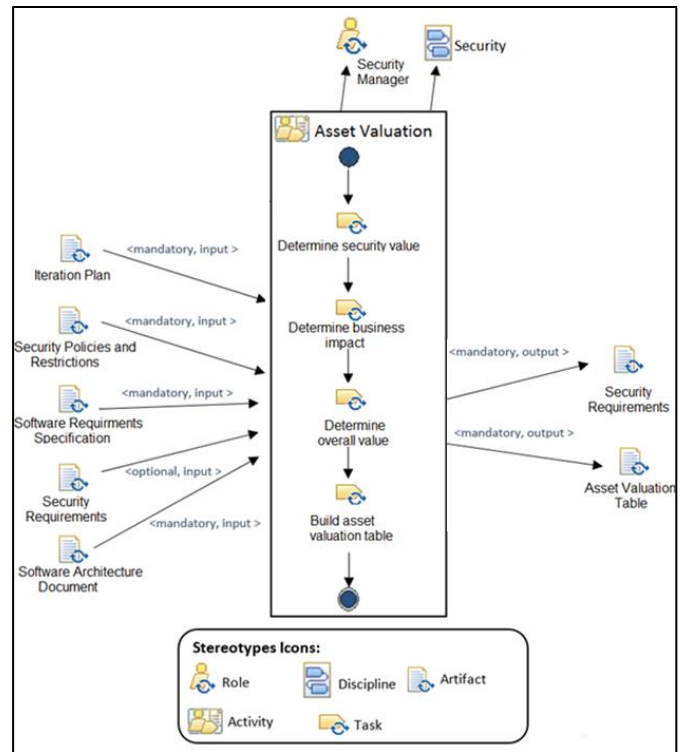

Figure 2. Details of the process component Asset Valuation

In Figure 3, the process area PA08 - Assess Security Risk is shown associated with four components of different processes that aim at satisfying it. The contexts of the component and of the project are assessed and compared according to the calculations proposed by each prioritization method to assist in choosing the best components.

V. SPRO SYSTEM

In this section, a tool that supports the use of the framework for tailoring of processes, using software process lines, called SPro System is described. Process components defined from RUP and XP were inserted into the repository. Process lines have been defined to organize the components and architectures to represent the variants.

The processes tailoring are performed through four stages, which are: i) definition of the project context; ii) selection of the tailoring requirements and of the processes architecture; iii) prioritization of activities; and iv) creation of the tailored process. To illustrate the stages, the implementation of an example of use is described.

The situational context of the project is defined in order to select the most appropriate process components for the project. This example refers to a new development in a well-known domain that involves only loss of money and it is being developed by a local team of 25 people, the values were defined as follows: size = medium, change of rate = less than 10, type of architecture = new, age of the system = new development, business model = commercial, criticality = loss of money, distribution of the team = local and governance = simple rules.

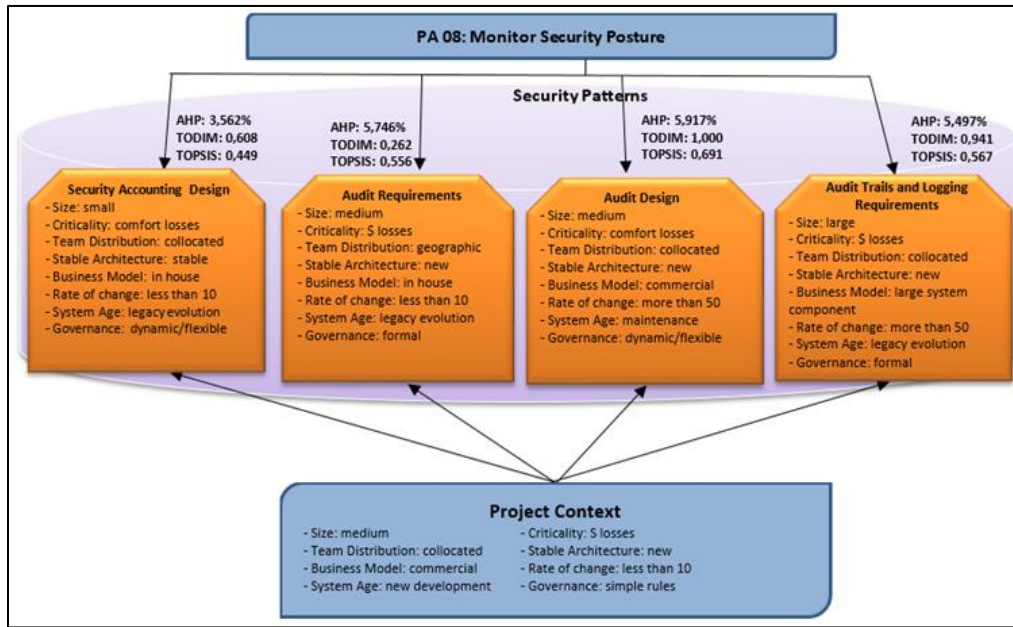

Figure 3. Selection of the Process Patterns

In the second stage, the process engineer selects the tailoring criteria and the architecture. For the tailoring criteria, the PAs 03, 05, 07 08, 10 were selected as showed in Figure 4 (A). In the tool, different tailoring criteria can be used, such as risks, quality, however, this article is limited to describe on tailoring criteria based on the ISO/IEC 21827.

For each selected tailoring criterion, the SPro System searches in the repository the process components that were previously associated with the tailoring criteria through rules, that is, the components that aim at meeting the tailoring criterion. For these components, the similarity between the context of the project and of the component is calculated. The similarity values generated by the application of multi-criteria techniques help process engineers' decision-making, however, the selection is their responsibility. The multi-criteria techniques are an important source of information because they are based on different methodologies of analysis, prioritizing the most relevant activities for the development in particular. Figure 4 (B) shows the results of the prioritization of the components. From the defined process architecture and the recovered process components, prioritized and selected, the specific process for the project was created (Figure 4 C).

VI. VALIDATION USING CASE STUDY

For the validation, a case study was carried out, which was applied to a class of the Master's course in Computer Science from the Federal University of Santa Maria in the discipline of Software Process Improvement. The following materials were used for the experiment:

- A set of 11 cards with the name of the PAs proposed by the ISO/IEC 21827, which are the tailoring criteria to be selected;
- A set of 45 cards representing the process components, elaborated from the security patterns, contextualized

according to the attributes proposed by the Octopus Model;

- Description of two scenarios of development of a software;
- Description with examples of associations of PAs with process components elaborated from the literature;
- Sheet of paper to be filled in by the group with the PAs and the process components selected for the project described in the scenario.

Initially, the students were divided into 2 groups with 4 members each. Each group received the support material described above. The group's objective was to develop a software development process from the scenario. To this end, they needed to identify which PAs should be selected in the described project and, then, select the appropriate process components to the PAs and to the context of the project. In the first stage, the experiment was performed without SPro System and in the second stage the SPro System was used. In each stage, a different scenario was used.

A. Observed Results

The most striking factor was the decrease in time to elaborate the process. The time spent in the first stage was about 1 hour and 15 minutes. In the second stage, the average time was 25 minutes, thus the SPro System helped the team to reduce the time by approximately 60%.

Regarding the context of the project, the two groups correctly extracted the characteristics of each project from the provided scenario. According to the analysis performed in the process architectures developed in the first stage, it was possible to verify that group 1 was able to determine the exact process areas that encompassed the scenario. In contrast, group 2 included two extra process areas, which were not required by the scenario.

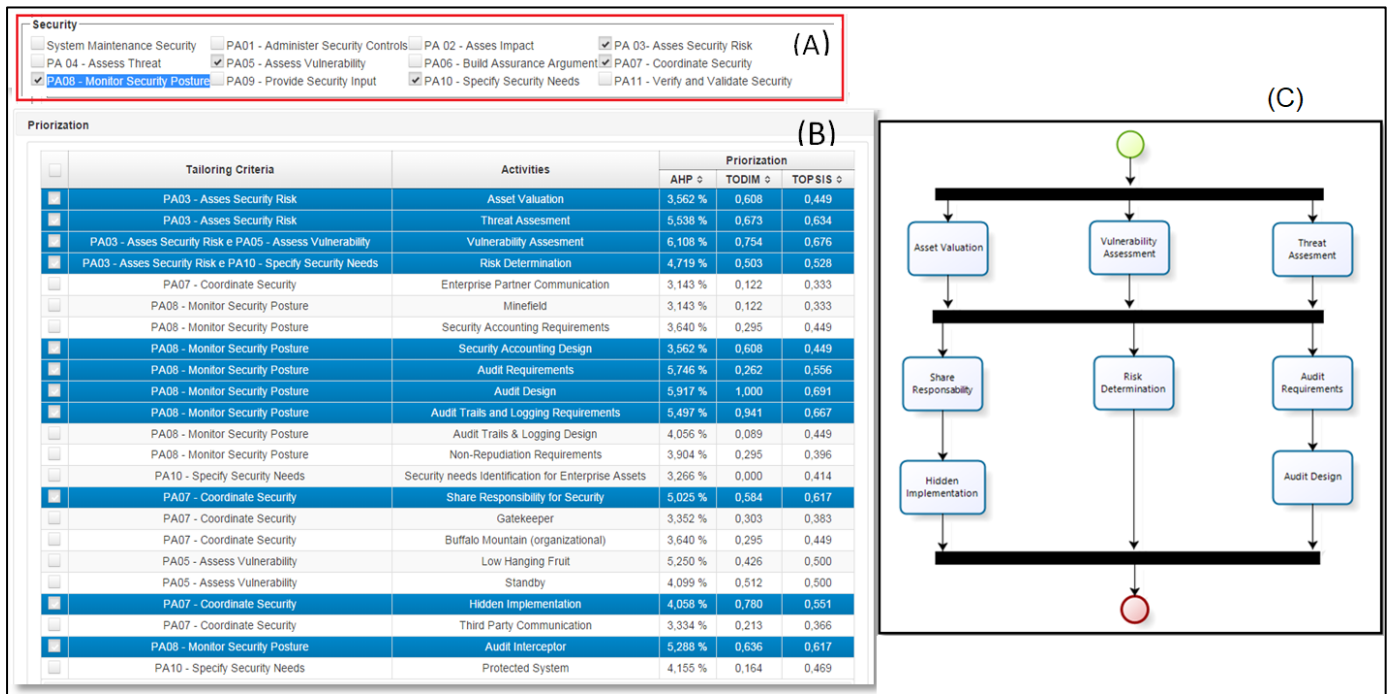

Figure 4. SPro System

Regarding the process components selected for each tailoring criterion, it was possible to verify that group 1 selected 10 activities for 5 tailoring criteria. Thus, it was verified that this group correctly compared the contexts of the activities and the project, besides an analysis of the description of the activity. Group 2 has determined 19 activities for 5 tailoring criteria, however, it was found that this group ignored the context and the activity characteristics, giving greater attention to the description of the activity. In this stage, both groups were able to determine the activities and the tailoring criteria considered as essential in the presented scenarios.

In the second stage, the activity was developed according to the first step, however using the SPro System and with another scenario. It is possible to state that the groups obtained more satisfactory and significant results when using the tool because they selected the activities and the tailoring criteria considered as essential in each presented scenarios

B. Assessment Questionnaire

To complement the analysis, a questionnaire was applied so that the students could assess the framework and the SPro System. The questionnaire responses are showed in the Figure 5.

All participants agreed that the use of the tool facilitated the processes tailoring aiming at meeting the security requirements (Q.4). Furthermore, they fully agreed on the importance of maintaining a repository with adapted process components to facilitate new adaptations (Q.8). Regarding the ease of understanding and the translation of the security patterns for the activities so that they can be added to a software process, there was a partial agreement (Q.2).

Only one participant partially disagreed that the provided patterns were sufficient to meet the tailoring criteria (Q3), wherein four answers partially agreed and the other 3 totally agreed. In this sense, it can be highlighted that the groups considered that the use of security patterns may be a viable solution to solve the security problems in the project, however, it may not be the only solution that should be applied.

The participants recognized that the pre-defined process components associated with the tailoring criteria facilitated the development of the process lines (Q.5). All participants agreed that the SPro System tool assists in the processes tailoring considering security requirements (Q.6).

Nonetheless, when asked if the tool expresses the stages required to define processes, there were different responses, wherein four participants fully agreed, three partially agreed and one neither agreed nor disagreed (Q.7). From these responses, there was the need to improve the stages to be used in the tool for the processes tailoring. In addition to this improvement, in the descriptive responses, suggestions regarding the SPro System were given.

Moreover, in the space for comments, the participants reported the difficulty in detecting security patterns and activities that meet the tailoring criteria.

Regarding the prioritization methods, it was possible to verify that the groups thoroughly analyzed the numbers obtained and brought in the calculations made by the AHP, TODIM and TOPSIS methods. According to the participants, the methods were an excellent source of information and guided the groups in the decision-making regarding which process components they should select.

Figure 5. Responses of the applied questionnaires

From the development of this case study, it was possible to evaluate the use of the SPro System tool and to apply the concepts presented in the elaborated framework.

VII. FINAL CONSIDERATIONS

This paper presented a framework proposal that aims at selecting process components that can be used for the tailoring of security processes. The process components were developed and derived from security patterns and were proven efficient in the development and tailoring using software process lines. Furthermore, with the use of multi-criteria techniques, the framework assists the process engineer to choose the most relevant components for the development process, considering the contexts of project and of the components. With the support of the SPro System tool, the use of the proposed framework was demonstrated.

The validation showed that the framework and the SPro System facilitated the process tailoring and decreased the time spent in the definition of security processes. In addition, the students, even without security expertise, were able to select activities appropriate to the scenario, properly creating the process according to the problem they received.

As future studies, we suggest the semi-automatic selection of process components and the expansion of the repository comprising other security standards.

Abstract— Faced with the severe financial and reputation implications associated with data breaches, enterprises now recognize security as a top concern for software analysis tools. While software engineers are typically not equipped with the required expertise to identify vulnerabilities in code, community knowledge in the form of publicly available vulnerability databases could come to their rescue. For example, the Common Vulnerabilities and Exposures Database (CVE) contains data about already reported weaknesses. However, the support with available examples in these databases is scarce. CVE entries usually do not contain example code for a vulnerability, its exploit or patch. They just link to reports or repositories that provide this information. Manually searching these sources for relevant information is time-consuming and error-prone. In this paper, we propose a vulnerability detection approach based on community knowledge and clone detection. The key idea is to harness available example source code of software weaknesses, from a large-scale vulnerability database, which are matched to code fragments using clone detection. We leverage a clone detection technique from the literature, which we adapted to make it applicable to vulnerability databases. In an evaluation based on 20 reports and affected projects, our approach showed good precision and recall.

Security; Code Clones; Information Systems

I. INTRODUCTION

In today's interconnected world, security is one of the most important challenges for companies and institutions [16]. Vulnerabilities in a software system allow hackers to intrude and maliciously alter its behavior. The impact can range from minor, such as bypassing the copyright of a movie, to major, such as the malicious intrusion into a control system of a nuclear reactor [4]. An example for the latter case is the Stuxnet worm, which used a weakness in a vendor driver library to infect 100.000 systems worldwide and inflict physical damage. Consequently, organizations begin assigning a higher priority to security as a quality attribute in software development.

A key challenge is to check the complete source code for
DOI reference number: 10.18293/SEKE2019-183

vulnerabilities to avoid the associated exploits. Since software developers are not equipped with the required security expertise, ideally, security experts should review the whole source code of a project. However, in the face of realistic projects that often include hundreds of thousands of lines of code, a manual check of the project by security experts is infeasible. To the rescue may come available community knowledge from vulnerability databases, such as the Common Vulnerabilities and Exposures (CVE) [18]. The CVE provides detailed knowledge about a large number of reported security flaws, including their impact. Developers may want to leverage this knowledge by detecting instances of the flaws in their projects. Unfortunately, the associated manual process is time-consuming and error-prone: Developers have to use a search engine in order to find relevant entries based on the names of the used libraries. Then they must manually scan the source code to uncover problematic uses of the affected libraries. Even worse, support with available examples in these databases is scarce. CVE entries usually do not contain an example exploit or patch, but just a link to a report or to a repository that provides additional information on proof of concepts, patches, and exploits.

In this paper, we address the following research question: *How can we harness available community knowledge to facilitate the detection of security vulnerabilities in software code?* We present an approach that uses *code clone detection* to detect instances of known vulnerabilities in source code. Clone detection aims to locate exact or similar code snippets, called *clones*, in or between software systems [21].

Our approach, illustrated in Fig.1, involves on a *security code repository* that contains security-relevant code snippets. Each snippet instantiates a known vulnerability.

Figure 1. Approach Overview

The security code repository is created in a semi-automated process using automated searches over the CVE database and a large-scale code repository such as GitHub [6], and manual

refinement by developers. We detect duplicates of entries by using clone detection. To this end we have adopted an existing technique called SourcererCC [19], which fulfills two main prerequisites of our approach: It is efficient, as it scales to huge code bases with 100K LoC, and language-independent, as it supports arbitrary programming languages.

Our contributions are as follows:

- A *vulnerability detection technique* that uses and adapts an existing clone detection technique in order to detect security vulnerabilities, based on the given security code repository (Sec. III).
- A process for creating a *security code repository* with code snippets that instantiate known vulnerabilities, together with an initial version of such a repository (Sec. IV).
- An evaluation, in which our approach was able to detect the considered vulnerabilities with high precision and recall (Sec. V).

Clone detection has been used during vulnerability detection before. However, previous approaches were mostly limited to a particular programming language and suffered from scalability issues. We discuss related work in Sec. VI.

II. BACKGROUND

We recall a common taxonomy of code clones and its implications for security.

Clone types. The common taxonomy of code clones [9] distinguishes four clone types, based on the degree of similarity: *Type-1 clones* are code fragments that are accurate copies of each other, excluding whitespaces, blank lines, and comments. *Type-2 clones* are structurally identical code fragments that may differ in the names of variables, literals and functions. *Type-3* or *near-miss clones* are syntactically similar code fragments that, opposed to Type-1 and Type-2 clones, may include changes like added or removed statements. *Type-4 clones* are code fragments with a different syntax, but similar semantics. The example in Fig. 2 shows a code fragment CF_0 together with each clone type.

Security considerations. The clone types have different implications for security vulnerabilities. A vulnerability in a code fragment most likely also affects Type-1 clones of that fragment, since in most programming languages white spaces, blank lines and comments do not change the behavior. Neither does the change of variable names in Type-2 clones. However, the change of literal and method names can have an impact: a vulnerability may only occur when a specific method is called or when specific literals are used. Type-3 are particularly challenging for our approach, since an added line may render an insecure fragment secure, and vice versa. For example, consider the infamous buffer overflow weakness, where the problem is that the buffer size is not checked before writing or reading of it. A range check before accessing the buffer would fix this error, but the resulting code fragment is still a Type 3 clone. Type-4 clones regard the semantics of code snippets. The security impact of these clones depends on the chosen semantic representation. The typical means for checking semantic equivalence (such as pre- and post-conditions) are orthogonal to

contained security vulnerabilities. Therefore, we do not consider Type 4 clones in our approach.

Initial Code Fragment CF_0	CF_1 – Type-1 Clone	CF_4 – Type-4 Clone
<pre>for(i = 0; i < 10; i++) { // foo 2 if (i % 2 == 0) a = b + i; else // foo 1 a = b - i; }</pre>	<pre>for(i = 0; i < 10; i++) { if (i % 2 == 0) a = b + i; //cmt 1 else b = b - i; //cmt 2 }</pre>	<pre>while(i < 10) { // a comment a = (i % 2 == 0) ? b + i : b - i; i++; }</pre>
CF_2 – Type-2 Clone	CF_3 – Type-3 Clone	
<pre>for(j = 0; j < 10; j++) { if (j % 2 == 0) y = x + j; //cmt 1 else y = x - j; //cmt 2 }</pre>	<pre>for(i = 0; i < 10; i++) { // new statement a = 10 * b; if (i % 2 == 0) a = b + i; //cmt 1 else a = b - i; //cmt 2 }</pre>	

Figure 2. Clone-Types 1 to Type 4

III. VULNERABILITY DETECTION

Our vulnerability detection approach involves four steps: *Pre-Processing*, *Code Processing*, *Clone Detection* and *Results*. The Pre- and Code Processing consists of the substeps Parsing & Tokenizing and Indexing. Only the Pre-Processing also contains the step of the CVE Data linking to enrich the code snippets with meta-information out of the CVE.

The input for the Pre-Processing step are the vulnerable code snippets of the security code repository including their assigned CVE metadata. During parsing, we identify contained methods and constructors of each source file. Within the tokenization, we create for each found method and constructor a separate token file containing the occurred tokens. Furthermore, for each of these files a file with bookkeeping information, in particular the CVE id to later query concrete CVE details, will be created. They also consist of links to code fragments which represent an example patch and their exploit to give developers a better understanding of the weaknesses for patching them afterward. The resulting tokens will be indexed and are the outcome for the preprocessing as well as the bookkeeping CVE information. It has to be applied once each time if the content of the code repository changes.

The Code Processing takes place every time if the source code has been changed. Thereby, the same Parse & Tokenizing and indexing like in the pre-processing will be applied but without adding CVE data to the bookkeeping information. The output of this step are the indexed tokens of source code files.

During the clone detection phase for each code fragment of the security repository and for each method as well as constructor inside of source files will be analyzed whether there are code clones. In detail, the tokens of methods and constructors will be compared. If a match is found, then the checked source code is a code clone of an insecure code fragment, which implies that it potentially also contains a security flaw. These code clones will be interleaved with the CVE data out of the bookkeeping information, which are the results of the vulnerability detection. Thus, should help developers to receive

more knowledge to patch insecure source code fragments. The described approach is visualized in Fig. 3. Later in this chapter, the clone detection will be described in detail.

The effectiveness of this approach relies among others on the data of the reference repository. Therefore, it is inevitable to ensure the adaption and enrichment of knowledge by developers or a repository maintainer. They are able to add new vulnerable, patch and exploit code and modify already stored data.

A big problem for the code clone detection is the time complexity to compute the pairwise similarity for each code fragment combination. Execution time majorly scales with the size of the input precisely of the number of lines of code (LOC) that are processed and searched. For code clone detectors it is prohibited as a time complexity of scalability - $O(n^2)$. If the granularity of the code clone detector is method based, the similarity comparisons increase quadratically with the number of methods. For the SourcererCC various heuristics for reducing the number of similarity computations are described by Sajjani et al. [19]. In comparison of their approach to other state-of-the-art code clone detectors like CCFinderX [8], Deckard [29], iClones [30] and NiCad [31] they reach almost the same time complexity of inputs less than one million LOC. For all bigger input sizes, the SourcererCC has the best execution time. Furthermore, the SourcererCC is the only clone detector of the competing tools that scale to large input sizes of 100 million LOC and is able to consider type 1 to 3 clones.

Figure 3. Vulnerability Detection Process

SourcererCC. As a basis for clone detection, we have adopted a state-of-the-art code clone detector named SourcererCC [19]. The detector supports Type 1 to 3 clones and scales to large-scale project repositories while providing high precision and recall. To quantitatively infer if two code snippets are clones a similarity function is applied which returns the non-negative degree of similarity between two code snippets. The higher the value of similarity, the bigger is the likeness between them. This function includes a threshold value ϑ that identifies the lower-bound of the similarity value from which two code fragments count as code clones. In other words, it is a percentage value that represents how many tokens at least should be shared by two code fragments to be identified as code clones. This similarity value is the output of the clone detection process. In the following, the similarity measurement is described formally:

Given two projects P_x and P_y , f as similarity-function and ϑ as threshold, the aim is to find all code block pairs $P_{x,B}$ and $P_{y,B}$ such that $f(|P_{x,B}|, |P_{y,B}|) \geq [\vartheta * \max(|P_{x,B}|, |P_{y,B}|)]$.

Adaptation of SourcererCC. We performed two main adaptations of SourcererCC for our approach:

First of all, we adapted the format of the token files to our needs and implemented a suitable tokenizer; thus its resulting

token files will be interleaved with related information out of the CVE Database. Secondly, we adopted the code clone detector itself to consider only inter-project clones, as discussed later in this section. The main reason for this is that we plan to find clones between an external code repository and a project and not within a single project, like the clone detection is often used for.

Tokenizer. SourcererCC comes with a tokenizer for Java, C and C#. However, for our approach, we needed a method to interleave tokens with CVE meta-information such that clone detection results could provide further security information. Therefore, a custom token format was designed that combines the token information with the additional bookkeeping details, including the CVE id and the metadata of vulnerabilities. This information allows us to trace back from code fragments to the underlying weakness.

To apply the tokenizer a parsing of the source files is needed, such that the tokenizer gets software artifacts of source files like method names and constructors. For exemplary apply and evaluate our approach, we focus on java source code such a java parser is used for parsing code. For each method or constructor, a new list of tokens is created. Whitespaces, operators and comments are ignored. During this procedure, the tokenizer loads the needed metadata out of the security repository. The output of our tokenizer are two files, one including the tokens of a code fragment and the other with the described bookkeeping information enriched with security knowledge.

For further illustration, we present an example method before the preprocessing was applied in Fig. 4.

```

1 public class TokenizerExample
2 {
3     private boolean isEven(int n)
4     {
5         int two = 2;
6         return n % two == 0;
7     }
8 }
  
```

Figure 4. Example: Java Input Source Code for Tokenizer

Figure 5 presents the output of the tokenization of Fig.4.

```

1 {0,private,2,boolean,isEven,int,two,n,return}
  
```

Figure 5. Created tokens of Fig. 4

To complete the tokenization, we count the number of appearances of each token and add them to the output. Hence, a token-file consist of every occurred method name, variable name and its datatypes as well as return values that are named and counted. Regarded to the design constraint for the Java and C# languages, all executable code must be contained inside of method bodies. Therefore, the granularity level for the implemented tokenizer is set to method-based tokenization. This means that only method respective constructors will be processed inside of a class. Imports and class names will be ignored. For other languages like C and C++ it is necessary to

adapt the tokenizer to a class-based tokenization through the absence of this design constraint.

Inter-project clones. Clones can be either intra- or inter-project clones, meaning that the instances of a clone may come either from the same project or from different ones. In our approach, we are only interested in inter-project clones, since we aim to find matches between a given project source code and our security code repository. More formally, let A be the set of source files from the input project and B the set of snippets from the security code repository. Furthermore, let (a_0, \dots, a_n) and (b_0, \dots, b_m) with $n, m \in \mathbb{N}$ code fragments, for which $a_i \in A$ and $b_j \in B$ with $i, j \in \mathbb{N}$. We are interested in pairs of code fragments (a_i, b_j) being code clones.

SourcererCC finds both intra- and inter-project clones, and by default it does not provide a configuration option to deactivate the detection of intra-project clones. Therefore, the *Pre-Processing* phase was added and the inputs for the clone detection was adapted to ignore intra-project clones. Figure 3 presents the modified behavior of the clone detector.

IV. SECURITY CODE REPOSITORY

In our approach, a prerequisite for vulnerability detection is a reference code repository called *security code repository*. This repository contains source code snippets that instantiate already reported weaknesses. Each snippet consists of example code for a vulnerability, its exploit and a patch. We now describe the procedure for creating a security code repository, which we used to test and evaluate our technique. Our process relies on a large-scale repository in which such snippets can be found. To this end, we used GitHub, a suitable repository that is freely accessible to the public. Our process, shown in Fig. 6, contains the four steps *Extract*, *Search& Filter*, *Export*, and *Proof*.

Extract. To find security-related code snippets on Github, adequate terms for the search are needed. We extract them from the CVE database. A possible way to identify a concrete vulnerability is its unique CVE identifier [18]. Therefore, we extract these CVE-ids for the search to find security issues.

Search and Filter. For searching vulnerabilities on Github, the pre-extracted CVE-ids will be used. If a file or a commit within a project matches these identifiers, they will be considered for further processing. To adjust the results of the search to specific programming languages, we defined a file type filter. For example, to restrict the search to Java files, the file endings will be checked for the tag *.java*. Not every content of the found files is security-related. Therefore, a manual prove is necessary to ensure that resulted files contain only security-related code. This procedure is described later in this section.

Figure 6. Repository Creation for Reference Code Fragments

Classification. Furthermore, we defined terms to distinguish between the three classes of security-related files; vulnerabilities, exploits and patches. For this classification, we use a simple check whether terms are substrings of texts inside of commits or project descriptions. Examples terms for the class *patches* are fix, solve, update, patch for *vulnerabilities* the term vulnerability and for *exploits*, the substrings are proof of concept (POC) and exploit. We retrieved these terms by the manual unsystematic analyze of founds of the CVE id search received from GitHub. The founds will be automatically classified by these terms into the three mentioned classes.

Export. The classified founds are stored into a code repository with a SQLite database inside of its root. For all matches its related and stored meta-information inside of the CVE will be extracted into the SQLite database. This meta-information are for example the concrete CVE description, the CVE-id and a scoring which represents their characteristics, impact and severity. The vulnerability scoring is based on the Common Vulnerability Scoring System (CVSS) [28].

Proof. As post-processing the repository content has to be manually reviewed to exclude file parts that do not contribute to a vulnerability. If a file with a vulnerability in it is found, often only a part of the file represents a vulnerable code snippet. A security expert has to delete the unaffected methods in these files such that only the critical code remains.

For the creation of a code repository, 20 different weaknesses out of the CVE database were selected. Our previous explained semi-automated tool-based approach found source code examples of exploits, vulnerabilities and its patches assigned to CVE-ids. Thus, security-related code fragments are extracted out of Github. We have reviewed a subset of 102 reported security flaws to check their suitability for representing a vulnerability code snippet that is usable for the approach described within this work. For example, not eligible vulnerabilities can be patched by only importing a newer library version or loading them dynamically by a string literal. Furthermore, code fragments for which weaknesses are spread over multiple methods were partially also ignored. The reason for this is that in the most cases code changes were too small to match the three different types of code clones meaningfully. Table 1 shows the selected vulnerabilities with their associated CVE, their scoring and the affected product, as it is stored into the CVE Database. The created security code clone repository including the SQLite database is uploaded to Github [24].

V. EVALUATION

We evaluated the suitability of the described approach to address our initial research question: *How can we harness available knowledge to facilitate the detection of security vulnerabilities in software code?* To this end, we consider the following evaluation research questions:

RQ1: How many of the vulnerabilities inside of the CVE are attributed to source code?

Not for every vulnerability the reason is a weakness in source code. This question should identify how valuable the focus on source code vulnerabilities is and how many of them could be

TABLE I. CODE REPOSITORY WITH SECURITY-RELATED CONTENT

CVE	Scoring	Product
CVE-2006-2806	7.8	Apache Java Mail Enterprise Server
CVE-2007-5461	3.5	Apache Tomcat
CVE-2007-6203	4.3	Apache HTTP Server 2.0.x and 2.2.x
CVE-2008-2086	9.3	Sun JDK
CVE-2008-5515	5.0	Apache Tomcat
CVE-2009-2693	5.8	Apache Tomcat
CVE-2009-2901	4.3	Apache Tomcat
CVE-2010-4172	4.3	Apache Tomcat
CVE-2011-1475	5.0	Apache Tomcat
CVE-2011-3190	7.5	Apache Tomcat
CVE-2011-3377	4.3	Ubuntu Linux, Opensuse, Redhat Icedtea-Web
CVE-2012-1621	4.3	Apache Open For Business Project
CVE-2012-2459	5.0	Bitcoin und Bitcoin-Qt
CVE-2016-3897	4.3	Google Android
CVE-2016-6723	5.4	Google Android
CVE-2017-0389	7.8	Google Android
CVE-2017-0846	5.0	Google Android
CVE-2017-1217	4.3	IBM WebSphere Portal
CVE-2017-1591	4.3	IBM DataPower Gateway
CVE-2017-9096	6.8	iTextpdf iText

found through using the knowledge of source code of entries stored inside of the CVE by applying the described approach.

RQ2: How accurate is our approach at detecting previously reported vulnerabilities?

We want to check whether it is possible to identify source code reasoned weaknesses through a subset of the reported vulnerabilities stored inside of publicly accessible databases like the CVE.

RQ3: How well does our approach distinguish between vulnerable and patched code fragments?

Sometimes only the change of a few lines of code is necessary to remove a security flaw inside of a code snippet. We investigate on which granularity we can distinguish between patched and insecure code fragments through clone detection.

A. RQ1: How many of the vulnerabilities inside of the CVE are attributed to source code?

First, we investigate how feasible it is to use the information of known and documented vulnerabilities reported in databases like the CVE. For this proof, we check the ratio of entries that could be retrieved through errors within source code to them which do have other origins. The more weaknesses based on source code, the better is the concentration on detecting security flaws within code artefacts. Through this survey the capability of using the content of the publicly accessible database CVE to recognize security issues invoked through source code will be validated. To apply this investigation, the non-code content of the CVE was manually screened. We recognized that in August 2018 only for 62 % of the 103745 CVE entries, a Common Weakness Enumeration (CWE) identifier is assigned.

The CWE compresses different types of weaknesses, which are all identified through a unique CWE-id and categorize different manifestations of vulnerabilities. An example of these types is *CWE-306: Missing Authentication for Critical Function*. All to this type associated CVE entries are

vulnerabilities because of the absence of authentication for critical functions. Therefore, CWE-ids are a well-suited attribute found with our approach. A problem is that there is no identifier for a type that implies all security issues appear within source code. For every set CWE type, it was systematically proved whether it is possible to retrieve out of its description the origin they belong to; induced by source code or others like configurations. A further problem is the absence of assigned CWE-ids for 38 % of the entries of the CVE. The besides without any type information were investigated with the use of their description. Manual checks show that it is possible to find CVEs based on source code via checking their descriptions for the occurrence of substrings. The used substrings were divided into five groups: File Name Endings, Attack Strategies, Configurations, Rejects and Unclassified.

The group File Name Endings contains substrings that represents the data types of programming language source files. The hypothesis is that if a concrete file is addressed within the description of a CVE than their occurrence is provable within source code. Examples of file endings are *.java*, *.cpp*, *etc.*

As attack strategy count for example *Cross-Site Scripting (XSS)*, *Buffer Overflow* *etc.* The idea is to check for the names of attack strategies that maliciously uses a vulnerability occurred in source code like the buffer overflow example, which could be prevented to buffer length checks.

Configuration related vulnerabilities are identified through the occurrence of terms like *config*, *cfg* *etc.* We assume that for CVE descriptions that mention at least one of these terms, their belonging weakness is not detectable via source code analysis.

Rejects are the vulnerabilities that are still remain in the CVE database but were rejected after review. They are marked with the term *Rejected*. This are entries, which could be duplicates or not representing a vulnerability at all.

The left CVE entries that not belong to one of the mentioned groups were assigned to the group Unclassified CVE entries. They will be not considered to answer this research question. The partition of the CVE is summarized in a pie chart in Fig. 5.

Figure 7. Classification of CVE Database Content

To conclude the results, it is shown that 69 % of the public available vulnerabilities are induced to source code issues. This is composed through the 31% of entries with CWEs that describes security flaws detectable within source code artefacts, the 28 % with a description containing file endings of source code files and the 20 % of CVEs that contain in their description terms of attack strategies uses security flaws within source code. To respond RQ1.1, it is a well-suited strategy to focus on source code for identifying known and reported weaknesses.

B. RQ2: How accurate is our approach at detecting previously reported vulnerabilities?

Experimental Setup

As vulnerability selection for our evaluation, we use the code repository described into Sec. IV. To ensure that not only Type-1 clones are detected but also Type-2 and Type-3 clones we modified each vulnerable code fragment to match the corresponding clone types. For example, all variable names were renamed for Type-2 clones. To obtain Type-3 clones, we removed or added some void statements to Type-1 and Type-2 clones. Our evaluation based on metrics of the information retrieval like *Recall*, *Precision* and *F₁-measure* as described by Manning et al. [15]. We measured the recall based on the chosen vulnerabilities considering the three different types of clones. In this case, we know exactly the number of weaknesses so that the recall can be measured precisely. The precision was measured by a manual validation of the found and highlighted security code clones. To combine precision and recall, we used *F₁-measure*.

The underlying clone detector uses a similarity function inside its clone detection process. This function can be configured by the threshold value θ . Three different θ values were used for the evaluation in combination with the three different types of clones. That means that for every clone type exists three iterations with different thresholds. Beforehand we examined distinct thresholds by hand. On the one hand, lowering the threshold could harm precision. On the other hand, a too high threshold could harm recall. Therefore 3.0, 5.5 and 8.0 were selected as values for θ .

Results and Discussion

Each iteration passes every vulnerability with the given configuration values. The Security Code Clone Detector has flagged all Type-1 clones for the three different θ values. That means that precision, recall, and *F₁* are 100 % for Type-1 clones. The detection rate of Type-2 clones revealed that only eight security flaws out of 20 were detected with a θ of 8.0. The reason is that through the high θ value two code fragments must be too similar to be recognized as code clones. Due to this the higher the value of θ is the bigger the number of similar tokens inside of two code snippets have to be. Thus lead to the low recall for Types-3 clones cause the clones are too different to be code clones of each other.

In contrast, the precision always is 100 %. This could be attributed to the fact that we only focus on finding the three different types of security code clones. The set of data only consist of the given vulnerabilities and not of any secure code fragments. Table 2 summarizes the clone detection results for the security flaws and patches.

TABLE II. EVALUATION RESULTS

θ	Type-1 Clones				Type-2 Clones				Type-3 Clones				Fixes			
	TP	R	P	<i>F₁</i>	TP	R	P	<i>F₁</i>	TP	R	P	<i>F₁</i>	TP	R	P	<i>F₁</i>
3.0	20	100	100	100	20	100	100	100	20	100	100	100	1	100	5	9.52
5.5	20	100	100	100	20	100	100	100	12	60	100	75	3	100	15	26.08
8.0	20	100	100	100	8	40	100	57.14	0	0	100	0	11	100	55	70.97

In the result table TP stands for true positives, R means recall, P means precision and *F₁* stands for *F₁-measure*. The high recall values for all code clone types and θ modifications show that we are able to recognize known and reported weaknesses via our approach. The results for the recall are interleaved with the size of the θ threshold. For small θ values every vulnerability inside of the reference repository is detected, but this leads to a lower precision. Therefore, the answer for RQ2 is that the vulnerability detection for the described approach performs very well with a leak of precision for Type-3 clones.

C. RQ3: How well does our approach distinguish between vulnerable and patched code fragments?

Experimental Setup

In the next step, we have focused on checking precision. Thereto the patched code fragments for the given vulnerabilities were used to examine which security flaws will be detected as vulnerable code clones falsely. In this case, we did not modify the patched code fragments to match each of the three different types of clones but used the code fixes directly as input for the detection process. Patched code fragments distinguish to their vulnerable complement with some changes that removes the weak parts of that fragment. These changes differ in complexity. Some have an extent of multiple lines but other distinguish only by a single line to their vulnerable counterparts. The θ configuration setup for every iteration was the same we mentioned in RQ2.

Result and Discussion

As described in Sec. III, Type-3 clones are hard to detect. The low precision values summarized in Tab. II can be ascribed to the few code modifications inside the patches. Fundamentally, the patches represent Type-3 clones. If a patch has enough code modifications regarding its vulnerability, we can identify it as secure code correctly. If the code changes are too small, it may be flagged as weakness falsely. Relating to RQ3, it is possible to distinguish between vulnerable and patched code fragments as far as enough code modifications are present. On the one hand, the capability to detect code clones of Type-3 increases the amount of secure code, which is falsely identified as insecure. This reduces the precision of the described approach. On the other hand, through code clones of Type-3, the possibility exists to find more code clones of vulnerable code fragments, which increases the recall. Hence our goal is a high recall during detection. Therefore, we accept the false positives within the patch detection.

D. Threats to Validity

For the validity check of our evaluation, we consider the types of threats to validity for empirical software engineering research defined by Wohlin et. al. [26].

Conclusion: Maybe the selection criteria for building the test set influence the results in terms of recall, precision, and *F₁-measure*. To be more precise, it is possible that the size of selected code fragments influence the capability to distinguish between patched and weak code fragments. We have not considered the size of needed patches to close security flaws.

Internal: The used Java Runtime Environment version and the library version of used source code are not considered. Some code fragments are only insecure with specific Java versions or library versions and are secure within other versions. This could result in false positives for the classification of source code fragments as vulnerable that are secure with the used versions. Furthermore, it is imaginable that there are other code clone detection approaches, which tackles the problem of vulnerability detection inside of code fragments better than the chosen one.

Construct: The configuration and the θ adjustment of the code clone detection approach affect the effectiveness of the described procedure. Furthermore, the workflow and the granularity level of the tokenizer influences the results of the code clone detection approach.

VI. RELATED WORK

Vulnerability detection using clone detection. The clone detector ReDeBug [7] is language agnostic and uses a syntax-based pattern matching approach. It can detect some Type-3 clones but cannot detect Type-2 clones respectively clones with slight code modifications. Furthermore one of the design goals was a low false positive rate which harms recall. VulPecker [12] is a system for automatically detecting if a piece of software contains a vulnerability. It consists of a learning phase and a selection algorithm to identify vulnerabilities. This approach can detect Type-1, Type-2 and some Type-3 clones [13] in C/C++ code. CLORIFI [11] combines static and dynamic analysis to detect code clone vulnerabilities. It identifies the security code clones of known vulnerabilities with an n-token algorithm. With the help of concolic testing, CLORIFI tries to reduce false positives by verifying the security flaws. Our work is mostly complementary to the presented ones, as we focus on establishing a right balance between precision and recall, and use a state-of-the-art back-end clone detector that allows us to address scalability and language-independence simultaneously.

Static analysis for security. Our approach can be considered as a static analysis technique that can uncover vulnerabilities without executing the application at hand. Such techniques have been used successfully to uncover vulnerabilities, in some cases better than dynamic techniques such as penetration testing [20]. Most previous techniques are geared to detect specific vulnerabilities based on hard-coded solutions, such as SQL injections [14] and buffer overflows [27]. Fischer et al. [5] have used static analysis to study how severely Android apps are affected by vulnerabilities resulting from copying code snippets from StackOverflow examples. In our previous work [25] we present a tool-based approach that scans imported Java dependencies for known vulnerabilities. It checks the CVE if an entry for the corresponding library exists. Furthermore, we present an approach [3] for maintaining a knowledge base of security knowledge that is used to keep co-evolve the system design after changes in the availability knowledge (e.g., an encryption algorithm previously deemed as secure is broken). However, this work was focused on the design model level rather than on code-level vulnerabilities.

Code clone detection. Different code clone detection approaches with distinct capabilities exist. In their survey, Sheneamer et al. [21] distinguish the following main classes of

approaches. Text-based techniques (e.g. [1]) compares the similarity of code fragments based on terms of textual content. While focusing mostly on Type-1 clones without preprocessing, they are language-independent and easy to implement. Lexical techniques (e.g. [8,19]) divide the input code into a sequence of tokens that are converted into token sequence lines, which are then matched to another. Such techniques can detect various code clone types with higher recall and precision than text passing techniques. Syntactic techniques are either metric-based or tree-based. Tree-based (e.g., [2]) and graph-based techniques (e.g., [22]) parse the code into abstract syntax trees and find cloned code parts using tree-matching algorithms. Metric-based ones (e.g. [17]) compare source code snippet based on metric vectors created for each code snippet. This technique is able to detect Type-1 and Type-2 clones with high time complexity. It reduces the complexity of text-based approaches. Semantic techniques (e.g., [10]) detect two fragments of code that perform the same computation but have differently structured code, which was already named as Type-4 clone.

VII. CONCLUSION

The use of a single vulnerable code snippet can make a whole system insecure [23]. We introduce an approach to prove code fragments of reported vulnerabilities automatically. We detect insecure parts of source code via code clone detection by using code fragments that contain known vulnerabilities. As a result, a developer can be supported in the writing of secure code right from the beginning. With the aid of a database, it is possible to show information about reported security flaws. This information can be used to understand a weakness and, if necessary, provide a patch. The results of the evaluation show that detecting insecure code fragments work very well. We show that there are difficulties in distinguishing between patched and vulnerable source code fragments that are too similar to each other. The capability to detect small differences between them depends on the configuration and the distinction of line circumference from the vulnerable and patched fragments. Our work provides an *Eclipse* plug-in for supporting Java software developers [24]. Furthermore, we investigated the feasibility to distinguish between patched and vulnerable code snippets for our approach. We analyzed the CVE database content to underpin leveraging knowledge of reported vulnerabilities for the detection of security flaws within the source code.

Our future research is striving to compare artificial intelligence approaches in the form of neural networks with the static code clone detection approach described in this work. To solve the problem of our internal validity, we want to enhance the described approach such that the JRE Version of software projects and the recognition of library versions will be considered. Furthermore, a user study about the perception and effectiveness of helping developers and security experts to classify source code fragments is planned. The capability of the code clone detectors in the described approach relies on the data included in the reference code repository. Therefore, we expect to investigate further techniques to enhance the security-related source code within the code repository via leveraging community knowledge. Furthermore, we plan to improve the semi-automatically classification into exploit, vulnerable and patch code fragments.

VIII. ACKNOWLEDGMENT

Abstract - Intelligent computing techniques have a paramount importance to the treatment of cybersecurity incidents. In such Artificial Intelligence (AI) context, while most of the algorithms explored in the cybersecurity domain aim to present solutions to intrusion detection problems, these algorithms seldom approach the correction procedures that are explored in the resolution of cybersecurity incident problems that already took place. In practice, knowledge regarding cybersecurity resolution data and procedures is being under-used in the development of intelligent cybersecurity systems, sometimes even lost and not used at all. In this context, this work proposes to integrate Case-Based Reasoning techniques and IODEF standard in order to retain concrete problem-solving experiences of cybersecurity incident resolution to be reused in the resolution of new incidents. Experimental results so far obtained with a Case-based Cybersecurity Incident Resolution System (CbCSecIRS) implemented show that information security knowledge can be retained in a reusable memory, so improving the resolution of new cybersecurity problems.

Keywords— *Cybersecurity incidents; case-base reasoning; information security.*

I. INTRODUCTION

Information security issues have a critical impact on business mainly because the treatment of security incidents is highly expensive and time consuming to organizations. According to the ISO/IEC 27035 [1], processes of information security management should be grounded on approaches to the capture, structuring, and dissemination of security knowledge in each part of the organization. Fundamentally, security knowledge is expressed as various kinds of lessons learned constructed and refined over the time by cybersecurity experts about how to identify and treat cybersecurity incidents. As investigated here, this knowledge must be retained and reused systematically so that cybersecurity problems could be effectively approached. When such knowledge-based solutions are reused, for instance, the cost of reapplying them (instead of reconstructing them from scratch) each time a cybersecurity incident occurs can be reduced significantly. In crisis situations due to the occurrence of cybersecurity incidents, the collection and representation of incident resolution (CSecIR) procedures is fundamental to organizations since they can be revisited by security analysts as to promptly and comprehensively approach the treatment of cybersecurity issues.

The use of central systems in the collection, correlation, and analysis of data related to security incidents is a common practice in many countries, where Computer Emergency Response Teams (CERT) commonly detect and report thousands

of cybersecurity incidents a year. Each time an incident is reported by the CERT, it should be analyzed and solved by the Computer Security Incident Response Team (CSIRT) which is in charge of managing the computer network where the incident took place. To help the sharing of security information exchanged between CSIRTs or other operational security teams, the Internet Engineering Task Force (IETF) has proposed the Incident Object Description Exchange Format (IODEF) [2], which is a format directed to the broad representation of computer security information. Moreover, an IODEF extension aiming to facilitate the representation and exchange of enriched cybersecurity information was also proposed [3, 4]. Despite these efforts, it is still challenging to reuse security solutions [5, 6], especially those derived from concrete experiences of cybersecurity incident problem-solving.

In Artificial Intelligence (AI), while machine learning algorithms explored in the cybersecurity domain are aimed at presenting reliable intrusion detection solutions, these algorithms seldom approach the representation and reasoning with cybersecurity incident resolution procedural knowledge. In practice, such cybersecurity knowledge is being under-used in the development of intelligent cybersecurity systems, decreasing the effectiveness of Cybersecurity Incident Resolution Systems (CSecIRS). With the help of the Case-Based Reasoning (CBR) techniques [7], this paper approaches the collection and representation of this knowledge in the form of cases. Importantly, such cybersecurity incident resolution cases can be shared and reused as part of fundamental case-based knowledge management tasks [8, 9]. In this context, this paper shows how to build Case-based Cybersecurity Incident Resolution Systems (CbCSecIRS) based on information security attributes detailed according to the IODEF standard, including its cybersecurity extension. Instead of acting as a single cybersecurity solution, the overall idea of following the IODEF pattern is to permit to integrate the CbCSecIRS representation and reasoning capabilities from both intrusion detection systems and cybersecurity incident resolution systems.

The paper is structured as follows: Section II describes how cybersecurity incidents are approached and Section III presents related works where CBR techniques are explored in the cybersecurity domain. While Section IV presents our CbCSecIRS proposal, Section V describes experiments and results so far developed in our project. Finally, conclusions are presented in Section VI.

II. THE RESOLUTION AND REPRESENTATION OF CYBERSECURITY INCIDENTS

Knowledge regarding the resolution of cybersecurity incidents is a crucial asset to organizations. To be competitive, large amount of resources are being invested by security companies in order to not lose their valuable cybersecurity incident resolution experiences. By maintaining such lessons learned in a reusable memory, security analysts have the means of avoiding the costly reconstruction of “new” security solutions each time a cybersecurity incident problem occurs. Although large amount of data about incidents is being collected and explored by security companies via different AI approaches, the ISO/IEC 27035 standard [1] states that the processes of cybersecurity incident treatment can be organized in different activities: *i) Plan and prepare*: aim to develop incident treatment plans, check-lists of tasks to be executed when such cybersecurity threads occur, and communication plans aiming to record information about how entities involved should be prepare to communicate in the occurrence of security calamities; *ii) Detect and report*: as recommended in [10], multiples forms of reporting the cybersecurity incidents should be explored. In addition to the manual reporting, cybersecurity incidents can be reported automatically by security services or other entities as CERTs; *iii) Evaluate and decide*: the concrete occurrence of the cybersecurity incident should be evaluated, as well as the magnitude and consequences of such incident. Once this evaluation is developed, the origin of the cybersecurity incident can be traced properly; *iv) Respond*: involves the incident treatment actions that are properly planned in advance. Based on such treatment plans, recommended problem-solving steps aimed to deal with the cybersecurity incidents are executed. It means that appropriate resolution actions should be taken as to recover from the cybersecurity incident, in addition to incident documentation and communication to stakeholders; *v) Record*: the recording of the lessons learned should start as soon as the cybersecurity incident is closed. In doing so, this recording aims to assess whether the solution designed by the CSIRT was successful. An important task here is to document the cybersecurity incident, including not only its categorization but also its procedures of treatment.

In this paper, the techniques proposed are concerned with the outputs of the *detect and report* activities, retrieving past cybersecurity incident solutions that are relevant to the development of *evaluate and decide* activities. Then, cybersecurity incident resolution plans retrieved are used in *respond* activities, permitting to construct new plans to be explored in the *record* activities. So, a typical problem in such cybersecurity incident resolution scenario is the maintenance of lessons learned. We highlight such lessons are not only captured by the recording of factual information of cybersecurity incidents. In practice, alternative machine learning techniques can be successfully explored in the learning of how to automatically detect cybersecurity threads from such factual data. What we highlight in this work is that these lessons are also formed by the treatment procedures used by security analysts in the resolution of cybersecurity incident problems. So, this concrete experience-based knowledge ought to be collected and stored so that it can be shared among different security systems, in

addition of being queried and reused as to better solve new cybersecurity incidents.

In the processes of cybersecurity incident treatment, the IODEF standard defines a *data format* directed to the representation and exchanging of information about cybersecurity incidents [3, 4]. The IODEF data model includes data about hosts, networks and services; attack methodologies and forensic pieces of evidence; incident impact; and approach to document the cybersecurity investigation and treatment workflow. This standard also provides a framework to share the incident information that is usually exchanged by CSIRTs as to facilitate the machine-processing of such information. In essence, the IODEF data format is organized in set of data classes, derived from a basic class *Document* that contains one or more *Incident* class. Each aggregated Incident class describes in its derived classes commonly exchanged information when reporting or sharing derived analysis from security incidents. The cybersecurity incident IODEF extension [3, 4] increased Incident class representation capabilities. Despite the large number of resources provided by the IODEF, as it was developed to be adaptable to the different organizational needs, the classes that are required to represent a cybersecurity problem are of particular importance as this paper shows how a CbCSecIRS can explore them in the representation of concrete experiences of cybersecurity resolution problems (details in the section IV).

III. CASE-BASED REASONING IN THE CYBERSECURITY DOMAIN

In AI, Case-Based Reasoning [7] relies on a lazy-learning approach to machine learning which focuses the resolution of new problems by reusing solutions recorded in past problem-solving experiences represented as “cases”. Given a new problem to be solved as a query in such CBR systems, the key problem-solving steps are 1) the retrieval of similar cases from a case base, 2) the reuse of solutions recorded in the most similar cases retrieved, 3) the revision of such retrieved solutions as to deal with possible differences between past and new case situations and 4) the retention of new case-based problem-solving experiences in the case base as a way of learning how to solve new problems. Relevant works with CBR in cybersecurity research context follow.

In [11], a CBR system explores the organization of attack cases, where a hierarchical structure containing attributes from possible attack situations is used in the representation of such problem cases. To detail the solutions of such cases, the textual description of countermeasures and the user satisfaction degree for solution proposals are used. Although this work presents a relevant solution for this cybersecurity knowledge management problem, it only approach a limited set of response types to incidents.

With the use of CBR, [12] details a RFM (*Recency, Frequency, Monetary*) technique aimed at reducing false alerts. Considering how recent the security event occurred, its frequency and attributes values, this approach relies on the statistical analysis of log files to detect anomalies. Then CBR is applied on the identification of attack patterns that are similar to past ones. This work is also focused on the incident detection and determination of security event responses, where such responses are expressed as commands to computer security

services. However, this work does not explore the collection and representation of response plans to the treatment of cybersecurity incidents.

In [13], ontologies are integrated to CBR techniques in order to construct a decision-making and response system to the treatment of cybersecurity incidents. In particular, the ontology model is used in the standardized representation of such incidents, resulting on a hierarchical organization of attack types. While this work does not follow cybersecurity representation standards, the collection of automated attack information and manual attack information are the inputs of the resulting CBR system.

In [14], a CBR system to support the construction of cybersecurity incident responses is described. Using information from past attack cases, this system classifies new attacks to better maintain a secure network. While each attack is represented by a sequence of events, each response is represented by a partially ordered set of resolution actions. These attacks are compared with past attack cases stored in a case base, allowing the reuse of response plans recorded as a solution to the new attack situation. Although this work considers the determination of responses to cybersecurity incidents, it is mostly focused on the incident detection through CBR.

From such works, it is possible to state that the exploration of CBR techniques in the cybersecurity domain is limited and the benefits due to the integration of such AI technique with cybersecurity data standards are still open to investigation. Relying on the proposal of a CbCSecIRS proposal, this paper aims to further approach this gap.

IV. A CASE-BASED REASONING MODEL FOR CYBERSECURITY INCIDENT RECORDING AND RESOLUTION

The recording and reasoning with expert knowledge regarding to the resolution of cybersecurity incidents is crucial to the effective treatment of new incident problems. In our Case-based Cybersecurity Incident Resolution System (CbCSecIRS) this knowledge is approached as concrete experiences of problem-solving modeled as *cases*. Once such cases stored in a *case base* are available for similarity-based computations, detailed experience-based answers to the resolution of cybersecurity incidents can be better reused by security analysts. In practice, concrete cybersecurity incidents are recorded in a shared memory, allowing security teams to maintain reusable security treatment knowledge.

To allow cybersecurity incident cases (represented as problem-solution pairs) to be reused, the first modeling task is to represent the problem (incident) according to the IODEF standard. In this way, such incident representation is in conformity with other security proposals directed to the improvement of the operational capabilities of CSIRT teams [3, 4]. Once the incident representation complies with IODEF standard, the CbCSecIRS can communicate with other security systems to allow the acquisition/exchange of cybersecurity incident cases (i.e. problem part of such cases). In addition, security logs received along with incident descriptions can also be examined by security analysts as part of the case acquisition and representation tasks.

The case-based process of cybersecurity incident treatment starts when incidents represented in IODEF are captured by the security analysts. Using the CbCSecIRS, concrete occurrences of new cybersecurity incidents are taken as queries. Once retrieved cases (similar to the current incident situation) are available for examination, the incident treatment plans recorded in the cases retrieved can be re-executed. When such proposed solutions prove to be effective in the resolution of the current problem, such new experience of problem-solving can be recorded in the case base as part of a continuous improvement of the case knowledge which is maintained by the system. If there isn't a good solution and a new resolution is planned and executed, it also can be recorded in the case base. Such recordings allow the CbCSecIRS to dynamically learn new cases as to augment its capabilities of solving cybersecurity incidents.

A. The Case Base Modeling

In the modeling of a case, an incident (problem) is represented by a set of attributes and values along with the incident resolution (treatment plan) expressed by a set of actions. Each incident presents particular behaviors and requires particular attributes to be recognized. Thus, a cybersecurity incident in the CbCSecIRS is modeled by incident type, where types considered in our project are listed in Table I.

TABLE I. INCIDENT TYPES MODELED IN THE CASE BASE

Type	Description
<i>Bot</i>	An organization asset starts to be part of a malware infected computer network. The computers of this network are controlled by hackers (<i>botmasters</i>)
DoS	Deny of service attack. An inundation attack against a target (host or service) to turn it unavailable. This cybersecurity incident can be centralized or distributed (DDoS)
<i>Proxy</i>	A <i>proxy</i> server is infected in order to make anonymous the hackers that are using it. So, such anonymous hackers use the proxy server to make other attacks
<i>MaliciousURL</i>	It is a computer storing malicious files which are accessible by a URL
<i>Copyright</i>	A <i>host</i> shares or received protected material by copyright
<i>Spam</i>	Unsolicited message sent from a host to other users
<i>Scan</i>	A <i>host</i> scans other host ports in order to find vulnerabilities that may allow an attack
<i>LoginAttempt</i>	Login attempts by brute force in a service account. The overall aim is to obtain an un-authorized access on the system
<i>Phishing</i>	It is an attempt of deceive a legal user using a fake web page with is similar to a correct one
<i>Defacement</i>	Content modification of legal web site without authorization

The attribute selection by incident type derived from the incident characterization detailed in [11-14]. After the identification of such set of attributes from literature, its consistency was checked against the cybersecurity incident reported by the

Brazilian academic network CSIRT. While there are attributes that are common to different types of cybersecurity incidents, others are specific to one type. As a result, eight common attributes and twelve specific attributes were detected and selected to model the incidents in a case. Despite our selection, we highlight the expert can include others when necessary.

To represent the incident case, the modeled cybersecurity incidents were mapped to IODEF format. Figure 1 illustrates how the standard IODEF classes were adapted to support our case model. The *Incident* class derives from *IODEF-Document* class. It is mandatory in IODEF format. The *IODEF-Document* class contains the attributes *version* and *lang* that according to RFC4646 [15] must ever be filled. The *Incident* class expresses a standardized description of commonly shared incident attributes. It specifies the time the incident is reported (*DetectTime*) along with a textual description of the incident (*Description*). The *purpose* attribute is mandatory and it is used to express the reason by which the IODEF document was created (traceback, mitigation, reporting, other). The *Flow*, *System*, *Node*, *Address*, and *OperatingSystem* classes describe environment features involved in the cybersecurity incident. The *Method* class describes the method used in the attack and its derived *Reference* class makes reference to vulnerabilities, alerts from IDSs, data about malwares, and other information from the IODEF cybersecurity extension format. The *Service* and *Application* classes describe details about attributes related to resources involved in the incident. Finally, *AdditionalData* class is included to extend the IODEF model, representing different attributes like Logs, HashFromMalware, Agent, Title, Size, IpCC, IpOrigin, TtConnections, ProxyType.

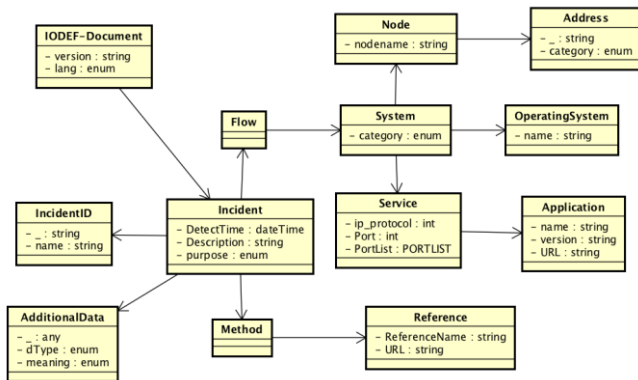

Fig. 1. The IODEF representation used by incident resolution cases.

B. Resolution of Cybersecurity Incidents

The cybersecurity incident experiences of problem-solving retrieved from the case base ought to be the most similar cases to the current problem. As implemented in the CbCSecIRS, this similarity is indicated by a numerical value between 0 and 1, where 1 is the highest similarity between two cases. The similarity computation is developed by comparing n pairs of a_i and b_i attributes represented in the case structure. Once such local similarities (similarities between attributes) are computed, a global similarity (similarities between cases) is measured. To compute this global similarity, an aggregation functions make use of weight values associated to each attribute

used in the similarity computation. As described in the Equation (1), these weight value W_i represent the relative importance of the i attributes in the solution of the problem. Based on this similarity assessment, the resulting similarity computation indicates how similar the cases a and b are.

$$sim(a, b) = \sum_{i=1}^n W_i \times sim_i(a_i, b_i) \quad (1)$$

To compute the distance between two cases, the Euclidean distance function is used. The solution of a cybersecurity incident problem involves the characterization of a problem situation and the consequent selection and execution of a set of actions/procedures directed to the correction (mitigation) of the problem. In this work, these actions are recorded in body of cases as simplified plan-like structures of incident treatment. Figure 2 illustrates a plan constructed by security analysts from the security division of a commercial data center to approach a Bot incident type. In practice, this plan details a cybersecurity resolution script that is followed by these analysts when they need to treat a cybersecurity incident situation.

Incident Response Plan

Incident #997164

1. Quickly disable the host access to the institution's network
2. Open a new ticket to inform the incident to the User Support Center in order to send a technician to the computer's place
3. Analyze evidence to identify the incident
4. Execute a complete scan using the antivirus software
5. If some infected file was found, follow the instructions prompted by the antivirus software
6. If the antivirus software cannot be executed, reboot the computer in "safe mode" and repeat the steps 4 and 5 of this plan and then reboot the computer in "regular mode"
7. If the antivirus software can't be executed in "regular mode" or "safe mode", use the specific tool for the infected file removal
8. If some Operation System file is infected, reinstall the Operation System
9. Ensure that the Operation System is working with the most recent updates, and the updates are set to be automatic
10. Enable the access of this host to the network of the organization
11. Ensure that the computer's firewall is installed with the most recent updates
12. Ensure that the antivirus is installed with the most recent updates
13. Recommend the user to follow orientations from the Internet Security Document available at <https://cartilha.cert.br>
14. Contact the Incident Security Center in order to inform them about the response given to this incident

Fig. 2. Response plan used in the treatment of a Bot incident.

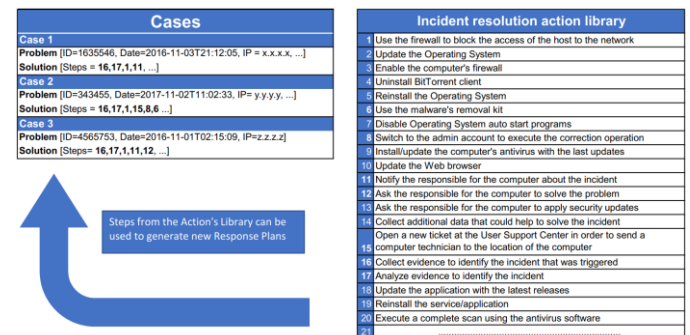

Fig. 3. Incident cases represented according to a cybersecurity incident resolution action library.

To standardize the description of cybersecurity incident resolution plans, a set of actions was represented in a library. So, resolution actions are reused from this repository in the specification of treatment plans for different kinds of cybersecurity incidents. For instance, Figure 3 presents three different cases in which their respective treatment plans were detailed according to plan step indices defined in the library (labeled according to such indices). In practice, the library reflects the steps used in the treatment of the cybersecurity incidents stored in the case base of the CbCSecIRS.

In our project, the CbCSecIRS implemented the K-Nearest Neighbours algorithm, where a (weighted) Euclidian distance function was used in the computation of case similarities, and the consequent retrieval of cases from the case base as to provide cybersecurity treatment answers to incident situations detailed as queries.

V. EXPERIMENTS AND RESULTS

Experiments were developed as part of the evaluation of the CbCSecIRS approach proposed in this work. The goal was twofold: first, to assess the reuse of past experiences of cybersecurity incident problem-solving in the resolution of new problems in this cybersecurity domain and, second, to assess the accuracy of the CbCSecIRS implemented. To approach these goals, a set of 259 cybersecurity incidents used in the experiments were collected from the security division of a commercial data center.

To approach the first experimental goal, new cybersecurity incident situations were collected and used in the tests: the cybersecurity incidents number 2102389 and 2261674 (these are solved cybersecurity incident problems by different participants of the security team of the company, although they were not known during the system development). Each one of these new case problems was expressed as a query in the CbCSecIRS, allowing one to retrieve the most similar cases to them from the case base. In many senses, the aim was to examine if the cybersecurity resolution procedures recorded in the retrieved cases could be reused on the treatment of the current problem. In doing so, the retrieved cases for each executed query were presented to a security expert from the commercial data center organization. Whenever possible, this expert offered positive feedback when the resolution plan retrieved could be properly reused on the treatment of the current problem situation. An example of such research in action case study is presented in Figure 4.

Fig. 4. Incidents number 2102389, 1483711 and 1510754.

In Figure 4, the 2102389 incident was used as a query in the CbCSecIRS, allowing one to retrieve the 1483711 and 1510754 incidents from the case base. All these incidents were characterized as Bot types. These retrieved cases have treatment plans that were considered similar to the plan recorded in the query case. So, the CbCSecIRS was successful on the resolution of this 2102389 test case, showing that the proposed technique was able to maintain the cybersecurity incident resolution knowledge to this kind of problem.

Another example is presented in Figure 5. To the 2261674 incident used as query, the 1022675 and 1620589 cases were retrieved from the CbCSecIRS case base. Both retrieved cases were of the *Copyright* type detailing the illegal sharing of movies in the *BitTorrent* platform. In relation to the treatment plan represented in the retrieved cases, only the 1022675 case contained a highly similar treatment plan in relation to the plan recorded in the query case. Although a solution to the 2261674 query situation could be obtained with the reuse of the plan recorded in the most similar case retrieved, the 1620589 case recorded a new kind of treatment in relation to the other cases considered. Figure 5 presents these cybersecurity incident treatment plans side-by-side, allowing one to observe that the 2261674 incident contained more detailed resolution steps than the more general resolution ones represented in 1620589 case. It means that the retrieved solution could not be fully reused in the solution of the test case situation. That was because it was necessary to develop more particular resolution actions in the treatment of the current problem situation. All in all, as part of traditional knowledge acquisition and representation tasks, improvements in the ways cybersecurity resolution procedures are represented in cases still have to be applied in the CbCSecIRS proposal.

IdIncident	2261674	1620589
Step 1	Collect evidences to identify the incident that was triggered	Collect evidences to identify the incident that was triggered
Step 2	Analyze evidences to identify the incident	Analyze evidences to identify the incident
Step 3	Use the firewall to block the access of the host to the network	Use the firewall to block the access of the host to the network
Step 4	Open a new ticket at the User Support Center in order to send a computer technician to the location of the computer	Notify the administrator of host/network/server/webpage about received incident
Step 5	Uninstall the client of BitTorrent protocol	Request the administrator of the host/network/server/webpage to block the communication with the network
Step 6	Guide the user to follow the published security tips	After incident treatment, request access
Step 7	After incident treatment, request access	After incident resolution, unblock the access in the firewall
Step 8	After incident resolution, unblock the access in the firewall	Notify the CAIS about incident resolution
Step 9	Notify the CAIS about incident resolution	

Fig. 5. Incident resolution plans for cases 2261674 and 1620589.

In addition to such research in action case study experiments, tests aiming to evaluate the CbCSecIRS accuracy were developed as part of the second experimental goal. To do so, the cases in the case base were randomly divided in p partitions of equal size, where $p = 10$. Then, a *K-Fold Cross Validation* technique was used in the evaluation of the system accuracy. In different test runs, for instance, the cases belonging to one of these partitions were used as query cases, while the remaining cases were maintained in the case base so that they could be retrieved as solutions for such a query. In case the retrieved cases and the query cases contained similar cybersecurity incident resolution plans, the answer generated by the system was considered correct. Otherwise, the system offered an incorrect answer to the current problem situation. In

a first run, tests were developed using a similarity function in which a weight = 1.0 was attached to all case attributes being used in the similarity computations, indicating that such attributes have the same importance in such computations. In a second run, the weight values for such case attributes were adjusted according to the opinion of a cybersecurity domain expert from the commercial data center organization.

Table II shows the accuracy results obtained when the K-Fold Cross Validation technique was executed. Although considering different similarity thresholds in the retrieval algorithm used by the CbCSecIRS (95% and 60% minimal similarities), these accuracy results were positive (i.e. as good as to accuracy results presented by other works in this application domain [11-14]) when adjusted weight values were used and when all weight values were equal to 1.0 in the similarity function used by this system.

TABLE II. THE ACCURACY OF THE CBCSECIRS

	1-NN	2-NN	3-NN	4-NN	5-NN
Similarity threshold = 60%, weights w = 1	87.50	84.38	88.89	83.33	80.00
Similarity threshold = 95%, weights values determined by a domain expert	93.33	90.00	95.24	91.67	90.00

VI. CONCLUDING REMARKS

Organizations spent a lot of time and money on the treatment of cybersecurity incidents due to the fact that it is still challenging to maintain their concrete experiences of cybersecurity problem-solving. To approach this problem, this work describes the knowledge acquisition and representation activities that cybersecurity system developers can explore when building CbCSecIRS. In doing so, the cybersecurity incident case model used by these CbCSecIRSs is based on attributes detailed in the IODEF standard. Instead of acting as an isolate cybersecurity solution, the overall idea of following the IODEF standard is to permit to integrate the reasoning capabilities from both intrusion detection systems and cybersecurity incident resolution systems.

As discussed in this work, the CbCSecIRS offers the capability of retrieving cybersecurity incident data and incident resolution procedures represented in cases. Such cybersecurity knowledge is are organized and specified explicitly in the case structure, allowing to be reused by security analysts in different cybersecurity problems. In particular, cybersecurity knowledge regarding incident resolution actions now recorded in cases amount to a concrete explanation about how to better approach those kinds of problems. This explanation capability is crucial when cybersecurity emergency circumstances occur (i.e. after an attack happened, even in face of protection barriers). That is because security analysts are required to promptly and effectively explain their actions in such crisis situations as to mitigate the damage that a cybersecurity event very often causes in the computer infrastructure of an organization.

The CbCSecIRS proposal detailed in this work can have a dual application since it can be explored in both the cybersecurity incident detection and the cybersecurity incident resolution. In practice, cybersecurity incident cases do express incident resolution knowledge which can complement the func-

tionalties required to automatically detect and prevent those incidents as explored by other AI techniques in the cybersecurity domain. Although the experiments presented here can be expanded in different ways, the results show a positive scenario in which our CbCSecIRS proposal is relevant for cybersecurity analysts because it accurately relies on similarity-based computations to connect incident detection data with incident resolution procedures which can now be maintained in the structure of reusable cases.

Verifying Static Aspects of UML models using Prolog

Feng Sheng Huibiao Zhu* Zongyuan Yang Jiaqi Yin Gang Lu*

School of Computer Science and Software Engineering

East China Normal University, Shanghai, China

Abstract—The Unified Modeling Language (UML) provides a number of diagrams to describe the modeling system from different perspectives, which contain overlapping information about the systems. However, it does not provide any means of meticulously checking consistencies among the overlapping elements. In this study, we propose an approach for consistency checking of UML class diagrams and object diagrams using Prolog. First we formalize the model elements based on metamodel and convert the models into Prolog facts. Then we define some consistency rules that are encoded into Prolog. The Prolog's reasoning engine automatically checks the consistencies of models. In addition, we provide interfaces to query models for properties, elements and submodels. The design errors can be effectively avoided and the correctness of code-generalization can be guaranteed according to our approach.

Index Terms—Class Diagram, Object Diagram, Consistency Checking, Prolog

I. INTRODUCTION

The Unified Modeling Language [1] has been developed as a standard object-oriented modeling notation in Model Driven Engineering (MDE) and is widely used in industry. It provides numbers of diagrams to model different aspects of the systems, such as the static views (class diagrams, object diagrams) and dynamic views (sequence diagrams, statecharts). In addition, it offers a variety of tools that cover all the features of the system modeling for a more complete description of the models. However, the syntax and semantics of the UML are semi-formally defined in terms of a metamodel combining natural language descriptions, UML notations and Object Constraint Language (OCL), which is not sufficient to express the semantics of the UML models precisely. Moreover, UML uses the different models to characterize the same system from different perspectives. Change in one diagram may ultimately affect the other diagrams, and result the inconsistencies between different diagrams.

UML models can be represented in the form of a theory in mathematical logic, such as the description logic [2], data refinement [3] and category theory [4]. By transforming UML models into mathematical logic, the problem of inconsistencies can be regarded as the problem of contradictions in the logic theory. A system is consistent if it does not contain any contradictions. Inconsistencies in UML models reveals design errors in software development. Moreover, the inconsistencies will

not be propagated to the codes if we perform the consistency checking at design phase.

Various approaches [6] [13] [15] [16] have been proposed to check the consistency in UML. Typically, approaches devoted to the verification of UML models convert the models into formal semantic domains. Besides, different types of consistency rules are defined on the basis of these conversions. The models' consistencies are verified according to the possibility that the models satisfy these consistency rules. Straeten et al. [2] developed an extension of UML metamodel and presented a classification of inconsistency problems using description logic. They expressed the detection and resolution of consistency conflicts by means of rules. Egea and Rusu [11] demonstrated the structural and semantic conformance between models and metamodels by transforming the models into Maude. Besides, the satisfiability modulo theories (SMT) is often used to support the consistency verification of UML models. Soeken et al. [8] presented an automatic approach that checks the verification for the UML dynamic models. The underlying verification problem is encoded as an instance of the satisfiability problem and subsequently solved using a SAT Modulo Theory solver. However, the SMT solvers typically only support decidable theories and are not sufficient for consistency checking. Storrie [12] proposed a representation of models based on Prolog. He provided query interfaces to identify elements, properties and submodels. Khai et al. [10] proposed an approach for consistency checking of class and sequence diagrams based on Prolog. Cabot et al. [21] presented an automatic method for the verification of UML class diagrams extended with OCL constraints. They transformed the UML/OCL model into a Constraint Satisfaction Problem. The correctness properties such as weak and strong satisfiability or absence of constraint redundancies are checked. Khan and Porres [7] proposed an approach to automatically validate the consistency of UML models using logic reasoners for the Web Ontology Language OWL 2. They translated the models into OWL 2 and presented a tool supporting UML modeling tools to perform the translation from the models into the OWL 2.

In this paper, we propose an approach for the fully automatic, expressive verification of UML class diagrams and object diagrams using Prolog. First we formalize the model elements based on metamodel and convert the models into Prolog facts. Then we summarize several different types of consistency problems and encode into Prolog rules. Finally the

*Corresponding authors: hzbzhu@sei.ecnu.edu.cn (H. Zhu).
glu@cs.ecnu.edu.cn (G. Lu).

reasoning engines such as SWI-Prolog, are used to check the inconsistencies through analyzing the models and feedback the error information if any inconsistency error occurs. According to our approach, the design errors can be effectively avoided in design phase and the correctness of code-generalization can be guaranteed.

This paper is structured as follows. In Section II, we introduce the background about model consistency and our approach. Section III presents the formalization and conversion from UML models to Prolog. Section IV describes the different types of consistency. We have implemented a prototype tool which automatically translates the UML models into Prolog codes in Section V. Section VI shows some experiments to indicate the performance of our approach. Section VII concludes the paper and discusses the further work.

II. BACKGROUND

A. Consistency checking of UML models

In the past few years, the consistency problems in UML have become a hot issue. The term *model consistency* [18] is defined as “the overlapping elements in different models of the same system satisfy certain properties”. There are many studies that classify the consistency of models. One of the most widely accepted classifications is the Engels’ classification [6], which classifies the model consistency into four categories:

(1) *Vertical consistency* occurs when an abstract model is refined into a more concrete model. It is desirable that the concrete model should be consistent with the abstract one. The refinements of models cause the vertical consistency problems. (2) *Horizontal consistency* arises in case where different models describe the same system from different aspects containing overlapping elements. The overlapping elements should satisfy some elementary properties to ensure the consistency between the different models.

(3) *Syntactical consistency* ensures that a model conforms to the abstract syntax. The abstract syntax of models is usually defined by the metamodel. In other word, we consider that the models are syntactically consistent if the models are the instances of classes and associated by the instances of associations in the metamodel.

(4) *Semantic consistency* occurs when the developers expect to get more accurate models through additional constraints on models. The semantics of UML is usually specified in natural languages and OCL. It is hard to check the semantic consistency in UML especially for static diagrams since the OCL is not precisely defined in UML.

In this paper, we mainly consider three kinds of consistency issues: horizontal, syntactical and semantic consistency. The vertical consistency involving the refinements of the models is out of the scope of this paper.

B. Overview of the approach

We propose a general framework to check the consistency for a subset of UML static diagrams including class diagrams and object diagrams. The basic route of our approach is shown

as Fig. 1. First the designer provides a target model, created by UML CASE tools, and transforms the models into XMI files. Then the concepts of the models are automatically converted to the facts in Prolog database. Next the consistency rules with the facts are imported into the SWI-Prolog. The SWI-Prolog analyzes and queries the elements to verify the consistency of the target model and feedback the error information if any inconsistency occurs.

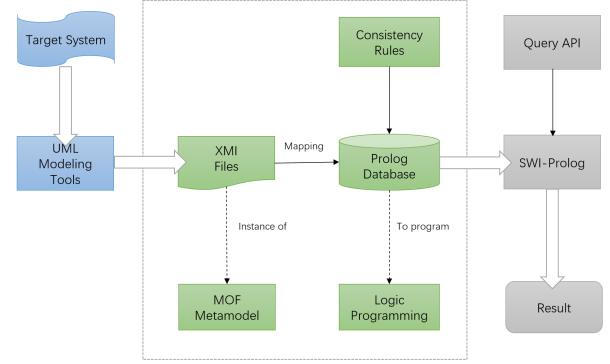

Fig. 1. An Outline of Our Approach

III. FROM UML MODELS TO PROLOG

A. From Class Diagrams to Prolog

The metamodel is a language that contains certain metadata describing the concepts and relations for providing a modeling language. The *Meta Object Facility* (MOF) standard defines the Essential MOF (EMOF), a subset of MOF that is used to define the metamodels. In this study, we formally define the syntax of the models according to the EMOF metamodel.

Definition 1: The syntax of the class diagrams is a structure

$$\mathcal{M} = \{class, attribute, operation, association, rolename, multiplicity, \prec\}.$$

where

- *class* is a set of classes.
- *attribute* is a set of signatures for functions mapping a class c to an associated attribute value.
- *operation* is a set of signatures for user-defined operations of a class c .
- *association* is a set of associations.
- *rolename* is a set of roles.
- *multiplicity* is a set of multiplicities of associations.
- \prec is a partial order on classes reflecting the generalization hierarchy of classes.

The class diagrams are denoted as a series of Prolog facts. Each model element in \mathcal{M} is described as a set of facts with the same clause and different parameters. Every element of class diagrams is assigned an identifier that identifies the actual objects that are to be instances of the various classes in the metamodel. In the following, each model elements is considered in details.

The most important part of the class diagrams is the classes. A class is a collection of objects that have the same attributes, operations, relationships, and semantics. The `class/3` clause in Prolog is used to denote the class, including an identifier, a class name and a boolean type indicating whether it is abstract.

class(classid, classname, isAbstract).

Note that the abstractions of the objects are classes, and the instantiations of the class are objects. The classes can be considered as the types of objects according to the Model Driven Architecture (MDA).

The classes define a group of objects' states and behaviors. More specifically, the attributes and associations of classes define the objects' states and relationships respectively, and the operations describe the behaviors of objects. The attributes are the values describing the object's properties, including a name and a type that specifies the domain of values. The `attribute/4` clause describes the attributes of class diagrams in Prolog.

attribute(attrid, attrname, attrtype, classid).

where `attrid` is an identifier of attribute, `attrname` is an attribute name, `attrtype` is the type of attribute, and `classid` is an identifier of class to which this attribute belongs.

The operations are parts of a class declaration in models. They describe the behavioral properties of classes, represented by the `operation/4` clause in Prolog.

operation(opid, opname, [parameters], classid).

where `opid` is an identifier of the operation, `opname` is a name of the operation, `[parameters]` is a list of parameters' id, and `classid` is an identifier of class to which this operation belongs.

The `parameter/3` clause in Prolog denotes the parameters in operations.

parameter(pid, pname, ptype).

where the `pid` and `pname` denote the identifier and name of the parameter respectively, and `ptype` denotes the type of the parameter, including the primitive types and class types.

The associations describe the structural relationships between the classes. In general, a class can have more than one associations, and an association can connect two or more classes. In this study, only binary associations are considered, the n -ary associations can be obtained by extending parameters in the `association/4` clause, where the `assoctype` can be directional, nondirectional, aggregate or compositive.

association(associd, classAid, classBid, assoctype).

In an association, the class can appear more than once playing different roles. The role names are usually useful in the navigations of models. The `rolename/4` clause assigns a unique role name to each class that participates in the binary association. The order of names in role names should coincide

with the order of classes in the corresponding associations. If the role names are omitted in a class diagram, we define the role names by changing the first letter of the name of target class to lower case.

rolename(roleid, nameA, nameB, associd).

Associations may also have multiplicities which specify the possible numbers of links for associated classes. The multiplicity describes the number of allowable objects of a range class to link with the objects of a domain class. The `multiplicity/5` clause has a minimum and maximum number of instances of the target classes, defined by the `lowval` and `upval` attributes. Unbounded ranges can be modelled using the value n for the upper attribute in Prolog.

multiplicity(multid, classid, lowval, upval, associd).

A generalization indicates that one of the two related class (subclass) is considered to be a specialized form of the other (superclass). The superclass is a generalization of the subclass. Generalization relationships form a hierarchy over the set of classes. A generalization hierarchy \prec is a partial order on the set of classes, shown as the `generalization/3` clause.

generalization(genid, subid, superid).

We define a recursive function `parents` to get all superclasses of a given class as follows.

$$\text{parents} : \begin{cases} \text{class} \rightarrow \mathcal{P}(\text{class}) \\ c \mapsto \{c' \mid c' \in \text{class} \wedge c \prec c'\} \end{cases} \quad (1)$$

The `parents/2` clause indicates the parent classes can be directly or indirectly derived through the generalization relationships. We can query the parent classes using `all_parents/2` where `findall` get all parent classes from the `parents` and put them into the variable `IDS`.

```
parents(Superid, Subid) :-
    generalization(_, Subid, Superid).
parents(Superid, Subid) :-
    generalization(_, Subid, X),
    parents(Superid, X).
all_parents(Subid, IDS) :-
    findall(Y, parents(Y, Subid), IDS).
```

B. From Object Diagrams to Prolog

The object diagrams show a complete or partial view of the structure of a modelled system at a specific time. The object diagrams is composed of the snapshots of running systems. An instance of a class is called an *object*, whereas an instance of an association is called a *link* that is a connection between two or more objects of classes at corresponding positions in the association. The object diagram focuses on the set of objects and attribute values, and the links between these objects at a particular time.

Definition 2: An object diagram for a model \mathcal{M} is a structure

$$\sigma(\mathcal{M}) = \{\text{object}, \text{link}, \text{attrval}\}.$$

where

- *object* is a set of objects.
- *link* is a set of links connecting objects.
- *attrval* is a set of functions assigning attribute values to each object.

The representation of the object diagrams in Prolog is similar to the representation of class diagrams.

```
object(objid,objname,classid).
link(linkid,objAid,objBid,associd).
attrval(attrvalid,attrid,value,objid).
```

The finite sets of *object*/3 clauses contain all objects and the finite sets of *link*/4 clauses contain links connecting objects. The *attrval*/4 clauses assign attribute values to each object. The *classid* in *object*/3 should be related to the *classid* in *class*/3, the same as *associd* and *attrid*.

Definition 3: The domain of a class is defined as a set of object identifiers that are the instances of the class.

$$\text{domain}(c) = \bigcup \{ \text{objects}(c') \mid c' \in \text{class} \wedge c' \prec c \}. \quad (2)$$

where the function *objects* gets all the objects of a given class. The domain of a class is defined using recursive predicate in Prolog. The *all_objects_ids*/2 returns the list of objects' identifiers for a given class identifier.

```
objects_ids(Classid, Objid) :-
    object(Objid, _, Classid).
objects_ids(Classid, Objid) :-
    generalization(_, Z, Classid),
    objects_ids(Z, Objid).
all_objects_ids(Classid, IDS) :-
    findall(Y, objects_ids(Classid, Y), IDS).
```

IV. CONSISTENCY CHECKING RULES

A. Syntactical Consistency

A metamodel defines the abstract syntax of the models. The models are syntactically consistent if they conform to the metamodel. More specifically, the elements of the model should be the instances of the classes in the associated metamodel, and the links of two elements are the instances of associations related by the associated classes in the metamodel. The MDA is described in four-layer architecture, each layer model can be regarded as instances of the upper layer model. The representation of UML concepts in this study is based on the EMOF metamodel. The models defined in our approach satisfy the syntactical consistency since they are the instances of the metamodel.

B. Semantic Consistency

A metamodel may also define a set of validity constraints on the metamodel using OCL, called semantic consistency [19]. For instance, a class should not define two attributes having same names. These OCL constraints are defined between the metamodels and models in order to describe more detailed

models. In a sense, any OCL expressions can be converted to the Prolog rules having the same semantics. The models are semantically consistent if the models conform to the rules. First the OCL representation is presented, and then we give the Prolog code for these constraints. Only several common constraints are presented because of the limited space.

Name Unique. The names of classes and associations should be unique and the names of attributes are unique in one class.

```
context Class inv:
    self.attribute -> forall(a1, a2 : attribute |
        a1 <> a2 implies a1.name <> a2.name).
```

Acyclic Generalization. There are no direct or indirect cycles in the generalization relationship.

```
context Class inv :
    self.allParents -> excludes(self).
```

The *list_reps*/2 shows the repetitions in the list. The list of names is the first parameter and the result of repetition elements is the second parameter. The circular generalization error occurs if any class is in the list of its parents classes. The *inheritSelf* returns true if the parameter class *X* has cycles in the generalization relationship.

```
list_reps([], []).
list_reps([X|Xs], Ds1) :-
    x_reps_others_fromlist(X, Ds, Os, Xs),
    list_reps(Os, Ds0),
    append(Ds, Ds0, Ds1).
x_reps_others_fromlist(_, [], [], []).
x_reps_others_fromlist(X, [X|Ds], Os, [X|Ys]) :-
    x_reps_others_fromlist(X, Ds, Os, Ys).
x_reps_others_fromlist(X, Ds, [Y|Os], [Y|Ys]) :-
    dif(Y, X),
    x_reps_others_fromlist(X, Ds, Os, Ys).
canGoTo(X, N, Nodes) :-
    member(X2, [X|Nodes]),
    generalization(_, X2, X1),
    \+ member(X1, Nodes),
    canGoTo(X, N, [X1|Nodes]).
canGoTo(_, N, N).
canGoTo(X, Nodes) :-
    canGoTo(X, Nodes, []).
inheritSelf(X) :-
    canGoTo(X, Nodes), member(X, Nodes), !.
```

We also offer query interfaces to query properties in SWI-Prolog. For example, the variable *List* indicates the set of the classes' name and the variable *R* represents the repetition elements if there are any repeating elements in the models.

```
?- bagof(Y, X^class(X, Y, _), List), list_reps(List, R).
```

C. Horizontal Consistency

The problems of horizontal consistency is caused by the overlapping elements of different diagrams. There are some overlapping elements between the class diagrams and object diagrams. For instance, a class should exist in the class diagram if the objects of the class exist in the object diagram.

When the inconsistency occurs, we can quickly locate the wrong place based on the feedback information.

Class Existence. The related classes of objects in the object diagrams should exist in the class diagrams since the objects are the instances of the classes.

$$\forall o \in \text{object}, \exists c \in \text{class}, o.\text{classid} = c.\text{classid}.$$

Association Existence. There are links between objects in object diagrams and the associations referred to these links between corresponding classes exist in class diagrams.

$$\begin{aligned} \forall l \in \text{link}, \exists o_1, o_2 \in \text{object}, \exists a \in \text{association}, \\ l.\text{objAid} = o_1.\text{objid} \wedge l.\text{objBid} = o_2.\text{objid} \wedge \\ o_1.\text{classid} = a.\text{classAid} \wedge o_2.\text{classid} = a.\text{classBid} \wedge \\ a.\text{associd} = l.\text{associd}. \end{aligned}$$

Generalization Satisfaction. If class c_1 is a sub class of class c_2 , the domain of c_1 is a subset of the domain of c_2 . The set of objects connected to its subclasses should also be disjoint.

$$\forall c_1, c_2 \in \text{class}, c_1 \prec c_2 \Rightarrow \text{domain}(c_1) \subseteq \text{domain}(c_2).$$

$$\forall c \in \text{class}, \text{domain}(c) = \bigcup_{c_i \in \text{sub}(c)} \text{domain}(c_i).$$

$$\forall c \in \text{class}, \bigcap_{c_i \in \text{sub}(c)} \text{domain}(c_i) = \emptyset.$$

where function $\text{sub}(c)$ gets all the subclasses of class c . Note that the domain of an abstract class is comprised of the domain of the subclasses since there are no instances of an abstract class.

Multiplicity Satisfaction. The number of the instances of an association must satisfy the multiplicity. A set of links should satisfy the multiplicity specifications defined for an association. A minimum and maximum number of instances of target classes must be satisfied using the *lower* and *upper* functions.

$$\forall as \in \text{association}, \text{lower}(\text{multiplicity}(as)) \leq \text{card}\{l' \in \text{link}(as)\} \leq \text{upper}(\text{multiplicity}(as)).$$

Part of the representation of the horizontal consistency rules in Prolog is listed as follows:

```
object_rule(Objectid, Classid) :-
    object(Objectid, _, Classid),
    class(Classid, _, _),
    write("Object: "), write(Objectid), nl,
    write("Class: "), write(Classid).
assoc_exist(Msgid, Sndobjid, Recobjid,
            ClassA, ClassB) :-
    link(Msgid, Sndobjid, Recobjid),
    object(Sndobjid, _, ClassA),
    object(Recobjid, _, ClassB),
    association(_, ClassA, ClassB);
    association(_, ClassB, ClassA).
gen_rule(Superid, Subid) :-
    generalization(_, Superid, Subid),
    all_objects_ids(Subid, IDS), write(IDS), nl,
    all_objects_ids(Superid, IDS2), write(IDS2), nl,
    subset(IDS, IDS2).
```

V. REASONING

We provide an automated tool to transform the models into Prolog. The original models are described in XMI format, generated directly from the UML CASE tools such as StarUML and Astah. Then the models in XMI format are transformed into the Prolog facts automatically. The algorithm of automatic transformation is shown as follows. The code is also available online in [22].

Algorithm 1 Transformation From class diagrams To Prolog

Require: The models represent in XMI format.

Ensure: The Prolog Facts of the model.

```
1: for each packagedElement ∈ uml:model do
2:   exact(Class.name).
3:   exact(Association.name).
4: end for
5: for each ownedAttribute ∈ uml:Class do
6:   if hasAttribute('association') then
7:     exact(association detail).
8:     exact(multiplicity).
9:   else
10:    exact(attribute).
11:   end if
12: end for
13: for each association ∈ association list do
14:   exact(rolename).
15: end for
16: for each ownedOperation ∈ uml:Class do
17:   exact(operation).
18: end for
19: for each generalization ∈ uml:model do
20:   exact(generalization).
21: end for
22: return The Prolog facts of the model.
```

After the model conversion to Prolog facts, the consistency rules along with the converted models are import into SWI-Prolog. The SWI-Prolog checks whether the Prolog-based models satisfy the consistency rules. The models are consistent if the models satisfy all consistency rules. If there are any models that cannot satisfy rules, the SWI-Prolog gives the error messages. Besides, the query interfaces, similar to OCL, are provided to query the relevant information in the models.

VI. PERFORMANCE EVALUATION

In order to determine the performance of the translation and reasoning tools, we conducted an experiments using UML class diagrams and object diagrams with invariants consisting of 10 - 437 model elements. We use a desktop computer with an Intel(R) Core(TM) i5-7400 CPU processor running at 3.00GHz with 16GB of RAM. The results are shown in Table I.

The performance tests are conducted for both consistent and mutated models. The mutated models contain the randomly introduced inconsistencies such as the same names of models, the direct and indirect cycles in generalizations and

TABLE I
TIME TAKEN BY THE TRANSITION TOOL AND REASONING ENGINES TO
PROCESS UML MODELS

Classes	4	7	16	19	32
Model Element	10	52	107	257	431
Translation time (ms)	9.3	39.1	66.7	140.2	321.3
Valid (ms)	150.2	206.9	359.0	561.3	993.5
Mutated (ms)	165.3	248.1	415.3	613.2	1023.1

the multiplicity inconsistencies between the class diagrams and object diagrams. For each test, we measure the time required to translate a model from UML to Prolog and the time required by the SWI-Prolog reasoner to analyze the models. The experimental results show that our approach can find all the inconsistencies mentioned in this paper and the time complexity of Prolog reasoning the consistencies is linear.

VII. CONCLUSION AND FURTHER WORK

In this paper, we present a Prolog-based consistency checking for UML class diagrams and object diagrams. We have implemented an automatic transformation from the models in XMI format to the Prolog facts. Then the SWI-Prolog is used to check whether the facts satisfy the consistency rules. The models are consistent if all consistency rules are satisfied. The reasoning engine will give error information if any inconsistency occurs. Besides, we provide query interfaces, similar with the OCL, to query the relevant information. Our work provides a novel approach to automatically detect the consistency of models and promise the errors will not propagate to the implementation stage.

This study only gives a brief formalization of class diagrams and object diagrams. However, these diagrams are not enough to describe the whole system in real world. We expect to construct a complete UML framework that covers the static structure and dynamic behavior of the systems. Besides, the types of consistency checking in this study are far from enough. More consistency checking rules should be covered to have a confidence for systems.

Abstract—Cloud computing is an emerging computing paradigm in IT industries. The wide adoption of cloud computing is raising concerns about management of data in the cloud. Access control and security are two critical issues of cloud computing. Time efficient secure access control (TESAC) model is a new data access control scheme which can minimise many significant problems. This scheme has better performance than other existing models in a cloud computing environment. TESAC is attracting more and more attentions from industries. Hence, the reliability of TESAC becomes extremely important. In this paper, we apply Communication Sequential Processes (CSP) to model TESAC, as well as their security properties. We mainly focus on its data access mechanism part and formalize it in detail. Moreover, using the model checker Process Analysis Toolkit (PAT), we have verified that the TESAC model cannot assure the security of data with malicious users. For the purpose of solving this problem we introduce a new method similar to digital signature. Our study can improve the security and robustness of the TESAC model.

Index Terms—TESAC; Cloud computing; CSP; Access control; Modeling; Verification;

I. INTRODUCTION

Cloud computing is considered to be an important driver of world-wide IT industries [1]. With the development of cloud computing technology, many data access models (ACMs) have been proposed by researchers [2]–[4]. Time efficient secure access control (TESAC) [5] model is a new data access control scheme which uses asymmetric encryption to guarantee data security. This scheme is more efficient than other existing solutions after an evaluation in terms of both theoretical and experimental results.

The main types of access control models can be roughly divided into three categories [6]: Mandatory Access Control (MAC), Discretionary Access Control (DAC), Role Based Access Control (RBAC). In order to achieve the goal of the network as a high-performance computer, cloud service providers specify suitable access control policies for users to access data and other resources. For limiting user access rights in different situations, Ferraiolo et al. [2] put forward the role-based access control (RBAC), where cloud service provider determines the user access to the system by means of the job role. Gao et al. [3] came up with novel data access control (NDAC) to ensure secured and confidential data communication between users and cloud servers. For the express purpose of providing a superior decision-making ability, Danwei et al. [4] presented usage control-based access (UCON) model which can easily implement the security strategy of DAC, MAC and RBAC. It is a scheme that combines all the merits of the traditional access control models. These models attach great importance to security issues, but they adopt only informal methods to analyze and there is few work on the formalization of these

models. Due to the superb characteristics of TESAC, the industry will definitely draw a great amount of interests in this scheme. So it is extremely important to verify and analyze it by formal methods. we use classical process algebra language Communicating Sequential Processes (CSP) [7], [8] to model TESAC, and in terms of a model checking tool Process Analysis Toolkit (PAT) [9] to verify some vital properties. The verification results demonstrate and show that the security problem really exists in this scheme. Through the formalization, we want to provide a deeper understanding of TESAC as well as its security properties, and we hope that other researchers can realize the security problems that may presence in their system from our verification results.

This paper is organized as follows: Section II presents an overview of TESAC, as well as introduction to CSP. Section III is devoted to the modelling of TESAC. The results that we use PAT to verify the original model are presented in Section IV, and give the improvement for better performance. Finally, conclusions and future directions are given in Section V.

II. BACKGROUND

In this section, we will give a briefly introduce of TESAC, especially its data access control scheme in cloud computing. After that, we also give a brief introduce of process algebra CSP.

A. TESAC

TESAC is a new data access control scheme based on the users' profiles. It is different from traditional access control models implementing a cloud environment. It can resolve many problems, such as high overhead of the system, high searching time for providing the public key of the data owner, high data accessing time, etc. The scheme consists of three entities:

- **Cloud service provider:** It possesses a number of servers having sufficient storage space and power to provide infrastructure and cloud services for both users and data owners.
- **Data owner:** It sends its encrypted data or file to the cloud database and managed by servers. Data owner can be any user.
- **User:** It must be registered at the cloud server for accessing a data or file.

The specific meaning of some notations of keys are listed in Table I. The process of encryption and decryption is given in Steps 1-8. When the user wants to get data from server, the following sequence of actions occurs:

- 1) First, the user sends a data access request to the server.
- 2) When the server receives the request, it encrypts PUOWN by using its own PRSP and PUUSR, and then, provides it to the users.
- 3) The user obtains PUOWN through two layers of decryption. Then the user sends a request to the data owner for obtaining the secret key and the certificate. The user encrypts the request message with PRUSR and PUOWN, and then, sends it to the data owner.

Corresponding authors: hbzhu@sei.ecnu.edu.cn (H. Zhu),
yuanfei@shnu.edu.cn (Y. Fei).

- 4) The data owner uses PROWN and PUUSR to decrypt the package to get the users message. The data owner needs to verify the legality of the user to the server.
- 5) The server sends a feedback message to the data owner.
- 6) If it is a positive feedback, the data owner uses PROWN and PUUSR to encrypt its secret and certificate. Finally, the data owner sends this package to the user.
- 7) The user uses PRUSR and PUOWN to decrypt the message. After the user acquires the secret and the certificate, it uses PRUSR and PUSP to encrypt the certificate. The user then sends it to the server.
- 8) The server decrypts the message. If the user's presented certificate is matched with the corresponding certificate of the requested data. The server provides the data to the user. Finally, the user uses PRUSR, PUSP and secret to decrypt the message to get the desired data.

TABLE I
NOTATION AND DESCRIPTION

PUOWN	public key of the data owner
PROWN	private key of the data owner
PUUSR	public key of the user
PRUSR	private key of the user
PUSP	public key of the server
PRSP	private key of the server

B. A brief overview of CSP

In this subsection we give a brief overview of CSP (Communication Sequential Processes). It is a process algebra proposed by Hoare in 1978. As one of the most mature formal methods, it is tailored for describing the interaction between concurrency systems by mathematical theories. Because of its well-known expressive ability, CSP has been widely used in many fields [10]–[12].

CSP processes are constituted by primitive processes and actions. We use the following syntax to define the processes in this paper, whereby P and Q represent processes, the alphabets $\alpha(P)$ and $\alpha(Q)$ mean the set of actions that the processes P and Q can take respectively, and a and b denote the atomic actions and c stands for the name of a channel. The syntax of CSP is given as below.

$$P, Q ::= \text{Skip} \mid \text{Stop} \mid a \rightarrow P \mid c!v \rightarrow P \mid c?x \rightarrow P \mid P; Q \\ \mid P \parallel Q \mid P \square Q \mid P \triangleleft b \triangleright Q \mid b * Q \mid P[[a \leftarrow b]]$$

- 1) **Skip** indicates a basic process that terminates successfully.
- 2) **Stop** represents that a process can't do anything any more.
- 3) $a \rightarrow P$ denotes a process first engages in action a , then acts due to the specification of process P .
- 4) $c!v \rightarrow P$ describes a process sends a value v through channel c , then behaves according to the specification of P .
- 5) $c?x \rightarrow P$ represents a process receives a value and assigns it to the variable x , then the behavior is like process P .
- 6) $P; Q$ indicates only when process P has terminated can process Q start to perform.
- 7) $P \parallel Q$ means process P and process Q perform in parallel. And they must synchronize facing the same events.
- 8) $P \square Q$ stands for external choice. A process behaves following the specification of process P or Q . However, the choice depends on the environment.
- 9) $b * Q$ expresses circulation. If the value of variable b is true, a process behaves like process Q circularly. Otherwise, it ends the circulation.
- 10) $P \triangleleft b \triangleright Q$ shows conditional choice. If the condition b is true, a process acts like P , otherwise, like Q .
- 11) $P[[a \leftarrow d]]$ indicates event a is replaced by d in process P .

III. MODELING TESAC

A. Sets, Messages and Channels

In order to formalize the protocol more conveniently, we give the fundamental information about sets, messages and channels. We define seven sets in our model. **Entity** set represents entities including servers, users and data owners. **Req** set denotes request and confirming messages. **ACK** set means feedback messages. **Content** set contains the content to be encrypted. **PUKey** set contains all the public key of entities, **PRKey** set contains all the private key of entities, **Sec** set contains the key that the data owner uses to encrypt the data.

Two core elements of modeling are internal processing procedures of entities and message packets transmitted between entities. Based on the sets defined above, we abstract them into different messages. We use the form $E(k, d)$ to indicate that k is utilized to encrypt the message d . Each message includes a tag from the set $\{msg_{req}, msg_{key1}, msg_{data1}, msg_{ack}, msg_{key2}, msg_{data2}, msg_{ackin}\}$.

The messages that are transmitted among entities as follows:

$$\begin{aligned} MSG_{req} &= \{msg_{req}.a.b.req, msg_{req}.a.b.cof \mid \\ &\quad a, b \in Entity, req, cof \in Req\} \\ MSG_{key1} &= \{msg_{key1}.a.b.E(K_1, E(K_2^{-1}, d)) \mid a, b \in Entity, \\ &\quad K_1 \in PUKey, K_2^{-1} \in PRKey, d \in Content\} \\ MSG_{data1} &= \{msg_{data1}.a.b.E(K_1, E(K_2^{-1}, E(K, d))) \mid \\ &\quad a, b \in Entity, K_1 \in PUKey, K_2^{-1} \in PRKey, \\ &\quad K \in Sec, d \in Content\} \\ MSG_{ack} &= \{msg_{ack}.a.b.x \mid a, b \in Entity, x \in Ack\} \\ MSG_{key2} &= \{msg_{key2}.E(K_1, (K_2^{-1}, d)).K_1^{-1}.K_2 \mid d \in Content, \\ &\quad K_1, K_2 \in PUKey, K_1^{-1}, K_2^{-1} \in PRKey\} \\ MSG_{data2} &= \{msg_{data2}.E(K_1, E(K_2^{-1}, E(K, d))).K_1^{-1}.K_2.K \mid \\ &\quad K_1, K_2 \in PUKey, K_1, K_2 \in PUKey, \\ &\quad K_1^{-1}, K_2^{-1} \in PRKey, K \in Sec, d \in Content\} \\ MSG_{ackin} &= \{msg_{cont}.y \mid y \in Content\} \\ MSG_{out} &= MSG_{req} \cup MSG_{key1} \cup MSG_{data1} \cup MSG_{ack} \\ MSG_{in} &= MSG_{key2} \cup MSG_{data2} \cup MSG_{ackin} \\ MSG &= MSG_{out} \cup MSG_{in} \end{aligned}$$

MSG_{req} represents the set of request messages. MSG_{key1} stands for the set of two-layer encryption messages. MSG_{data1} indicates the set of messages whose real data encrypted by public and private keys. MSG_{ack} denotes feedback messages. MSG_{key2} stands for the set of three-layer encryption messages. MSG_{data2} indicates messages sent to the process specially for internal processing. MSG_{ackin} represents messages that return data to entities by internal process. MSG_{out} represents the set of messages transmitted between entities, MSG_{in} denotes internal processing messages of entities.

Then, we give the definitions of channels to model the communications between processes:

- channels between users, data owners and servers, denoted by COM_PATH : ComUS, ComUD, ComDS.
- channels of intruders who intercept users, data owners and servers, represented by $INTRUDER_PATH$: FakeU, FakeS, FakeD.
- channels of processing messages, depicted by $PROCESS_PATH$: GetU, GetD, GetS.

The declarations of the channels are as follows:

$$\begin{aligned} \text{Channel } COM_PATH, INTRUDER_PATH &: MSG_{out} \\ \text{Channel } PROCESS_PATH &: MSG_{in} \end{aligned}$$

B. Overall Modeling

As mentioned above, the whole scheme contains three important entities, including *User*, *DataOwner* and *Server*. We formalize the whole system as below.

$$\begin{aligned} \text{System} &=_{df} \text{System}_0[|INTRUDERPATH|] \text{Intruder} \\ \text{System}_0 &=_{df} \text{User}[|DataOwner|] \text{Server} \\ \text{User} &=_{df} \text{User}_1[|PROCESSPATH|] \text{ProcessU} \\ \text{DataOwner} &=_{df} \text{DataOwner}_1[|PROCESSPATH|] \text{ProcessD} \\ \text{Server} &=_{df} \text{Server}_1[|PROCESSPATH|] \text{ProcessU} \end{aligned}$$

User, *DataOwner* and *Server*, as their names demonstrate, represent the user, the data owner and the server. *ProcessU*, *ProcessD* and *ProcessS* denote the internal processing procedure of the user, the data owner and the server. Considering the existence of intruders, we also build process *Intruder* to simulate the behavior of intruders who eavesdrop and modifies messages. Interprocess communication between processes are illustrated in Fig.2.

C. User Modeling

We first formalize process *User₀* to describe the behavior of a user process without intruders.

$$\begin{aligned} \text{User}_0 &=_{df} \\ &\text{ComUS!msgreq}.U.S.reqdata \rightarrow \\ &\text{ComUS?msgkey1}.S.U.E(\text{PUUSR}, E(\text{PRSP}, \text{PUOWN})) \rightarrow \\ &\text{GetU!msgkey2}.E(\text{PUUSR}, E(\text{PRSP}, \text{PUOWN})). \\ &\text{PRUSR.PUSP} \rightarrow \text{GetU?msgackin}.PUOWN \rightarrow \\ &\text{ComUD!msgkey1}.U.D.E(\text{PUOWN}, E(\text{PRUSR}, reqsc)) \rightarrow \\ &\text{ComUD?msgkey1}.D.U.E(\text{PUUSR}, E(\text{PROWN}, (s, c))) \rightarrow \\ &\text{GetU!msgkey2}.E(\text{PUUSR}, E(\text{PROWN}, (s, c))). \\ &\text{PRUSR.PUOWN} \rightarrow \text{GetU?msgackin}.s.c \rightarrow \\ &\text{ComUS!msgkey1}.U.S.E(\text{PUSP}, E(\text{PRUSR}, c)) \rightarrow \\ &\text{ComUS?msgdata1}.S.U.E(\text{PUUSR}, E(\text{PRSP}, E(s, data))) \rightarrow \\ &\text{GetU!msgdata2}. \\ &E(\text{PUUSR}, E(\text{PRSP}, E(s, data))).\text{PRUSR.PUSP}.s \rightarrow \\ &\text{GetU?msgackin}.data \rightarrow \text{User}_0; \end{aligned}$$

Fig. 1. Interprocess communication between processes in model

where, *req_data* represents the data request sent from the user to the server. *req_sc* represents the request of the secret and the certificate that the user sends to the data owner. *s* represents the secret and *c* represents the certificate. The six actions on channel *ComUS* and *ComUD* correspond to Steps 1-8 of User in Fig.1

in order. After receiving the encrypted messages, entity *User₀* sends them to internal processing part *ProcessU* by way of channel *GetU*, as well as accepts the decrypted messages.

Then the existence of intruder actions needs to take into consideration. For example, we must allow the instances of data request to be faked, the instances of responses of *PUOWN* to be intercepted, etc. We do this via renaming.

$$\begin{aligned} \text{User}_1 &=_{df} \text{User}_0[|ComUS?\{ComUS\} \leftarrow ComUS?\{ComUS\}|, \\ &ComUS?\{ComUS\} \leftarrow FakeU?\{ComUS\}|, \\ &ComUS!\{ComUS\} \leftarrow ComUS!\{ComUS\}|, \\ &ComUS!\{ComUS\} \leftarrow FakeS!\{ComUS\}|, \\ &ComUD?\{ComUD\} \leftarrow ComUD?\{ComUD\}|, \\ &ComUD?\{ComUD\} \leftarrow FakeU?\{ComUD\}|, \\ &ComUD!\{ComUD\} \leftarrow ComUD!\{ComUD\}|, \\ &ComUD!\{ComUD\} \leftarrow FakeD!\{ComUD\}|] \end{aligned}$$

$\{c\}$ denotes the set of all communications over channel *c*. Whenever *User₀* does an action on channel *ComUS* or *ComUD*, *User₁* will does a corresponding action on channels with prefix *Com* or channels with prefix *Fake*. Here, channels with prefix *Com* only include *ComUS* and *ComUD* and channels with prefix *Fake* only include *FakeU* and *FakeS*.

We can define CSP processes representing the data owner and server similarly.

D. ProcessU Modeling

In order to simulate the internal process of the user, we use *ProcessU* to deal with decrypting message. We must consider the possibility of intruder actions.

$$\begin{aligned} \text{ProcessU} &=_{df} \\ &\text{GetU?msgkey2}.E(\text{PUUSR}, E(\text{PRSP}, \text{PUOWN})). \\ &\text{PRUSR.PUSP} \rightarrow \\ &\left(\begin{aligned} &\text{GetU!msgackin}.PUOWN \rightarrow \text{ProcessU} \\ &\triangleleft(((\text{PUSP} == \text{PRSP})) \vee (\text{PUI} == \text{PRI})) \\ &\wedge (\text{PUUSR} == \text{PRUSR})) \triangleright \\ &(\text{GetU!msgackin}.NO \rightarrow \text{ProcessU}) \end{aligned} \right) \\ &\square \text{GetU?msgkey2}.E(\text{PUUSR}, E(\text{PROWN}, (s, c))). \\ &\text{PRUSR.PUOWN} \rightarrow \\ &\left(\begin{aligned} &\text{GetU!msgackin}.PUOWN \rightarrow \text{ProcessU} \\ &\triangleleft(((\text{PUOWN} == \text{PROWN})) \vee (\text{PUI} == \text{PRI})) \\ &\wedge (\text{PUUSR} == \text{PRUSR})) \triangleright \\ &(\text{GetU!msgackin}.NO \rightarrow \text{ProcessU}) \end{aligned} \right) \\ &\square \text{GetU?msgdata2}.E(\text{PUUSR}, E(\text{PRSP}, E(sec, data))). \\ &\text{PRUSR.PUSP}.s \rightarrow \\ &\left(\begin{aligned} &\text{GetU!msgackin}.PUOWN \rightarrow \text{ProcessU} \\ &\triangleleft(((\text{PUSP} == \text{PRSP})) \vee (\text{PUI} == \text{PRI})) \\ &\wedge (\text{PUUSR} == \text{PRUSR}) \wedge (sec == s)) \triangleright \\ &(\text{GetU!msgackin}.NO \rightarrow \text{ProcessU}) \end{aligned} \right) \end{aligned}$$

We use *PUI* to represent the public key of the intruder, *PRI* represents the private key of the intruder. *ProcessU* receives the encrypted message with decryption keys by channel *GetU*. Then it judges whether the decryption key can decrypt the message successfully. If the key does not match, *ProcessU* returns a negative message to *User₀*. Else, it sends the decrypted content to *User₀*. The internal process *ProcessD* of the data owner and *ProcessS* of the server can be defined similarly.

E. Intruder Modeling

Finally, we give the formalization of the intruder. We also regard the intruder as a process that can perform any attack as a real world intruder can be. It can intercept or fake messages in the

communication on channel *ComUS*, *ComUD* and *ComDS*. We define the set of facts that an intruder might learn as follows:

$$\begin{aligned} Fact =_{df} & \{U, S, D\} \cup \{PUOWN, PUUSR, PUSP\} \\ & \cup \{E(k, content) | k \in \{Sec, PUKey, PRKey\}, \\ & content \in Content, (s, c)\} \cup MSG_{out} \cup \{PUI, PRI\} \end{aligned}$$

Intruder can derive new facts from the set of *Facts* it has learned. We use the symbol $F \mapsto f$ to indicate that the fact f can be derived from the set F of facts. The definition is given as follows:

$$\begin{aligned} \{K_1^{-1}, E(K_1, E(K_2^{-1}, d))\} & \mapsto E(K_2^{-1}, d), \{K_2, E(K_2, d)\} \mapsto d \\ \{K_2, d\} & \mapsto E(K_2^{-1}, d), \{K_1, E(K_2^{-1}, d)\} \mapsto E(K_1, E(K_2^{-1}, d)) \\ F \mapsto f \wedge F \subseteq F' & \Rightarrow F' \mapsto f \end{aligned}$$

The first two rules represent encryption and the third and the fourth represent decryption. The final rule means if the intruder can derive the fact f from a set of facts F , then f can also be derived from a larger set F' .

We give a definition of **Info** function in which the intruders can learn by seeing the intercepted messages, shown as follows:

$$\begin{aligned} Info(msg_{req}.a.b.req) &=_{df} \{a, b, req\} \\ Info(msg_{req}.a.b.cof) &=_{df} \{a, b, cof\} \\ Info(msg_{key1}.a.b.E(K_1, (K_2^{-1}, d))) &=_{df} \{a, b, E(K_1, (K_2^{-1}, d))\} \\ Info(msg_{data1}.a.b.E(K_1, E(K_2^{-1}, E(k, d)))) &=_{df} \\ & \{a, b, E(K_1, E(K_2^{-1}, E(k, d)))\} \\ Info(msg_{ack1}.a.b.x) &=_{df} \{a, b, x\} \end{aligned}$$

where $a, b \in Entity$, $req, cof \in Req$, $K_1 \in PUKey$, $K_2^{-1} \in PRKey$, $d \in content$, $k \in Sec$, $x \in Ack$.

We define a channel *deduce* to be used for deducing new facts. The definition is given as follows:

Channel deduce: Fact.P(Fact)

All the messages transmitted between entities can be overheard by the intruder. It can deduce a new fact from ones it has already known.

It can also fake some messages if he knows all the sub-messages. The formalization of *Intruder₀* is defined as below:

$$\begin{aligned} Intruder_0(F) &=_{df} \\ \Box \Box m \in MSG_{out} FakeU?m \rightarrow \\ FakeS!m\{user_fake_success = true\} \rightarrow \\ Intruder_0(F \cup Info(m)) \\ \Box \Box m \in MSG_{out} FakeS?m \rightarrow \\ FakeU!m\{server_fake_success = true\} \rightarrow \\ Intruder_0(F \cup Info(m)) \\ \Box \Box m \in MSG_{out} FakeU?m \rightarrow \\ FakeD!m\{user_fake_success = true\} \rightarrow \\ Intruder_0(F \cup Info(m)) \\ \Box \Box m \in MSG_{out} FakeD?m \rightarrow FakeU!m \rightarrow \\ Intruder_0(F \cup Info(m)) \\ \Box \Box m \in MSG_{out} FakeD?m \rightarrow FakeS!m \rightarrow \\ Intruder_0(F \cup Info(m)) \\ \Box \Box m \in MSG_{out} FakeS?m \rightarrow \\ FakeD!m\{server_fake_success = true\} \rightarrow \\ Intruder_0(F \cup Info(m)) \\ \Box \Box f \in Fact, f \notin F, F \mapsto f deduce.f.F \rightarrow \\ Intruder_0(F \cup f) \end{aligned}$$

When *Intruder₀* receives some messages, if it is not encrypted by another entity with its public key, *Intruder₀* can replace some content in the message and send it to the original receiving entity; If the message is encrypted with the entity's public key, *Intruder₀* can not know or replace the content of the message. Because it does not know the private key that matches the public key. However, *Intruder₀* has its own public key and private key, allowing it to fake messages to send to the entities. We give the definition of *IK* to represent the initial knowledge of the intruder:

$$\begin{aligned} Intruder &=_{df} Intruder_0(IK) \\ IK &=_{df} \{U, S, D, PUI, PRI\} \end{aligned}$$

IV. VERIFICATION AND IMPROVEMENT

In this section, we will verify the four properties (deadlock freedom, user faking, server faking and protocol completeness) by virtue of the model checker PAT. According to the verification results, we improve the original model for a better safety performance.

A. Security Specification

We allow intruders to perform a series of intrusive actions and give some facts that intruders can learn. Under these conditions, whether the intruders can attack the system successfully by intercepting and faking. If the intruder can get *PUOWN* or data from the server, then it can be concluded that the system was successfully attacked by the intruder. This is in the ideal situation, but the protocol is running in an open environment, then *PUOWN* is public as a public key. Once an intruder knows the data owner's public key, it is critical that the system can detect and prevent the disclosure of the message. Thus we will verify our systems against the following specification:

$$\begin{aligned} SPEC_u &=_{df} CHAOS - \left(\sum -\{FakeU\} \right) \\ SPEC_d &=_{df} CHAOS - \left(\sum -\{FakeD\} \right) \\ SPEC_s &=_{df} CHAOS - \left(\sum -\{FakeS\} \right) \end{aligned}$$

If the system with intruders refines these specifications, then it would indeed be secure.

B. Properties Verification

We describe some security properties as well as their assertion descriptions in PAT code and give the verification result. We do not give a description of the intruder disguised as the data owner, because the disguise as a data owner has no realistic meaning. Because the data owner can be any user and intruders will not use this protocol to get its own data. We use *System* to represent the original model.

Property 1: Deadlock Freedom

The model should not run into a deadlock state. In PAT, there is a primitive to describe this situation:

$$\#assert \text{System deadlock free};$$

Property 2: User Faking

This property represents that the intruder has successfully pretended to be a legal user without being realized by the system. We define a boolean variable *user_fake_success* for verification in PAT.

$$\begin{aligned} \#define \text{User_Fake_Success} \\ \text{user_fake_success} == true; \\ \#assert \text{System reaches User_Fake_Success}; \end{aligned}$$

Property 3: Server Faking

Similarly, this property represents that the intruder has successfully

pretended to be the server without being realized by other entities. We define a boolean variable *server_fake_success* for verification in PAT.

```
#define Server Fake Success
    server_fake_success == true;
#assert System reaches Server_Fake_Success;
```

Property 4: Protocol Completeness

Because *PUOWN* is a public key, if the intruder already acquires the *PUOWN*, then the protocol cannot be fully executed. The server receives three different requests when it executes a complete protocol. We use a constant *n* to record whether the server has accepted three requests. We define a boolean variable *protocol_completeness* for verification in PAT.

```
#define Protocol Completeness
    protocol_completeness == true;
#assert System reaches Protocol_Completeness;
```

The verification results are shown in Fig.2. Deadlock freedom is valid which means that the *System* model does not run into a deadlock state. The *User_Fake_Success* property is valid and PAT provides a trace which leads to a state where this property is satisfied. Intruder can implement an event *req_sc* on channel *FakeD* to be a legal user without being realized. Similarly, the *Server_Fake_Success* property is valid shows that intruder can successfully pretend to be a legal server without being realized. The third property *Protocol_Completeness* is not valid. It represents that intruder can obtain data without executing the complete protocol. Property 2, 3 and 4 verified the insecurity of TESAC.

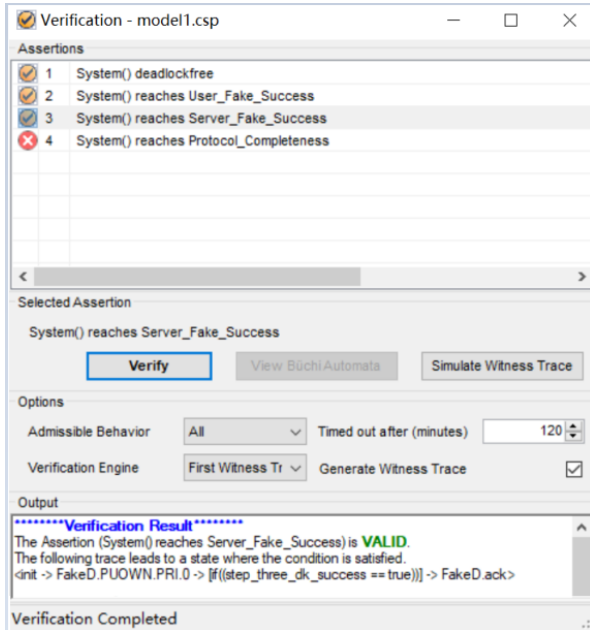

Fig. 2. Verification Result of the model

C. Attack and Improvement

As the verification result shows above, although this scheme adopts asymmetric encryption and the server uses the certificate to authenticate the user, the system is still not reliable. The server

only requests users to obtain the data decryption key and certificate from the data owner for decrypting the data at the time of first data accessing. When users initiate a data access request for the subsequent time, the server directly grants the data. So once the intruder successfully obtains data for the first time, there will be no security in the system. An example trace of the intruder acquires data successfully, which is presented as below:

```
ComUS!msgreq.U.S.req_data ->
FakeU?msgkey1.S.I.E(PUI, E(PRSP, PUOWN)) ->
FakeD!msgkey1.IU.D.E(PUOWN, E(PRI, req_sc)) ->
ComDS?msgreq.D.S.cof -> FakeD!msgreq.IS.D.ack ->
FakeU?msgkey1.D.U.E(PUI, E(PROWN, (s, c)))
```

First of all, the user sends a data request to the server by channel *ComUS*. The intruder intercepts the message sent by the server to the user through channel *FakeU*. Then the intruder pretends to be a user to request the secret and the certificate from the data owner. Data owner validates the users authenticity from the server, this message is intercepted by the intruder and returns a positive feedback message to the data owner. Finally, the data owner provides the certificate and secret key to the intruder.

That is to say, once an intruder obtains a legitimate identity using the above path, the intruder can obtain data before deleting it from the servers user list, which will undoubtedly cause disaster. Next we will make changes to the protocol and not to reduce its time efficiency.

The request information sent by the user for *PUOWN* cannot confirm the origins, as well as the confirm feedback information sent by the server to data owner. In order to change this situation, we will improve the protocol. When the user requests to obtain *PUOWN*, it needs to sign with his own private key, in this way the server can use the digital signature to authenticate the user. Similarly, the confirm message sent by data owner to server and the feedback message of server return to data owner are all signed with their own private key. The specific updating of the model are as follows:

$$MSG_{req} = \{msg_{req}.a.b.E(K_1, E(K_2^{-1}, req_data)), \\ msg_{req}.a.b.E(K_1, E(K_2^{-1}, cof)) | a, b \in Entity, \\ K_1 \in PUKey, K_2^{-1} \in PRKey, req, cof \in Content\}$$

$$MSG_{ack} = \{msg_{ack1}.a.b.E(K_1, E(K_2^{-1}, x)) | \\ a, b \in Entity, x \in Ack, K_1 \in PUKey, K_2^{-1} \in PRKey\}$$

The message changed in the new model corresponds to actions 1, 4 and 5 in Fig. 1. These messages are all related to the server. So we give the updated server process which can be formalized as follow:

```
SERVER0 =df Initialization{n = 0} ->
ComUS?msgreq.U.S.E(PUSP, E(PRUSR, req_data)) ->
GetS!msgkey2.E(PUSP, E(PRUSR, req_data))
.PRSP.PUUSR -> GetS?msgackin.req_data ->
ComUS!msgkey1.S.U.E(PUUSR, E(PRSP, PUOWN)){n = 1} ->
ComDS?msgreq.D.S.E(PUSP, E(PROWN, cof)) ->
GetS!msgkey2.E(PUSP, E(PROWN, cof))
.PRSP.PWOWN -> GetS?msgcont.cof ->
ComDS!msgack.S.D.E(PUOWN, E(PRSP, ack)){n = 2} ->
ComUS?msgkey1.U.S.E(PUSP, E(PRUSR, c)) ->
GetS!msgkey2.E(PUSP, E(PRUSR, c)).PRSP.PUUSR ->
GetS?msgackin.c ->
ComUS!msgdata1.S.U.E(PUUSR, E(PRSP, E(s, data))){n = 3} ->
SERVER0;
```

We define a variable *n* to record the number of messages sent by the server. First, *SERVER₀* initializes the variable *n*. It will be assigned a value of 1 when the server sends *PUOWN* to the

user by channel *ComUS*. *SERVER_0* communicates with its internal process *PROCESSSS* through channel *GetS*. The server will return a feedback message to the confirmation message sent by the data owner. If this action completes successfully, the value of *n* becomes 2. The server provides the data to the user if the user's presented certificate is matched with the corresponding certificate of the requested data. Meanwhile, the value of *n* is modified to 3.

Then we update *ProcessS* to be *PROCSSS* correspondingly.

$$\begin{aligned}
& PROCESSSS =_{df} \\
& \text{GetS?msg}_{key2}.E(PUSP, E(PRUSR, req_data)). \\
& PRSP.PUUSR \rightarrow \\
& \left(\begin{aligned} & \text{GetS!msg}_{ackin}.req_data \rightarrow PROCESSSS \\ & \triangleleft ((PUSP == PRSP) \wedge (PUUSR == PRUSR)) \triangleright \\ & (\text{GetU!msg}_{ackin}.NO \rightarrow PROCESSSS) \end{aligned} \right) \\
& \square \text{GetS!msg}_{key2}.E(PUSP, E(PROWN, cof)).PRSP.PUOWN \rightarrow \\
& \left(\begin{aligned} & \text{GetS!msg}_{ackin}.cof.YES \rightarrow PROCESSSS \\ & \triangleleft ((PUSP == PRSP) \wedge (PUOWN == PROWN) \wedge \\ & (n == 1)) \triangleright (\text{GetS!msg}_{ackin}.cof.NO \rightarrow \\ & PROCESSSS) \end{aligned} \right) \\
& \square \text{GetS?msg}_{key2}.E(PUSP, E(PRUSR, c)).PRSP.PUUSR \rightarrow \\
& \left(\begin{aligned} & \text{GetS!msg}_{ackin}.c \rightarrow PROCESSSS \\ & \triangleleft ((PUSP == PRSP) \wedge (PUUSR == PRUSR)) \triangleright \\ & (\text{GetS!msg}_{ackin}.cof.NO \rightarrow \\ & PROCESSSS) \end{aligned} \right)
\end{aligned}$$

PROCSSS receives the message sent by *SERVER_0* through the channel *GetS*. It should be noted that if the message is a confirmation message, *PROCSSS* will judge whether the value of *n* is 1. This is to confirm that the user is getting PUOWN from the server instead of others.

D. Overall Modeling

We formalize the new system as below.

$$\begin{aligned}
& SYSTEM = SYSTEM_1[INTRUDERPATH]INTRUDER, \\
& SYSTEM_1 =_{df} USER[DATAOWNER]SERVER, \\
& USER =_{df} USER_1[PROCESSPATH]PROCESSU, \\
& DATAOWNER =_{df} \\
& \quad DATAOWNER_1[PROCESSPATH]PROCESSD, \\
& SERVER =_{df} \\
& \quad SERVER_1[PROCESSPATH]PROCESSS.
\end{aligned}$$

The verification results are given as below:

The verification results show that **User_Fake_Success** and **Server_Fake_Success** properties are invalid, which means that system realized that the intruder were performing actions of invading and immediately stopped the process. The **Protocol_Completeness** property is valid, which means that after we improve the protocol. It can be guaranteed that the protocol is executed completely once when the user requests data.

E. CONCLUSION AND FUTURE WORK

In this paper, we have formalized the TESAC using classical process algebra language CSP. Then, we have fed the model into the model checker PAT and verified the security of the model by asserting four properties (deadlock freedom, user faking, server faking, protocol completeness). The verification results show that user faking property and server faking property are valid. It means intruder can successfully pretend to be a legal user or server without being realized. Protocol completeness property is not valid. It demonstrates that TESAC cannot guarantee users to follow all the steps for data accessing when the intruder attacks. This means that TESAC is not secure in a cloud computing environment. In order to solve these problems, we have made improvements to TESAC by introducing a method similar to digital signature. We have verified the improved

Fig. 3. Verification Result of the improved model

model with respect to the four properties, and the new verification results indicate that the improved model can prevent intruders from invading the system. The security and robustness of TESAC would be improved through our efforts.

PRISM Code Generation for Verification of Mediator Models

Weidi Sun and Meng Sun

LMAM & DI, School of Mathematical Sciences, Peking University, Beijing, China

{weidisun, sunm}@pku.edu.cn

Abstract—Component-Based Software Engineering (CBSE) has played an important role in software industry for several decades. The Mediator language is proposed to formally model complex hierarchical component-based systems, which provides a proper automata-based formalism for specifying both high-level system layouts and low-level behavior units. In this paper, we develop a framework for translating Mediator models into the model checker PRISM, and build such a “translator” which can generate PRISM codes from Mediator models automatically and cooperates with PRISM to verify properties of Mediator models. **Keywords:** Mediator, PRISM, Code generation, Model checking, Verification

I. INTRODUCTION

Component-based software engineering has played an important role in software industry for several decades. Implementation details inside components are encapsulated and different components are composed together to construct value-added systems through interfaces. Mediator [10] is a hierarchical modeling language that provides proper formalism for both high-level system layouts and low-level automata-based behavior units of component-based software systems, together with a full-featured type system and powerful coordination mechanisms. However, having powerful modeling languages does not mean correctness of the system models. In practice, errors can still be introduced by the modeling activities. Therefore, we need to investigate the formal analysis and verification techniques for Mediator to guarantee the correctness and reliability of Mediator models.

Model checking [5] is a widely adopted technique for verification of both hardware and software systems. PRISM [9] is a probabilistic model checker that provides a specification language based on the Reactive Modules formalism [1] and a powerful tool support for model checking properties specified in different temporal logics such as LTL, CSL, PCTL, PCTL*, etc. [14]. It has been successfully applied in many areas, including network protocols [7], security protocols [8], coordination languages [4], and so on.

In this paper, we present a framework for translating Mediator models into PRISM such that we can make analysis and verification of Mediator model behavior by using the probabilistic model checker PRISM. This is a further extension to our previous work on the Mediator language [10] and its Arduino C code generation [11].

The following of this paper is organized as follows: After this general introduction, we briefly review some main concepts of the Mediator modeling language in Section II. In Section III, we show how different elements in Mediator can be translated into PRISM. Finally, Section IV concludes the paper and discusses some future work.

II. A MEDIATOR PRIMER

In this section, we briefly review the primary concepts in the Mediator language which concentrates on both high-level system layouts and low-level automata-based behavior units. More details about the language and its semantics can be found in [10], [12].

The syntax tree of a Mediator program is defined as follows:

$$program ::= (typedef \mid function \mid automaton \mid system)^*$$

Typedefs. Mediator provides various data types that are widely used in different formal modeling languages and programming languages. Basic types such as *Integer*, *Bounded Integer*, *Boolean* and *Enumeration* can be easily used to define new data types in Mediator.

Functions. Functions can be either *common functions* which have both interfaces describing inputs and return types of the functions, and function bodies specifying the behavior of functions, or *native functions* that have no function bodies but only interfaces. More discussions about functions can be found in [10].

Automata. *Automata* and *system* are the core modeling elements in Mediator. They are also called *entities* or *components* in a Mediator program. The syntax of *automata* is shown as follows.

<i>automaton</i>	::=	automaton <i>template</i> [?] <i>identifier</i> (<i>port</i> [*]) { (variables { <i>varDecl</i> [*] } [?]) transitions { <i>transition</i> [*] } }
<i>port</i>	::=	<i>identifier</i> : (in out) <i>type</i>
<i>transition</i>	::=	<i>guardedStmt</i> group { <i>guardedStmt</i> [*] }
<i>guardedStmt</i>	::=	<i>term</i> \rightarrow (<i>stmt</i> { <i>stmt</i> [*] })
<i>stmt</i>	::=	<i>assignStmt</i> <i>iteStmt</i> sync <i>identifier</i> ⁺
<i>assignStmt</i>	::=	<i>term</i> := <i>term</i>
<i>iteStmt</i>	::=	if (<i>term</i>) <i>stmt</i> ⁺ (else <i>stmt</i> ⁺) [?]
<i>varDecl</i>	::=	<i>identifier</i> : <i>type</i> (init <i>term</i>) [?]

An *automaton* consists of four parts: *templates*, *interfaces*, *local variables* and *transitions*, which are interpreted as follows:

- 1) *Templates*. Templates include a set of parameter declarations. A parameter can be either a type or a value.
- 2) *Interfaces*. Interfaces consist of directed ports and describe how automata interact with their contexts. Ports can be regarded as structures with three fields: *value*, *reqRead*, and *reqWrite*, which correspondingly denote the values of ports, the status of reading requests and the status of writing requests.
- 3) *Local Variables*. Each automaton contains a set of local variables.
- 4) *Transitions*. The behavior of an automaton is defined by guarded transitions. Each transition consists of a boolean term guard and a sequence of statements. Transitions encapsulated in a group are not ruled by priority in Mediator. In other words, when the guards of two transitions are both satisfied we cannot decide which transition occurs. However the *stmts* in a *guardedStmt* are ruled by priority, they will occur according to the order in the sequence of statements.

The following three types of statements are supported by our translation framework:

- 1) Assignment statement, including an expression and an assignment target, that evaluates the expression and assigns the result to its target if possible,
- 2) Ite (if-then-else) statement that acts as a conditional choice statement in other programming languages,
- 3) Synchronizing statement, labeled with *sync*, that are the flags requiring synchronized communication with other entities.

Systems. A *system* organizes its sub-entities which can be *automata* or *systems*. The syntax of *system* is as follows:

<i>system</i>	::=	system <i>template</i> [?] <i>identifier</i> (<i>port</i> [*]) { (internals <i>identifier</i> ⁺)? (components { <i>componentDecl</i> [*] } [?]) connections { <i>connectionDecl</i> [*] } [?] }
<i>componentDecl</i>	::=	<i>identifier</i> ⁺ : <i>systemType</i>
<i>connectionDecl</i>	::=	<i>systemType</i> <i>params</i> (<i>portName</i> ⁺)

Besides the *templates* and the *interface*, a *system* contains the following parts:

- 1) *Components*. Entities can be placed and instantiated in systems as components. Each component is considered as a unique instance and executed in parallel with other components and connections.
- 2) *Connections*. Connections are used to connect the ports of the system itself, the ports of components and the internal nodes. Inspired by the coordination language Reo [6], [3], [2], complex connection behavior can also be determined by other entities.
- 3) *Internals*. Sometimes we need to combine multiple connections to perform more complex coordination behavior. Internal nodes declared in **internals** segments are untyped identifiers which are capable to weld two ports with consistent data-flow direction.

III. FROM MEDIATOR TO PRISM

In this section we introduce our framework for translation from Mediator to PRISM. The aim of this work is to make analysis of Mediator model behavior by using the probabilistic model checker PRISM.

A Mediator entity will be translated into a module in PRISM. First of all, we consider the “Flat” algorithm which was proposed in [10] and can be used to flatten a hierarchical system into a canonical automaton. The syntax of canonical automata is as follows:

<i>automaton</i>	::=	automaton <i>identifier</i> () { (variables { <i>varDecl</i> [*] }) transitions { <i>transition</i> } [*] }
<i>transition</i>	::=	group { <i>guardedStmt</i> [*] }
<i>guardedStmt</i>	::=	<i>term</i> \rightarrow (<i>stmt</i> { <i>stmt</i> [*] })
<i>stmt</i>	::=	<i>assignStmt</i> <i>iteStmt</i>
<i>assignStmt</i>	::=	<i>term</i> := <i>term</i>
<i>iteStmt</i>	::=	if (<i>term</i>) <i>stmt</i> ⁺ (else <i>stmt</i> ⁺) [?]
<i>varDecl</i>	::=	<i>identifier</i> : <i>type</i> (init <i>term</i>) [?]

Such a flattening of Mediator system model has been proven to be valid, and the syntax of the resulting canonical automaton is similar to the corresponding PRISM model defined by a module as follows:

```

model ::= module identifier
        declaration+;
        (transition;) *
endmodule

```

Both the variables declarations and guarded statements for the transitions in an automaton can be easily mapped to the corresponding PRISM model as well.

In our framework, we have six components that work together to generate PRISM code from Mediator models: *entity generator*, *typedef generator*, *term generator*, *virtual term generator*, *transition generator* and *automaton generator*. We will show details about these generators, especially the last two, in this section.

A. Generators for Entity, Typedef, Term and Virtual Term

The *entity generator* is designed for calling the algorithm for flattening and fed the returning canonical automaton to the *automaton generator*. The canonical automaton has no parameters and ports which indicates that it does not communicate with the environment.

With the help of *typedef*, we can give an alias to an existing definition to simplify the expression in Mediator. Although we cannot use the *typedef* and alias in PRISM, the absence of similar syntax can be overcome by using the original definitions directly. The *typedef generator* returns a map which maps aliases to original definitions and helps us find the original definition when meeting an alias.

There are some slight differences between terms in Mediator and PRISM. For example, in Mediator we use “==” to denote the equality operator, while in PRISM “=” is used instead.

Term generator and *virtual term generator* are designed for dealing with such subtle distinctions and the only difference between them is that the latter, as the name suggested, is for virtual terms. More details of these two generators can be found in [13].

B. Transition Generator

The transition generator is designed for generating transitions. There are two main differences between Mediator transitions and PRISM transitions:

- In Mediator, the *stmts* in a *guardedStmt* are ruled by priority. However, in PRISM we do not have priority because of its assignment method. For example, if we have $a = 0, b = 0$ and then make the assignment a, b : ' $a = 1, b = a$ '. In Mediator the result is $a=1, b=1$, because we first assign the value 1 to a and then assign the value of a , which has been changed to 1, to b . In PRISM the result is $a=1, b=0$ which is completely different. Because the assignment statement is ' $(a = 1) \& (b = a)$ '. We assign a', b' at the same time and then assign values of a', b' to a, b .
- The *ite* statements can be nested in Mediator, but this is not permitted in PRISM.

Transition generator cannot work while ignoring these two problems. To solve the first problem we take the transition apart and execute the transitions sequentially. Though the execution of transitions in PRISM does not have priority, we can create the priority by adding a "pedometer" to guards. A new variable *tranmark* is provided, which is a counter to record the number of executed *stmts*. For every transition with at least two *stmts*, we separate it into several transitions. In each new transition, the new *stmt* contains one original transition's *stmt* and an assignment statement: " $\text{tranmark_i} = \text{tranmark_i} + 1$ ", the new guard consists of the original transition's guard and a condition: " $\text{tranmark_i} = n$ ". Fig. 1 shows such an example of transition separation.

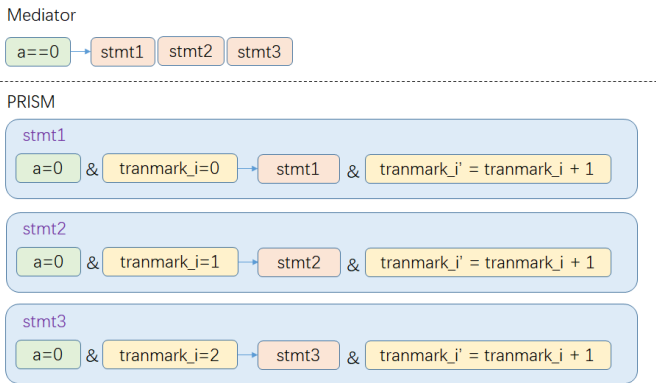

Fig. 1. Separation of transitions

In Fig. 1, we give every new transition a *tranmark_i* and initialize it to 0. When we want to execute a transition, the first new transition's guard " $a = 0 \& \text{tranmark_i} = 0$ " must be satisfied. If it is satisfied we can execute *stmt1* and add 1

to *tranmark_i*. After that, the second new transition's guard will be satisfied, and *stmt2* will be executed. These steps will be repeated until " $\text{tranmark_i} = n$ ". Following these steps we can execute every statement once and only once in order and the priority will be guaranteed.

However only separating the transitions is not enough for our framework. When we finish executing *stmt1* (for example *stmt1* is " $a' = a + 1$ "), the value of variable a may change, and the next new transition's guard " $a = 0$ " may not be satisfied. Here we need a new concept *virtual variable* to replace " a " in calculation. For example, " $a' = a + 1$ " in the transitions will be substituted with " $v_a' = v_a + 1$ " so that the original variables in guards will not change. Once all the executions of the original transition are finished, we assign the value of the *virtual variables* to the original variables. An example of such virtual variables for transition separation is shown in Fig. 2.

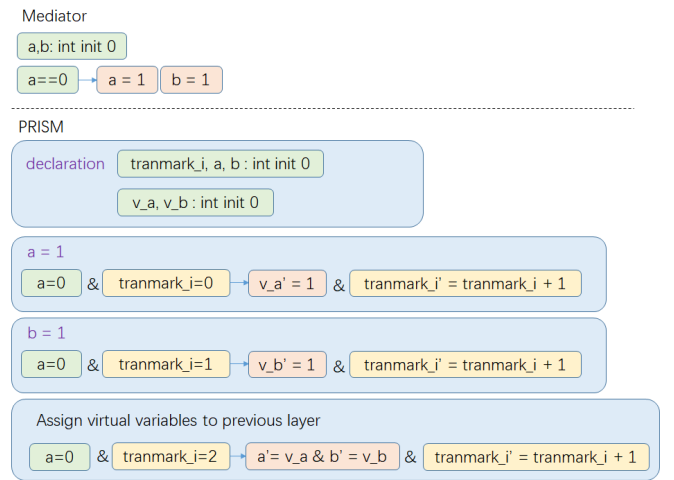

Fig. 2. Virtual variables for transition separation

The nesting problem for *ite* statements is entangled with the priority problem and thus more complicated. In other words, in the recursive generation, the nested *iteStmt* being treated as a new transition (regard the condition of *iteStmt* as a guard) shares all the troubles of the transition, the priority problem is no exception. We introduce a new variable: *layer* to denote the number of the current *iteStmt*'s nesting layers.

The new transition's guard generated from the nested *iteStmt* will be the combination of the old guard and the *iteStmt*'s condition. Furthermore, we will give every *iteStmt* a new *tranmark* as well, for example:

Once a new transition for *iteStmt* is created, the generating process will enter a new layer, and the value of *layer* will be increased by 1. A set of new *virtual variables* corresponding to the *virtual variables* in the previous layer is also needed so that the change of variable values does not affect the

satisfiability of the new guard which contains the *iteStmt*'s condition. The generating process will exit the current layer when the execution of the *iteStmt* is completed, and the value of *layer* will be decrease by 1. We also introduce a variable *maxlayer* to record the largest *layer* that appeared. Combining with the above solution the example is shown in Fig. 3.

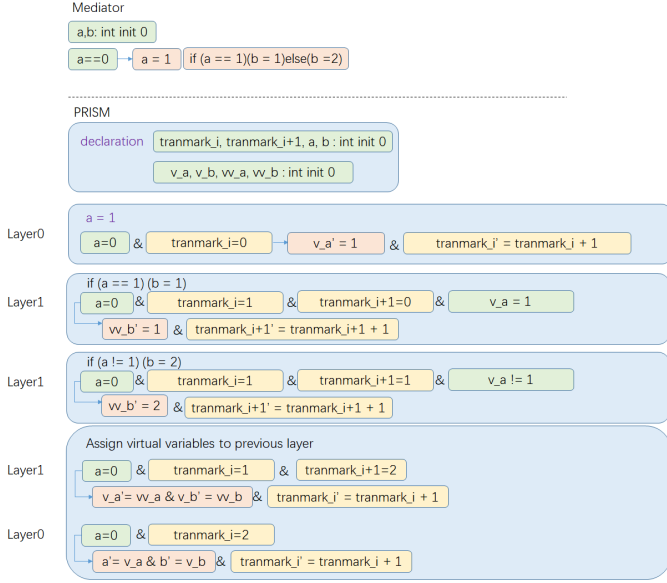

Fig. 3. Example of layer solution

The transition generator is designed as a recursive function *TGF*, which is invoked when we generate a transition and terminates when the generation process finishes. If we meet an *iteStmt* on the sidelines of a *TGF* execution, a new *TGF* will be invoked inside the old one.

To put it in a nutshell, the transition generator treats each statement as an atomic operation, i.e., an operation which cannot be interrupted and executes them in order.

C. Automaton Generator

The *Automaton Generator*'s goals are two-fold: adding the *global declarations* and combining different parts of the generated PRISM model.

Most types in *global declarations* which are supported by the PRISM language are easy to define. For these types, the only work we need to do is changing some grammar formats in Mediator's definitions. However, it does not work for *EnumType* and *ListType*. The solving of *EnumType* and *ListType* are similar, for *EnumType*, we define *IntType* variables for every identifier in it and initialize them to 0,1,2... in order. For *ListType*, we define *IntType* variables which is named as "ListName*i*" for every element in the list. It needs to be pointed out that the list we defined is a fixed-length list and all the elements in it are initialized to 0. Besides, before defining such variables we need to change the user-defined types to base types, and the changing approach is mentioned in the *typedefGenerator*.

Then we have the model type, the model name, the global declarations and the transitions which can be generated by *transition Generator*; the final step is to combine these parts to build the PRISM model. After finishing all these works, the *automaton Generator* returns the result module in PRISM.

IV. CONCLUSION AND FUTURE WORK

In this paper, we presented a code generator that converts Mediator models to PRISM models. Mediator provides a component-based modeling language in which components and systems can be defined in a hierarchical way. With the help of this code generator, the Mediator models for complex systems can be transformed into PRISM automatically such that properties of the Mediator models can be verified by using the PRISM model checker.

In the future we plan to extend the Mediator language and investigate more quantitative aspects of system models such as reliability, security, etc., in Mediator. Providing support for more hardware platforms and programming languages is in our scope for future work as well.

Abstract—Service composition is an important mean for integrating the individual Web services to create new value-added systems that satisfy complex requirements. Therefore, how to effectively analyze different types of services and find out the matching similarity between services to efficiently substitute failed services in a distributed and dynamic environment becomes crucial to service composition. In this paper, we propose a novel approach based on a data cell evolution model (DCEM) to support the dynamic adaptation of service compositions. The model combines data service information and biological cell behavior analysis to encapsulate data services into data cells. In order to reach optimum adaptations, we analyzed the static and dynamic structure of data cells based on bigraph theory to guarantee the consistency of service evolution. To evaluate the proposed approach, a series of simulation experiments and comparisons are conducted to demonstrate the effectiveness of service composition.

Keywords- Service Composition; Data Service; Bigraph; Data Cell; Service Evolution.

I. INTRODUCTION

Data as a Service (DaaS) is a new cloud computing service model that provides consumers on demand with data through different protocols on the Internet in a timely and low cost manner. However, as the function of a single Web service is simple and limited, it is difficult to meet the various requirements in a complex network environment. How to effectively model evolution of service composition and analyze its service behavior has become an issue that existing research must deal with.

Due to Web service with multi-source, heterogeneous, autonomous and dynamic characteristics, the evolution of service composition is different from traditional software evolution and faces more serious challenges. Many scholars have researched in this field through formal methods [1], semantic [2] or combinatorial models [3]. However, the above studies mainly focus on abstract behaviors and semantic analysis of services in specific field, without considering the dynamic contexts. Consequently, they easily lead to performance degradation and composition failure when the environment changes.

Biological cell is a precise structural, functional, and evolutionary unit, which structure can change dynamically with the environment during growth, differentiation and

physiological process. Comparing the dynamic behavior of service composition with biological cell, they have similarities in some aspects. It is possible to combine data service with biological cell to analyze the evolution of service composition [4,5].

In this paper, we encapsulate data services into data cells and analyze the dynamic behavior at the cell level. The data cell, like biological cell has a strong hierarchical structure. Thus, a formal method is needed to effectively explain the static and dynamic information of data cells and reflect the important characteristics such as functions and location interconnectivity of services. Bigraph [6] is a graphical formalization theory tool. It has more extensive applications in formal modeling and consistent evolutionary analysis [7].

In order to reason about the evolution of service composition better, we propose a data cell evolution model (DCEM) to increase the flexibility of service in Web system. The main contributions of this paper can be summarized as follows:

- We use bigraph theory to encapsulate data services into data cells, and construct evolution model for data cell to describe different information of service such as service name, service quality, service context, and so on.
- Because the composition processes may be canceled, or services may be moved or withdrawn, it is necessary to recombine it to provide a more powerful service, so that the service dynamic behavior based on bigraphical reactive system is analyzed. Meanwhile, we propose a self-healing algorithm which is used to dynamically adjust available service to substitute the failed ones.

II. DATA CELL MODELING BASED ON BIGRAPH THEORY

A. The Bigraph Theory

Bigraph is proposed by Milner and other scholars in 2001 to emphasize the location and connection of computing (physical or virtual) [6]. Bigraph is a 2-tuple $B = \langle B^P, B^L \rangle$. B^P is the place graph and B^L is the link graph. The place graph is used to represent the location of nodes, which are nested with each other in bigraph. The link graph ignores the nested relationship and only indicates the connection between nodes. Fig. 1 shows a bigraphical structure.

DOI reference number: 10.18293/SEKE2019-120

Fig. 1. Elements of bigraph

B. Data Cell Modeling

Based on the bigraph theory, we constructed DCEM that maps the structures and message interaction of services to bigraphs, so as to formalize the services and their compositions by process calculus. DCEM mainly consists of two layers: data cell and data cell cluster. The form is defined as follows:

Definition 1 (Data Cell). A bigraph definition of data cell is a 5-tuple $DC = \langle S, E, Ctrl, C^p, C^l \rangle: \langle m, X \rangle \rightarrow \langle n, Y \rangle$, where:

- S is a limited set of services in a data cell, $\forall s \in S$ is called a data service;
- E is a set of finite edges, $\forall e \in E$ is called a connecting edge;
- $Ctrl: S \rightarrow C$ is a mapping relation between services and service controls;
- C^p is the place graph to represent the location of services and C^l is the link graph to represents service dependencies;
- The inner interface $\langle m, X \rangle$ indicates that the bigraph has m sites and a set of inner names X . The outer interface $\langle n, Y \rangle$ indicates that the bigraph has n regions and a set of outer names Y .

Definition 2 (Service Control). A service control is a 5-tuple $C = \langle CN, CT, P, CL, U \rangle$, where:

- CN is a control name of service. CT is used to specify the type of this service, whether atomic or composite;
- P is a limited set of ports, which describes the inputs and outputs of service, $\forall p \in P$ is called a service port;
- $CL = \langle DL, CN \rangle$ is the dependency status of current service, including DL which is the dependent level with CN from other service;
- U is a probability value which represent the service reliability.

Definition 3 (Bigraphical Reactive System). A bigraphical reactive system for data cell is a 3-tuple $BS = \langle BC, R, BC' \rangle: BC \rightarrow BC'$, where:

- BC is the reactants and BC' is the products, which are corresponding to data cells with the bigraphical structures;
- R is a set of reaction rules and specifies the reaction process from BC to BC' .

As examples depicted in Fig. 2, the bigraph definition of data cell aims to represent the structural relationship and data characteristics in services. The core element correspondence between data cell and bigraphical structure is also shown in Table I.

TABLE I. DATA CELL STRUCTURE DEFINITION

Element in data cell	Element in bigraph	The example
DC	Root	$0, 1, \dots$
m	Site	s_1, s_2, s_3, \dots
S	Node	s_1, s_2, s_3, \dots
CL	Edge	e_0, e_1, e_2
C	Node control	C_1, C_2, C_3, \dots
pC	Node Ports	$\bullet, \bullet, \bullet$

Fig. 2. Bigraph form of data cells

In practice, in order to meet the increasingly complicated requirements of users, it is necessary to select appropriate services from the network and combine them according to certain business rules to construct a scalable, loosely coupled combination. The data cell cluster is based on four kinds of structures (sequence, conditional, parallel, and loop) in service composition and combines a plurality of data cells with bigraph operations. The relevant forms of data cell cluster proposed in this paper are as follows:

Definition 4 (Data Cell Cluster). A bigraph definition of data cell cluster is a 3-tuple $DCC = \langle DCS, CS, LinkS \rangle$, where:

- DCS is a limited set of data cells;
- CS is a limited set of composite structures in data cells;
- $LinkS$ is a limited set of link ports in the cluster, $\forall Link \in LinkS$ is called a connection between two ports.

The term language [13] is the basis for the formal specification and verification of dynamic evolution in bigraph. Fig. 3 shows the structure of DCC based on different workflows. Taking the parallel structure (Case 3) as an example, the cluster has three data cells DC_0, DC_1 , and DC_2 . The place graph indicates the positional relationship of services and other information (e.g., the number and distributivity of the cells). The link graph shows the dependency relationship of the services.

To adapt the dynamic environments to complex requirements, the data interaction between cells is constantly changing, forming new cell clusters or modifying the original cell cluster structure. Ensuring the structural integrity of data cells during this interactive process, while increasing the effectiveness of service composition, requires serious consideration. A checking technique for verifying the data flow of the process model and re-adjusting the model

according to the feedback has been proposed [14]. However, this process model has a large detection granularity and may easily detect distortion. We present the bigraph matching algorithm (Algorithm 1) to evolve data cells according to a bigraphical reactive system (see definition 3). During matching, the constraints of R in the bigraph are dynamically determined by the context and requirements. A reaction rule in R specifies the reaction process, and can take any number of parameters. Finally, a new bigraph is generated when the data cells match successfully.

The algorithm contains two phases and takes into account time, QoS, and service context information constraints. In the first phase, we take an initial bigraph BC and a set of reaction rules R . For each reaction rule r in R , the method $isMatch(BC, r)$ is called to determine whether the elements in the bigraph can be matched. In the second phase, if r is matched and the constraint is satisfied, the matching part in the bigraph will be replaced by products in r . $isMatch(BC, r)$ is a recursive method that is iteratively executed until the last node in the bigraph has been checked.

Algorithm1 BigraphMatch

Input: bigraph BC (an initial bigraph), a set of reaction rules R

Output: a new bigraph BC'

```

1: if  $R == \text{Null}$  then
2:   return  $BC$ 
3: else
4:   for each reaction rule  $r$  in  $R$  do
5:     flag = isMatch( $BC, r$ )
6:     if (flag == TRUE & & timeConstraints == true) then
7:       // If the match is successful and satisfies the time constraint, the
       // reaction proceeded
8:        $BC' = BC \cup \{BC \mid \text{the matching part in } BC \text{ with reaction in } r\}$ 
9:       return  $BC'$ 
10:    end if
11:  end for
12: Procedure isMatch( $BC, r$ )
13: Input: bigraph  $BC$ , term  $r$  in  $R$ 
14: Output: a flag to indicate whether the match is found
15: 1: for each service  $s$  in  $BC$  do
16:   2: if ( $r$  contains  $s$ ) then
17:   3: if ( $s.CN \neq r.CN \parallel s.CT \neq r.CT \parallel s.CP \neq r.CP$ ) then
18:     // Service control matching
19:     continue
20:   4: else
21:     for each port  $p$  in  $C$  do // Service port matching
22:       5: if ( $s.pI \neq r.pI \parallel s.pN \neq r.pN \parallel s.pT \neq r.pT \parallel$ 
23:          $s.pC \neq r.pC$ ) then
24:         6: continue
25:       7: else
26:         return True
27:       8: end if
28:     end if
29:   9: end if
30: 10: else
31:   continue
32: 11: end if
33: 12: end for
34: 13: return False

```

III. EVOLUTIONARY ANALYSIS OF SERVICE DYNAMIC BEHAVIOR

In actual use, service composition may face situations such as service failure and service composition disorder. These cause data cell variation, thus losing the original functional properties and structural stability.

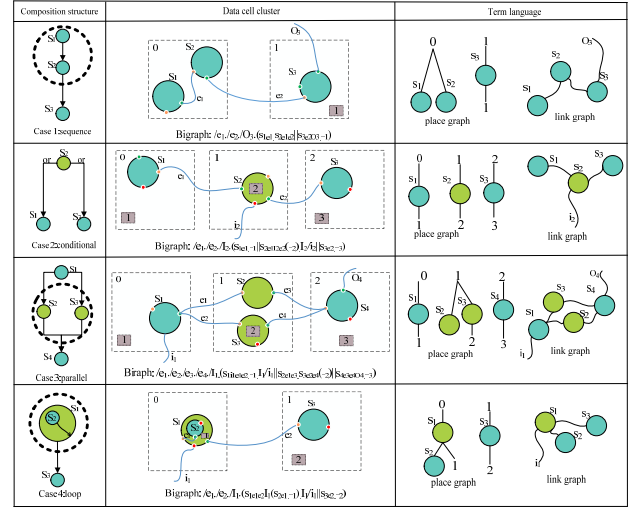

Fig. 3. The basic structures of data cell cluster

In our work, DCEM periodically tests the service availability through a data cell self-healing algorithm (Algorithm 2), allowing the structural variation of the cells to be fixed. This enables the service composition to restore the expected functions, and ultimately achieves the effect of self-repair to improve the service adaptability. The basic process of Algorithm 2 is as follows:

Algorithm2 Data Cell Self-Healing

Input: bigraph BC (an initial bigraph)

Output: a new bigraph BC'

```

1: for each service  $s$  in  $BC$  do
2:   flag = isInvalid( $s$ ) // indicate whether the services is invalid
3:   if (flag == true) then
4:     a broken bigraph  $BC^* = \text{BigraphReplace}(BC, s)$ 
5:     // Choose the most reliable service  $MDCC$ 
6:      $MDCC = \text{Max}(\text{CR}(DCC))$ 
7:     generate new reaction rules  $R = \text{createR}(s, MDCC)$ 
8:     // use algorithm 1 to ensure the structural integrity of DC
9:      $BC' = \text{BigraphMatch}(BC^*, R)$ 
10:   end if
11: end for

```

- Call method $isInvalid(s)$ at a specified time interval to check whether the service in data cell is fail.
- If the service fails then use Algorithm 3 to adjust the bigraphical structure, such as delete nodes and control belong to the failed service. Otherwise adjust the time interval to continue testing.
- Select the most reliable service from the similar service clustering to replace the fail one. There are many clustering algorithms; we mainly use the tag clustering algorithm in reference [15] and execute the aggregation process to construct the similar service clustering. Then the chosen service is considered as a reaction in rules R .
- Based on the previous steps and the bigraphical reactive system, generate the appropriate reaction rules R , and call Algorithm 1 to verify the rationality of reaction. Finally, a new bigraph is generated with a new reliable composition.

When service is detected as failed, Algorithm 3 needs to find out the failed service in the data cell. For given bigraphical information and a failed service s , we traverse each node in bigraph. If there is a surjection relationship

between the node and s , the corresponding structure is deleted and a broken bigraph is given. The specific algorithm is described as follows:

Algorithm3 BigraphReplace

Input: bigraph BC (an initial bigraph), s (a failed service)

Output: a broken bigraph BC^*

```

1: for each service  $s'$  in  $BC$  do
  //Indicate whether the service is match
2:   flag = node_conMatch( $s'$ ,  $s$ )
3:   if (flag == true) then
    //Delete structures belong to  $s'$ 
4:      $BC^* = \text{deleteBigraph}(BC, s')$ 
5:     if ( $s'.C.CL.DL \neq \text{single}$ ) then
      // Delete dependency belong to  $s'$ 
6:        $BC^* = \text{deleteDependent}(BC^*, s')$ 
7:   end if
8: end if
9: end for

```

IV. CASE STUDIES AND VERIFICATION

To illustrate the effectiveness of DCEM in service composition, we introduce a composite service that supports online book shopping at Orange Country Bookstore (OCB) [16] (depicted in Fig. 4).

Fig. 4. Composite service for online book shopping

The business process in OCB includes (1) Look for books, including *Search Book*, *Show Book Info*, *Show Related Titles*, which are all part of the *Barnes & Noble Books* composite service. (2) Add books to shopping cart in a loop, e.g., *Barnes & Noble Shopping Cart*. (3) Authentication and payment at checkout, such as *Google Authentication* or *Payment Calculator*. (4) Email and invoice service, such as *invalid Card*, *UPS Shipping Web*, and *E-mail Invoice*.

The service composition created by this instance may change the contextual events during the actual operation, resulting in service failure. In addition, the system requirements state that the service composition must maintain a main workflow after the evolutionary adjustment (for example, always ensuring that books are first searched and then added to the cart).

Here, we fully consider the evolution possibility of each service by analyzing its context. First, we construct the data cells based on the different business processes, as listed in

Table II, and then further evolve the data cells into cell clusters according to functional attributes and requirements. Table III lists the data cell clusters related to the main workflow of the shopping cart, searching for books, and payment in the OCB website.

When *Barnes & Noble Books* is unavailable, causing the functionality of s_4 to go missing (see Fig. 5), the system detects the failed service and traverses the data cell cluster according to Algorithm 3 to alter the structure. It then finds the substitute service *Amazon Books* (DCC_{AB}) from the similar service clustering via Algorithm 2 to repair the structure.

TABLE II. DATA CELL MODELING

Data Service	Data Cells	Term Language	Data Service	Data Cells	Term Language
Search Book		$/m(S_{id}) \rightarrow m(x)$	Show Book Info		S_2
Show Related Titles		S_2	Shopping Cart		$/m(S_{id} \rightarrow m(y))$
Google Authentication		S_5	Payment Calculator		S_6
Bank of America Credit Card Payment		$/m(S_{id}) \rightarrow m(y)$	E-mail Invoice		S_9
UPS shipping		S_9	Book Searching		$/k(S_{id}) \rightarrow k(z)$
Book Description		$/k(S_{id}) \rightarrow k(z)$	Related Titles		S_{12}

TABLE III. DATA CELL CLUSTER MODELING

Data Services	Data Cell Clusters	Term Language
Barnes & Noble Books Shopping Cart		$/e_1/e_2/e_3/e_4/e_5. (s_{1e2e4e5} (s_{1e1e2} s_{2e1e3} s_{3e2e4})) s_{5e5}$
Amazon Books		$/e_1/e_2. (s_{10e1} s_{11e1e2} s_{12e2})$
Credit Card Payment shopping		$/e_1/e_2. (s_{7e1e2} s_{8e1} s_{9e2})$

Fig. 5. Data cell cluster on OCB when *Barnes & Noble Books* has failed

Fig. 6. Self-healing process in data cell cluster with *Amazon Books*

Finally, as shown in Fig. 6, DCC_{AB} is absorbed by the data cell cluster, retaining an unchanged workflow order such as a looping structure with *Book Searching*, *Book Description*, *Related Titles*, and *Shopping Cart*. s_{10} , s_{11} , and s_{12} are added in the site of s_4 . After that, the output port of s_{12} is connected to the input port of s_4 by e_{13} . Tables IV summarize the term language operational sets as EO_I to formalize this process of evolution.

TABLE IV. TERM LANGUAGE OPERATIONAL SET FROM EO_I

DC	EO_I
DCC_{GE}	$EL_{rule}: /n. \rightarrow /e_{13}.$
	$Site: -0 \rightarrow s_{10}e_{11} s_{11}e_{11}e_{12} s_{12}e_{12}e_{13}$
	$x/y: n/y \rightarrow \Phi$
	$\prod_{i=1}^4 DC_{i \text{ ar}(f)}: (s_{4e_5n}(-0) -1 n/y s_{5e_5e_6} s_{6e_6e_7} s_{7e_7e_8e_9} s_{8e_8} s_{9e_9})$ $\rightarrow (s_{4e_{13}e_5}(s_{10e_{11}} s_{11e_{11}e_{12}} s_{12e_{12}e_{13}}) -1 $ $s_{5e_5e_6} -2 s_{6e_6e_7} s_{7e_7e_8e_9} s_{8e_8} s_{9e_9})$
DCC_{AB}	$EL_{rule}: /y. \rightarrow /e_{13}.$
	$U V: s_{10e_{11}} s_{11e_{11}e_{12}} s_{12e_{12}e_{13}} \rightarrow s_{4e_{13}e_5}(s_{10e_{11}} s_{11e_{11}e_{12}} s_{12e_{12}e_{13}})$

These actions express how to reorganize elements in the composition model to re-select suitable data cells from the same cluster when the *Barnes & Noble Books* composite service fails. The failed units are replaced by *Amazon Books* and *Related Titles* (according to the business process from Fig. 4).

The self-healing process in Fig. 6 is formalized by the following term language:

$/e_5./e_6./e_7./e_8./e_9./n.(s_{4e_5n}(-0)|-1|n/y||s_{5e_5e_6}||s_{6e_6e_7}|s_{7e_7e_8e_9}||s_{8e_8}|s_{9e_9})$
 $\rightarrow /e_{11}./e_{12}./e_{13}./e_5./e_6./e_7./e_8./$
 $e_9.(s_{4e_{13}e_5}(s_{10e_{11}}|s_{11e_{11}e_{12}}|s_{12e_{12}e_{13}})|-1||s_{5e_5e_6}|-2||s_{6e_6e_7}|s_{7e_7e_8e_9}||s_{8e_8}|s_{9e_9})$

V. EXPERIMENT ANALYSIS

To illustrate the effectiveness of the algorithm described in this paper, we conducted a series of experiments in different settings. The PC configuration was as follows: Intel Core i5-8250U CPU (1.6 GHz), Windows 8 and 6 GB RAM. We used all 12 of the atomic services discussed in Section 4. We then extracted their parameters and used them as a seed to randomly generate an extended dataset with 500-2000 services. Each service contained basic information such as the service name, input, output, and success probability. The experiments compared three kinds of algorithm: (1) The algorithm (DPSRM) based on the Dynamic Software Product Line approach [17]; (2) The algorithm (IASRM) based on the process ontology and multiple recovery [18]; (3) The data cell self-healing algorithm (DCSRM) proposed in this paper. In addition, we randomly set the effective service that failed as a variant v during the composition, which automatically triggers the service substitution. To ensure unbiased statistical results, all algorithms were executed independently 20 times.

Fig. 7a presents the results obtained using only DCSRM. The service number varies from 100 to 500 and the number of variants increases gradually from 1 to 8. We found that when the number of variants is small, an increase in the service number produces a steady increase in the reliability. However, as the number of variants increases, the reliability becomes relatively low, especially when the number of services is small. This is because there are fewer similar

services in the small service set, resulting in no suitable service being found when the number of variants grows. Fig. 7b shows results for $v = 9$ and the service number varying from 100 to 2000. Initially, IASRM gives the highest reliability, but this obviously decreases as the number of services increases. Furthermore, DCSRM always outperforms DPSRM.

Fig. 7. Comparison of reliability with different variants and services

From Fig. 8, we can see that the response time grows with the number of services and variants. Moreover, no matter how v is allocated, DCSRM performs much better and faster than IASRM and DPSRM. Thus, the experimental results illustrate that our algorithm significantly improves reliability and reduces the time cost of service composition.

Fig. 8. Comparison of response time with different variants and services

VI. RELATED WORK

A. Bigraphs and their application

Bigraphs were proposed by Milner and other scholars in 2001 to emphasize the location and connection of computing units (physical or virtual) [6], and has now become the tool of choice for many service-adaptive and software-reconfigurable systems because of its complete formal theory and dynamic mobility. For example, Lian et al. [7] simulated modeling using a bigraphical reactive system to analyze the mobile cloud. Calder et al. [8] proposed a model based on checking predicates from user-initiated and network events by extension to a bigraphical reactive system.

B. Evolution of service composition

Ensuring the rationality of business process structures after evolution is an important problem in the composition of services. If the evolution operation is not implemented properly, it may cause problems such as a logical deadlock or component service unreachability [20]. This section analyzes the evolution of service composition in terms of the rationality of service evolution operations and the current solutions for failure recovery.

1) Rationality of service evolution operations

The rationality of the service composition process and the correctness of the data flow are usually guaranteed by defining the evolution criterion in the operation process, thereby avoiding complex verification processes after evolution. To ensure the rationality of the service composition process, Zeng et al. [9] proposed a set of basic evolutionary operations for adjusting the service workflow structure based on workflow network modeling, which guarantees the rationality of the internal process logic during the business process. Urbieto et al. [3] propose an adaptive service composition framework that supports the dynamic reasoning of user requests and service behaviors in the smart city. Khanfir et al. [2] propose a framework for automatic generation and publishing of service descriptions by using OWL-S semantic annotations, the purpose of it is to analyze the process modeling and the choreography of service composite. In service behavior analysis, the research is mainly used by formal methods such as Petri net, process algebra, and π calculus, etc.

2) Current solutions to failure recovery

Self-adaptation is the ability of a system to adapt to changes in its environment to maintain the original functionality, and is used in different problem domains. Many recent studies have focused on enabling adaptation for BPEL processes. For instance, the monitoring mechanism embedded in the BPEL engine can be used to capture fault messages [10], allowing existing processes to be directly deployed without any modifications. Some scholars perform fault monitoring and recovery through transaction attributes of object states. Ettazi et al. [11] fulfilled user requirements in mobile environments by focusing on transactional aspects of context-aware services. In addition, there has been some research based on security monitoring and self-healing systems [12,19]. Asim [12] presented a framework that automates the monitoring of business processes and reports the compliance violations at runtime.

VII. CONCLUSION

Service composition is an important technology for integrating information to create new value in systems that satisfy complex requirements. In this paper we propose a novel approach for service composition with data cell modeling, which is inspired by biological cell and guided by the bigraph theory. This enables users to efficiently analyze the services in a dynamic distributed environment.

However, the preliminary data cells and clusters from model still need to be manually configured by analyzing and extracting the important characteristics from services. So, for future work, some tools may be applied to extract service features automatically. Another problem for future research is that more constraints from specific customer requirements, including service rating, service price and so on, need be considered to optimize the model in different scenes.

Abstract—Adaptation is a concern for elastic software systems. Conventional methods like Brownout try to deactivate optional computation per request after decoupling the software into different components, to lower the workload when peaks occur. However, resource-intensive components are not always easy to isolate, and some software systems are even not separable. In this paper, we propose a new paradigm that provides each core and mandatory component a corresponding alternative component, with similar function but lower resource consumption, and use reinforcement learning in a feedback loop control for the self-adaptation process. We modified the widely used benchmark RUBiS to make it weakly coupled and add alternative components. Experiments show that our framework dramatically improves both the efficiency and effectiveness of self-adaptation.

Index Terms—adaptive software, reinforcement learning, programming paradigm

I. INTRODUCTION

Elasticity is the degree to which a system is able to adapt to workload changes by provisioning and de-provisioning resources in an autonomic manner. Self-adaptation is the most obvious characteristic of elastic software systems that enables systems to continuously adapt themselves to uncertainty in the environment. One of the challenges in such kind of systems concerns how to make adaptation to themselves at runtime dynamically in response to possible and even unexpected changes from the environment and/or user goals [1].

Different approaches have been proposed for the design of self-adaptive software, a prominent one being architecture-based adaptation [2]. For example, a paradigm called brownout [3] successfully controls the load balance by separating software components into mandatory and optional parts and adaptively activating or deactivating optional parts to manage resource usage in software systems. However, subordinate and resource-intensive components are not always easy to be isolated, and some software systems are even not separable, like single-function mobile apps with only few but highly correlated modules. We thus propose a new adaptation framework that separates software into three different types of components: mandatory, optional and alternative. The mandatory parts must be kept running all the time, such as the critical services in the system, including data-relevant services. The optional parts, on the other hand, need not be active all the time and can be deactivated temporarily to ensure

system performance in the case of flash crowds. Compared to brownout programming paradigm [2] with only mandatory and optional components, we introduce a new type of component for the system design: alternative. Each mandatory component has its corresponding “alternative” one providing the same services but use less computation resources. Some “inseparable” software systems may not have “optional” parts, but definitely can build mandatory and corresponding alternative components.

After building self-adaptive software architecture, we also need to design a feedback loop control mechanism to fulfill the self-adaptation process. Control theory was used to adaptively determine when to activate/deactivate optional features in the applications through the feedback from software and environment, but applying control theory to adapt the software behavior is a complex problem [4], due to the difficulty of accurately modeling software, to the types of requirements and their tradeoffs [5] and to the need of instrumenting software to obtain sensor measurements and actuators [6]. Techniques from statistical machine learning have shown to be effective for feedback control in autonomic computing systems [7], and learning from system running environment can lead to improvements in accurately tuning parameters that avoids slow controller reactions to significant arrival rate changes [8]. Therefore, in this paper, we propose a reinforcement learning based framework to cope with non-stationary environment and changeable user goals at runtime by learning controlling rules to find appropriate thresholds. We also designed the algorithm to compute the priority of component in an application, and modified the benchmark RUBiS to make it separable. Experiments show that our framework dramatically improves both the efficiency and effectiveness of self-adaptation.

II. RELATED WORK

To enhance the adaptation of software system, the first step is to build the elastic software architecture with low-coupling characteristic, and then design a feedback loop control mechanism to fulfill the self-adaptation process. As discussed before, it is more efficient using machine learning than control theory as the control mechanism, so we only introduce existing works on feedback loop control through machine learning to support the online planning process of self-adaptive systems.

To make an application elastic, the designer needs to build a software architecture that can decompose the act of serving a request into different parts of the application, each dealing with a different part of the response. Some functions of a software application might be skipped when necessary. Rainbow [9] is a framework using reusable infrastructure to support runtime self-adaptation of software systems. Brownout [3] is a self-adaptive paradigm that enables or disables optional parts in the system to handle unpredictable workloads. In existing articles, the optional parts are identified as contents, components, and containers. Optional web contents on servers are to be showed selectively to users to save resource usage [10]. Components-based applications deactivate optional components to manage resource utilization [11]. In containerized clouds, each service is implemented as a container, and the optional containers can be activated/deactivated based on system status [12]. Optional parts might temporarily be deactivated so that the essential functions of the system are ensured and applications avoid saturation.

Several automatic policies based on machine learning and admission control were introduced. Desmeurs et al. [8] presented an event-driven brownout technique to investigate the tradeoffs between utilization and response time for web applications. Dupont et al. [13] proposed an automatic approach to manage cloud elasticity in both infrastructure and software. The proposed method takes advantage of the dynamic selection of different strategies. Moreno et al. [14] presented a proactive approach for latency aware scheduling under uncertainty to accelerate decision time, and applied a formal model to solve the nondeterministic choices of adaptation tactics. Li et al [15] [16] designed a multi-agents model to improve the self-adaptation of meta search systems.

Some existing works have the related idea with us to use Reinforcement learning (RL) to support the online planning process of self-adaptive systems. Amoui et al [17] use reinforcement learning to support action selection in the planning process and clarify why, how, and when reinforcement learning can be beneficial for an autonomic software system. Ho et al [18] present a model-based reinforcement learning approach that maintains a model to utilize the engineering knowledge and continuously optimizes system behavior through model-based reinforcement learning. Tianqi et al [1] combines reinforcement learning with case-based reasoning to overcome the limitations of rule-based adaptation in which decisions are only made based on static rules

The limitations of the past work are (i) the priority of software component is not discussed, and (ii) no strategy to deal with the inseparable components or applications. In next sections, we will discuss our proposed solutions.

III. LEARNING - BASED ADAPTATION FRAMEWORK

In this section, we first assign priority to each software component, and then propose a reinforcement learning based framework that supports self-adaptive activation/ deactivation of software components to avoid saturations.

A. Component Priority Assignment

Since some components of a system will be deactivated when unexpected peaks come, we want to know: which component should be deactivated first, i.e. how to determine the priority order of components that are deactivated? Two metrics are used to calculate the component priority: **computational complexity** and **usage frequency**. Computational complexity refers is the amount of resources required for running a component. The more complex a component, the more computing resources it needs. Usage frequency is the number of times that a component is invoked in the software system during a time interval. The algorithm of selecting the optional component is to choose the node with lower frequency but higher complexity first, because such kind of component needs more computing resources while it is less used by users. The more frequently a component being used, the more important and valuable it is. For component i , we have:

$$p = \delta.c/f$$

where p is the popularity of component i , δ is the control factor used for scaling component i 's priority, c refers to the computational complexity and f is the usage frequency.

B. Reinforcement Learning based Adaptation Framework

Conventional elastic software architectures usually separate software components into two parts: mandatory and optional, but not all software applications can be easily decoupled, so sometimes no components can be isolated. Another issue is what if a software still cannot adapt to the environment change after adjusting the running state of optional parts? For example, what if the workload of server is still high after deactivating the optional components? To deal with the above issues, we propose a new design paradigm that prepares alternative substitute for each of the mandatory components with similar functions but less complexity. Figure 1 illustrates the structure and working process of the proposed framework.

When the user traffic is low, the mandatory software components and the optional components are activated (if any), and the alternative parts are deactivated (Figure 1a). All functions are available and the complete service of the software is offered. When the traffic increases, the workload of server rises and the response time gets longer. In this case, optional components are deactivated in the order of priority. The user experience might be degraded, but the whole software will still work well instead of saturation. Figure 1b shows that all optional components are deactivated.

If the workload of server is still high after deactivating optional components, we need to switch the service running on mandatory components to alternative components (Figure 1c). The alternative code provides similar but "lighter" services than mandatory content such as a website with static picture instead of dynamic animation. Sometimes applications may not contain components that can be grouped as "optional", like mobile apps with few functions, so alternative substitutes are necessary.

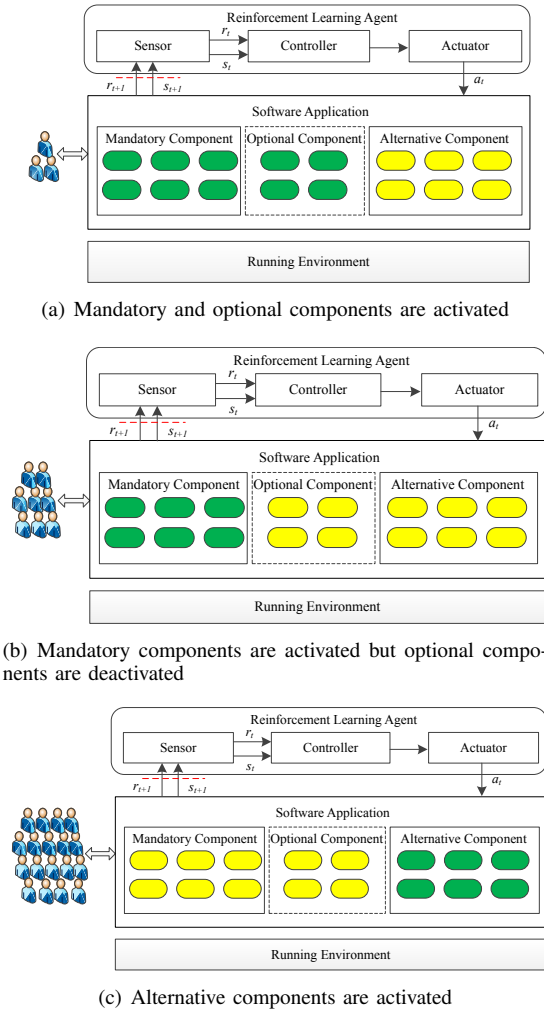

Fig. 1. The proposed reinforcement learning framework with three types of components: Mandatory, Optional and Alternative. The auto scaling process as the user traffic changes is depicted from subfigure (a) to (c)

To lower the maintenance effort, the whole feedback loop needs to be automatically managed. This would enable software applications to rapidly and robustly respond to environmental changes, and being self-adaptive. We use reinforcement learning to automatically acquire the optimal strategies as policies that controllers produce for different situations. In the reinforcement learning context, an agent takes action a_t when the system is in state s_t and leaves the system to evolve to the next state s_{t+1} and observes the reinforcement signal r_{t+1} . Decision making in elastic systems can be represented as an interaction between software controllers and environment through sensors and actuators, and the feedback reward is evaluated in the form of utility functions. An elastic system may stay in the same state, but should take different actions in different situations and workload intensity.

We study the adaptive management of resources task in which a Reinforcement Learning Agent (RLA) interacts with environment by sequentially choosing which software component to be activated or deactivated, so as to maximize

its cumulative reward. We model this problem as a Markov Decision Process (MDP), which includes a sequence of states, actions and rewards. More formally, MDP consists of a tuple of five elements (S, A, P, R, γ) as follows:

- State space S : A state $s_t \in S$ is defined as the metric function that quantifies the degree of auto-scaling variables, such as workload, response time, throughput and etc. The items in s_t are sorted in chronological order. The elasticity policy is defined in terms of rules based on the metric function: "IF workload is high AND response time is long THEN take action a_t ".
- Action space A : Each component has a running probability controlling how often it is executed, and the sum of running probability between a mandatory component and its corresponding alternative part should be 1. The action $a_t \in A$ of RLA is to change the probability of a component being activated. The action a_t is among three possible candidates:

$$a_t \in A = \{-\theta, 0, \theta\}$$

- Reward R : After the RLA taking action a_t at state s_t , i.e., changing the running probability of a component, the utility of software system changes and provides feedback, and the RLA receives immediate reward $r(s_t, a_t)$ according to the system's feedback. In this paper, we use the response time as the metric of system utility and have:

$$r_t = \lambda(resp(t) - resp(t-1))$$

where $resp(t)$ is the response time of the system at time t , and λ is a constant number scaling the reward value. If a controlling action leads to a decreased response time, the reward will increase, meaning the action is appropriate. Otherwise, if the reward is close to zero, it implies that the action is not appropriate.

- Transition probability P : Transition probability $p(s_{t+1}|s_t, a_t)$ defines the probability of state transition from s_t to s_{t+1} when RLA takes action a_t . We assume that the MDP satisfies:

$$p(s_{t+1}|s_t, a_t, \dots, s_1, a_1) = p(s_{t+1}|s_t, a_t)$$

- Discount factor γ : $\gamma \in [0, 1]$ defines the discount factor when we measure the present value of future reward. In particular, when $\gamma = 0$, RLA only considers the immediate reward. In other words, when $\gamma = 1$, all future rewards can be counted fully into that of the current action.

The upper part of each graph in Figure 1 illustrates the agent-software interactions in MDP. With the notations and definitions above, the problem of adaptive management of resources can be formally defined as follows: Given the historical MDP, i.e., (S, A, P, R, γ) , the goal is to find a controlling policy $\pi: S \rightarrow A$, which can maximize the cumulative reward for the software system. A widely-used reinforcement learning method is Q-learning that directly approximates the optimal quality function of a policy π :

$$Q^*(s, a) = \max Q^\pi(s, a)$$

and then derives the optimal policy from Q^* by selecting the highest valued action in each state:

$$\pi^* = \operatorname{argmax}_{a \in A} Q^*(s, a)$$

To approximate the optimal Q-function, Q-learning repeats the following two steps: 1) choose action a at s using policy derived from the current Q-function; and 2) take action a , and then update Q-function with the observed reward using the following formula:

$$Q(s_t, a_t) \leftarrow Q(s_t, a_t) + \alpha[r_{t+1} + \gamma \max_a Q(s_{t+1}, a) - Q(s_t, a_t)]$$

where α is the learning rate, and γ is the discount factor that determines the present value of future rewards.

IV. EXPERIMENT

A. Experiment Setting

We verify our framework based on a widely used benchmark e-commerce web application RUBiS, with the dataset ‘‘Oops! paper dump’’ from RUBiS official website¹. The evaluation setup includes a ThinkPad laptop with Intel Core i5 2.50 GHz processor and 10 GB RAM. This web application is deployed on the laptop, while the visiting traffic is generated by a load test tool named JMeter. JMeter allows to dynamically selecting the number of users and maintains a number of client threads equal to the number of users.

RUBiS benchmark implements three functions of an auction site: selling, browsing and bidding. There are two roles in this benchmark: server for an auction and client that can be a seller, buyer or visitor. To calculate the priority of each component, we assume that one file (.class, .html or .xml) represents one unit of complexity, which means if a component includes three files of .class, its complexity is three. Though it is not very accurate to compute the running time using this method, it has little effect to our project since the complexity of each file is close to the other. Therefore, we can view each file as a unit with the same resource requirement. We use ‘‘session mechanism’’ to identify users who are visiting the website and simulate the workload with the number of visits because it is not easy to get the actual workload of the server. When the user traffic changes, controllers can switch the running components dynamically.

We select ‘‘Recommendation for You’’ as the optional component according to the sorting result of priority value. In order to make a more obvious comparison, we add website effects to the page ‘‘AboutMe’’ to construct the mandatory component and its original plain webpage without any effects is regarded as the alternative part. The website effects are implemented by CSS and JavaScript. We also add a new alternative component ‘‘ViewItem_light’’ that introduces product items in words compared to the original indivisible ‘‘ViewItem’’ module that

TABLE I
SELECTED COMPONENTS FOR EXPERIMENTS

Component Type	Function	Description
Mandatory	AboutMe	AboutMe with web effects
	ViewItem	Introduction of products in pictures
Alternative	AboutMe_light	AboutMe without web effects
	ViewItem_light	Introduction of products in words
Optional	Recommendation	Recommendation for You

presents items in pictures. All the components used in our experiment are listed in Table 1.

For JMeter, three parameters need to be set before running the sampler: number of threads, ramp-up period and the number of times to execute the test. The ramp-up time tells JMeter how long to take to run full number of threads chosen. For example, if 10 threads are used, and the ramp-up period is 100 seconds, then JMeter will take 100 seconds to get all 10 threads up and running. Listeners added to the thread group are: ‘‘aggregate report’’, ‘‘view results tree’’ and ‘‘view results in table’’. ‘‘Aggregate report’’ shows results of measurements by calling the same page lots of times as if many users are calling that page. ‘‘Result tree’’ outputs the report in whether requests are responded successfully or not. In ‘‘result table’’, ‘‘sample time’’ means the time every request uses and ‘‘latency’’ indicates the time interval between request and response from the server.

B. Evaluation

To verify the effectiveness of our proposed framework, two experiments are done in this section: running RUBiS in non-adaptive configuration and self-adaptive configuration. We first need to find the maximum capacity of our platform to acquire the configuration parameters for the ‘‘traffic peak’’. By gradually increasing the number of threads in the sampler, we obtain the lower limit of the peak condition: ‘‘launch 4000 threads in 4 seconds’’. Figure 2 shows the result.

Label	# Samples	Average	Median	90% Line	Min	Max	Error %	Throughput	KB/sec
HTTP request	1407	1397	1138	1612	993	4353	89.98%	313.9/sec	647.3

(b) View of results with failed request

Fig. 2. Peak evaluation

Figure 2a shows that the total number of successful samples is only 1407 because the web server cannot process all requests

¹<https://rubis.ow2.org/>

given only a limited time. The maximum response time set to 4s is because a study made by Amazon shows that 25% users will leave when the responding time is over 4s. The error rate is 89.98%. Errors are reflected by warning status in Figure 2b.

Next, we make comparison experiments between non-adaptive and self-adaptive patterns on the module "About Me". It asks to register first before accessing the page, so we package username and password information as a request and send it to the server. To make it close to the real scenario, we simulate different users to visit the web page instead of one user visit multiple times. The method is to put 100 users' information extracted from database into a ".dat" file with "nickname" and "password" as the parameters and package it as a request (See Figure 3).

Fig. 3. Multi-users parameter. "Name" means the name list of variables used in the project. "Nickname" is the first (No. 0) column in test.dat and "password" is the second (No. 1) column in test.dat.

Non-adaptive Experiment: we observe the response time and error rate on three different running modes while the visits increase without adaptation mechanisms: 1) Mandatory + Optional components ("AboutMe" and "Recommendation") 2) Mandatory component only ("AboutMe") 3) Alternative component only ("AboutMe_light"). To evaluate the three modes, we set up samplers with the number of threads ranging from 250 to 3500 and launch in 4 seconds each time, and calculate the average response time and error rate for each sample. Figure 4 shows the performance of RUBiS with the three modes.

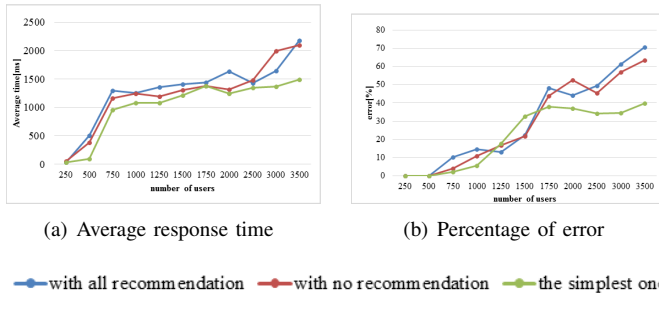

Fig. 4. Performance of RUBiS with three different modes.

Figure 4a shows that average response time increases with the number of visit users increases. It basically takes the longest time for a web server to support the functions in mode 1, because the "Recommendation" module involves frequent interactions with database. The performance improves a little after deactivating the "Recommendation" module in mode 2, and it improves obviously after switching the mode 2 to mode 3. In addition, Figure 4b shows that although some fluctuations appear in the graph, the trend is still very clear that the error

rate tends to be flat when it is approaching to saturation after switching Mandatory component into an Alternative one.

Self-Adaptive Experiment: to make the system self-adaptive, we first need to model the change of running environment. In this paper, we model the change of server workload. Since it is not easy to detect the real workload, we thus choose the response time as the metric, and the longer response time means the higher workload. However, we notice that the response time of failed requests are sometimes even shorter than successful ones in JMeter, which will interfere the whole process and make the result inaccurate. Figure 5 shows an example.

id	time	url	method	status	response	error	message
538	04:51:34.646	Thread Group 1-702	HTTP request	1026	1720	0	
539	04:51:34.580	Thread Group 1-680	HTTP request	1082	1720	0	
540	04:51:34.660	Thread Group 1-705	HTTP request	1005	1720	0	
541	04:51:32.917	Thread Group 1-34	HTTP request	4631	6285	4631	
542	04:51:32.924	Thread Group 1-38	HTTP request	4625	6285	4625	
543	04:51:32.924	Thread Group 1-40	HTTP request	4627	6285	4627	
544	04:51:32.871	Thread Group 1-16	HTTP request	4687	6285	4687	

Fig. 5. Sample time of failed requests are shorter than successful ones

Due to the above property of JMeter, we evaluate the self-adaptive experiment by launching a limited number of threads to make sure there are no failed requests and the response time is in linear growth. We set the maximum number of threads to 500 and ramp-up period to 5 seconds, and we make sure there are no errors with the number of requests less than 500. We set the control factor δ to 1 for each component and set two elasticity policies for state space: "IF response time is over 3000 ms THEN take action deactivate Optional components." and "IF response time is over 6000 ms THEN take action switch Mandatory components to Alternative parts." The whole self-adaptive process is controlled by the Reinforcement Learning Agent (RLA). Figure 6 shows the experiment results.

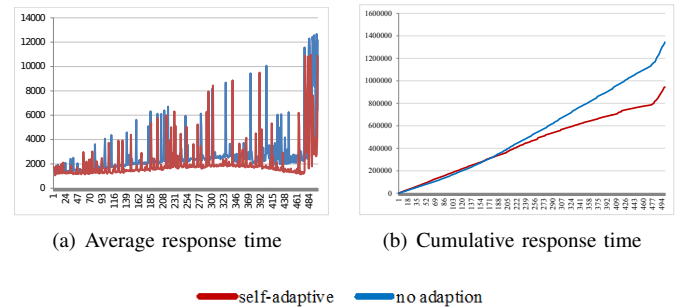

Fig. 6. Performance of running RUBiS with self-adaptive control in Mandatory, Optional and Alternative Components

When the number of visiting users is close to 150, the response time comes to 3000 ms that is our first threshold of "high workload". RLA captures the high workload through its sensor and take the action of deactivating the Optional components. However, we find that there is no obvious improvement in performance as shown in Figure 6. When the number of users is close to 200, the response time comes to 6000 ms that reaches our second threshold, so RLA takes the action of switching Mandatory components to their Alternative parts. We can see that the cumulative response time decreases

dramatically compared to the system without self-adaptation mechanism from Figure 6b.

Next, we verify the effectiveness of our framework to deal with the problem of "what if a software application cannot be easily decoupled?" When all the modules are highly correlated in a software application and cannot be easily isolated, the Brownout mechanism does not work anymore. As discussed before, we propose the method of switching the whole complex module or component into a simpler one, instead of isolating optional parts. As an example, we choose the function "ViewItem" with all its components related and cannot be decoupled. We set the maximum number of threads to 700 and ramp-up period to 5 seconds. We set an elasticity policy for the state space: "IF response time is over 35 ms THEN take action *switch Mandatory components to Alternative parts*". Figure 7 shows the experiment results.

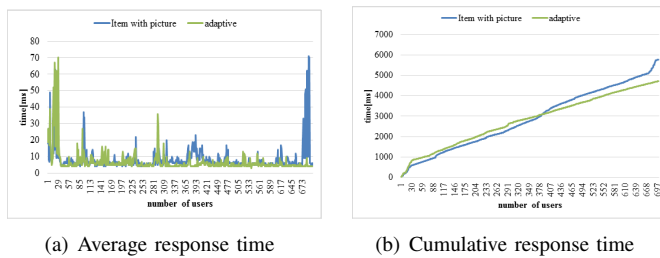

Fig. 7. Performance of running RUBiS with self-adaptive control in Mandatory and Alternative Components.

When the number of visiting users is close to 300, the response time comes to 38 MS that reaches our threshold, and then the action of switching the "ViewItem" component to its Alternative part "ViewItem_light" is taken. In Figure 7a, the response time is very high at the beginning because of the initialization of the module. After the modules switch, the response time of the system in self-adaptation mode is less than that without self-adaptation mechanism on average. From the cumulative response time shown in Figure 7b, we can see that it is very close for two curves at first, but the self-adaptive one outperforms the original one as the number of users increase.

V. CONCLUSIONS AND FUTURE WORK

In this paper, we propose a framework to support self-adaptation decision making. This framework separates software into three different types of components: mandatory, optional and alternative, and use reinforcement learning to design the "controller" aiming at coping with non-stationary environment and changeable user goals at runtime. It will be interesting to integrate our framework with containers to improve scheduling performance in the future.

Abstract—Self-Adaptive Systems (SASs) need to analyze software changes accurately and continuously, that is, recognize events caused by changes, and adjust structure or behavior. However, present event recognition methods frequently monitor events, resulting in waste of system resources. And most of them ignore the impact of operating environment uncertainty, causing errors in recognizing the event and directly affecting the reliability of SASs. Addressing the above problems, this paper proposes an event recognition method based on "detection-recognition" mechanism. Firstly, the Naive Bayesian Classification algorithm is used to detect the state of the system. If the system is judged to be abnormal, we will combine with rule reasoning and fuzzy reasoning to recognize events. The system does not have to monitor the occurrence of events from time to time, avoiding the waste of system resources. Moreover, the probabilistic reasoning method of Bayesian Classification and the introduction of fuzzy reasoning can cope with environmental uncertainty and improve the accuracy of event recognition. Finally, we exemplify this mechanism with the Web system, which proves the effectiveness of the methods.

Keywords—component; Self-Adaptive software; Analyze; Naive Bayes Classification; Rule reasoning

I. INTRODUCTION

Self-adaptive Systems (SASs) modify their behaviors or structures in response to their perception of the environment and the system itself [1]. Adaptation process for SASs generally includes monitor, analyze, plan and execution [2]. The **Analyze** is responsible for judging whether the system needs to be adjusted by observing the changes information of the Monitor, and to recognize accurately the events triggered by the changes.

At present, there are few researches on changes analysis. Some researchers apply **ontology** to analyze system situation [3][4]. The accuracy of ontology reasoning is higher, but the ontology has high demand for developers, and it is difficult to perform dynamic correction during system running, so we will not consider the ontology reasoning method. Some researchers use **rule** methods to recognize environmental events [5], and some recognize active database events [6]. The types of events recognized in the above studies are **single or limited**. Nowadays, the operating environment or system structure is highly likely to change. If the ontology or rules are **unchanged**, the **accuracy** of

event recognition will be low.

There are other methods for recognizing events, including event listeners [7], a generalized modeling framework of fault detection and correction processes [8]. Most methods lack research on system state detection, they usually recognize events directly. However, software changes do not necessarily trigger events, for example, fluctuations and surges of system status data will not affect the normal provisioning of system functions and system status, so they will not evolve into events as the system runs. Such frequent monitoring of events will frequently make use of system resources, resulting in **waste of resources**.

In addition, if the event is recognized incorrectly, even if the system performs a series of adjustments, it may not achieve the expected results, or even make the system crash, which seriously affects the **reliability** of the SASs. Nowadays, the dynamic operating environment of complex software and the complexity of its structure cause the process of event recognition faces **uncertainties** such as environmental complexity and ambiguity of demand. Most methods focus on recognizing events in a certain environment, its accuracy cannot be guaranteed in the dynamic and variable environments. The present ideas of processing uncertainty mainly include **fuzzy logic** and **probability theory** [9][10]. These methods only consider the research of design phase, or have specific scenario constraints.

In response to above issues, this paper proposes a “**detection-recognition**” mechanism, which first judge the system state, if it is abnormal, then recognize the event. In the “detection” stage, we establish the **Naive Bayesian Classification** model to judge system status quickly by analyzing the probability value. In the “recognition” stage, we combine the **rule reasoning** and **fuzzy reasoning** to recognize the event, which can improve the accuracy of event recognition and migrate this method to other systems through the addition and modification of rules.

This paper is organized as follows: section II provides the detail of our event recognition method; section III introduces our experiment and some discussions; conclusion is discussed in section IV.

II. THE EVENT RECOGNITION METHOD

We propose the "detection-recognition" mechanism to analyze events triggered by the changes. It contains two stages of abnormal state detection and event recognition.

A. Abnormal State Detection

Abnormal state definition: the system's functional or non-functional requirements are affected due to system events. To detect accurately and quickly the abnormal state of the system running, we apply the **Naive Bayesian Classification** model to judge the system status.

First, we convert the numerical data collected in the system log into character data by conversion threshold. The processed log is divided into the training set and the test set by the 4-fold cross-validation method.

Second, the frequency of occurrence of features or categories in the training set is counted to estimate the probability of occurrence. We adopt the *Laplace transformation method* to avoid the situation where the probability value is 0.

Then, we get the error rate of the model by operating the test set. If the error rate is higher than the preset tolerance, we will return to data processing process, and dynamically adjust the threshold of the converted numerical data. In general, the tolerance is set to 8%, this value will be verified in Section III.

Finally, the model calculates the system state, as in (1).

$$P(Category | FeatureValue) = \frac{(\prod_{i=1}^n P(FeatureValue_i | Category)) \times P(Category)}{\prod_{i=1}^n P(FeatureValue_i)} \quad (1)$$

As in (1), *FeatureValue* refers to the eigenvalues that can characterize the state of the system. *Category* is divided into *Normal* and *Abnormal* categories in this paper. When $P(Abnormal|FeatureValue)$ is greater than $P(Normal|FeatureValue)$, we consider that the current system is in an abnormal state, and further need to inference the event.

B. Event Recognition

We combine the rule-based reasoning and fuzzy reasoning to recognize events. The working process is shown in Fig.1. We first establish the events library. Then, according to the predefined recognition rule base, the event information that occurs is reasoned. At the same time, we apply fuzzy reasoning to supplement rule reasoning, further achieve feedback and correction of the rule base and ensure the accuracy of event recognition.

Fig.1. Event recognition method working process

1) Event recognition method based on rule reasoning

The process of this method is as follows. First, we define the corresponding mapping rules for the event. The rules indicate the relationship between system status and events, as in (2).

rule RuleName

when Judging condition , **then** Event information (&& action)
end (2)

We introduce the mapping rules between system states data and "Unit Fault" as an example, as shown in Fig.2.

```

rule UnitFault
  when SystemState (heartBeatInterval>threshold&&
    responseTime>threshold&&errorRate>threshold
    &&nodeState=="normal" )
  then <E0201> && getTime();
end

```

Fig.2. UnitFault rule example

Among them, the rule conditions are the judgment of the system status value, and the latter part of the rule is the event ID and the time that successfully matches the rule.

Then, we recognize events based on the mapping rules. We match the status information with the conditions of the rules in the rule base. If the current status information can match multiple rules, the rules will be placed in the conflict set. Conflict resolution strategies such as predefined rule priorities or definition rule groups are used to resolve conflicts between rules in conflict sets. Once the conflicts are complete, the rules will be executed in order. Then we will output event information or perform corresponding actions.

This method belongs to the category of precise matching, so events that have occurred can be accurately inferred according to the rules.

2)Event recognition method based on fuzzy reasoning

In this method, we establish fuzzy sets and membership function for the state eigenvalues of the system. Then, we establish fuzzy rules. In the rule base, the rules include the form of the fuzzy set in addition to the above-mentioned form of passing the threshold. Finally, the matching degree between the current system state and each rule is calculated by (3). We select a rule with the largest matching degree, output event or perform action in the latter part of the rule.

$$MatchingDegree_R = \sum_{i=1}^n (membership_i \times weight_i) \quad (3)$$

$MatchingDegree_R$ indicates the matching degree between the system state and rule A. n indicates the number of system state eigenvalues. $membership_i$ indicates that the eigenvalues i belongs to the membership of the fuzzy set of eigenvalues in rule R, and $weight_i$ indicates the weight corresponding to the i -th eigenvalues.

In summary, the event recognition method based on fuzzy reasoning mainly supplements and corrects rule reasoning to improve the accuracy of event recognition.

III. EXPERIMENT

To validate the methods of this paper, we choose *BookStore* System as the case to test the ability and accuracy of "detection-recognition" mechanism.

A. Bookstore system

BookStore is a e-commerce system that uses the B/S architecture to provide users with functions such as registration login, product browsing, product payment and so on. Various types of events such as server corruption, response timeout, network bandwidth change, etc. may occur during system running. And the user requirements, computing resources, system overhead, etc. in the system are easily affected by the open environment, it is not possible to define recognition rules for all events during the design phase. Therefore, *BookStore* can be used to test the ability of this method to recognize multiple event types and uncertain event.

B. The experiment for recognizing events

1) **Model system status.** When detecting the system status, we use the three characteristic values of **response time**, **page error rate** and **load** to characterize the system status. The node load is calculated by (4).

$$nodeLoad = 0.4 * CPU + 0.3 * memory + 0.3 * disk \quad (4)$$

2) **Establish event library.** We use tuples to represent event and store it in the event library to facilitate event information output during subsequent event recognition, as in (5).

$$Event = \{ E_Id, E_Name, E_Value, E_Time, E_Effect, E_Priority, E_Duration \} \quad (5)$$

E_Id is composed of 4 digits. The first two digits indicate the event type. "01" refers to the type of node resource changes. "02" refers to the type of unit resource changes such. "03" refers to the type of changes in the business logic layer. "04" refers to the type of communication environment changes. "05" refers to the type of hardware environment changes. The last two digits indicate specific events under a particular type.

E_Effect can be divided into local and global categories. The local effect refers to an event that affects only one software unit, and the global effect refers to an event that affects the global system. *E_Duration* indicates the duration of the event from being recognized to the current time, and it can be used as a reference to set the sequence of event processing.

3) Experiment Design and result

We continuously collect and store the running data of the Bookstore, and we set the dataset size as follows: the size of data set 1 to set 6 is 300, 500, 700, 900, 1100, 1300 data, respectively. The following tests are performed on a computer with Inter(R) Core(TM) i5-4570 processors and 8GB RAM.

We use the "detection-recognition" mechanism to detect the state of the *BookStore* system over a period of time and to recognize events, as shown in Table I.

TABLE I
THE SYSTEM STATUS AND EVENT DISPLAY OF BOOKSTORE

System status	Id	Name	Effect	Time	Priority
abnormal	0101	User server overload	global	11:28 2018-10-15	urgent
abnormal	0501	Home response timeout	global	12:05 2018-10-15	urgent
abnormal	0502	Reduce ads	local	12:43 2018-10-15	general
abnormal	0201	Product display page lost	local	13:18 2018-10-15	very urgent
abnormal	0301	Network delay	global	13:47 2018-10-15	urgent

We show the main attributes of the event. The priority refers to the urgency of the event to be processed, which is determined by the impact of the event on the functional and non-functional requirements of the system. We set the priority of events that have a large impact on functional or non-functional requirements to be *very urgent*, such as server damage events. The priority of a more influential event is set to *urgent*, such as response timeout. The priority of the less influential event is set to *general*, such as the user request to reduce the number of ads.

From Table I we can see that the mechanism of this paper can detect the state of the system and further recognize various types of events. It shows that the mechanism can effectively realize the main tasks of the analyze of the adaptive process.

To verify the time efficiency of the mechanism, we test the time when it processes data sets of different sizes, as shown in Fig.3. As the data size increases, the operation time of the mechanism increases, but the overall does not exceed 2500ms, indicating that the mechanism has higher time efficiency.

To verify the accuracy of the mechanism, we test the error rate of abnormal state detection under the aforementioned data sets, as shown in Fig.4. Meanwhile, the Accuracy, Precision and Recall of the method are verified under the aforementioned data sets, as shown in Table II.

Fig.3. Operation time of the mechanism

Fig.4. Error rate of state detection method

TABLE II

ACCURATENESS OF EVENT RECOGNITION METHOD UNDER DIFFERENT DATA SIZES

Set number	Accuracy	Precision	Recall
Set 1	95.33%	99.61%	95.27%
Set 2	96.2%	99.54%	96.24%
Set 3	96.85%	99.67%	96.88%
Set 4	97.33%	99.63%	97.45%
Set 5	97.64%	99.70%	97.75%
Set 6	97.76%	99.67%	97.94%

As shown in Fig.4, as the data size increase, the error rate of the detection method is declining and gradually gradual. Since the effect of the Bayesian model depends not only on the amount of training data, but also on the construction of the classifier and the characteristics of the data to be classified, there are inevitable errors in the method for state detection. As shown in Table II, the Accuracy, Precision and Recall of the event recognition method are higher in the data sets of different scales, indicating that the method proposed in this paper has a better recognition effect.

In the state detection, to select the appropriate error rate tolerance, we set different tolerances when realizing detection method. Then we recognize events under dataset 6 to obtain the accuracy of recognition, as shown in Fig.5. The accuracy has a significant continuous decline when the tolerance is greater than 8%. At 2% to 8%, the decline is lower. If the tolerance is smaller, the system will constantly adjust and cause system overhead. Therefore, we take 8% as the tolerance.

We compare the Recall of using only rule reasoning and our method under the aforementioned data set, as shown in Fig.6. The Recall of this method is higher than that of rule-based reasoning. Fuzzy reasoning supplements the rule reasoning when encountering an unknown situation. This also verifies the effectiveness of the event recognition method in this paper.

Fig.5. Impact of error rate tolerance on event recognition accuracy

Fig.6. Comparison of event recognition methods

IV. CONCLUSION AND FUTURE WORK

In this paper, we propose a "detection-recognition mechanism, which can effectively avoid the waste of system resources, and cope with the uncertainty in the environment, so that the accuracy of event recognition is improved. In the future, we will further observe the operating characteristics of the system, and consider the online dynamic correction method of the rules. And we will expand the type of recognition event to further enhance the range of recognized events.

Abstract—REST has become in the last decade the most common manner to provide web services, yet it was not originally designed to handle typical modern applications (e.g., mobile apps). GraphQL was released publicly in 2015 and since then has gained momentum as an alternative approach to REST. However, generating and maintaining GraphQL resolvers is not easy. First, a domain expert has to analyse a dataset, design the corresponding GraphQL schema and map the dataset to the schema. Then, a software engineer (e.g., GraphQL developer) implements the corresponding GraphQL resolvers in a specific programming language. In this paper we present an approach that generates GraphQL resolvers from declarative mappings specification in the W3C Recommendation R2RML, hence, can be used both by a domain expert as without the need to involve software developers to implement the resolvers, and by software developers as the initial version of the resolvers to be implemented. Our approach is implemented in morph-GraphQL.

Index Terms—GraphQL, R2RML, OBDA

I. INTRODUCTION

Introduced in 2000, Representational State Transfer (REST) has become the most common manner to provide web services in the last few years. Those web services that conform to the REST principles, known as RESTful web services, use HTTP/S and its operations to make requests to the underlying server, such as GET to retrieve objects, POST to add objects, PUT to modify objects and DELETE to remove objects, among others.

Over the years, the complexity of modern software concept has evolved since the inception of REST. For example, typical mobile applications have to take into account aspects that receive little attention in traditional applications, such as the size of data being exchanged/transmitted and the number of API calls being made. These aspects are relevant to the problem known as *over-fetching* and *under-fetching*. Over-fetching refers to the situation in which a REST endpoint returns more

data than what is required by the developer. For example, a developer may need some information about the name of a user so she hits the corresponding endpoint (`/user`). However, the endpoint may return information that is not needed by the client, such as birth date and address. The opposite also raises a problem, which is having the REST endpoint provide less data than required. Such a case is called under-fetching. It refers to the situation in which a single REST endpoint does not provide sufficient information requested by the client. For example, in order to obtain the names of all friends of a particular user, typically two endpoints may be needed: the first is the endpoint that returns the identifiers of all the friends (`/friends`), and the second is the one that returns the details of each of the friends based on the identifier (`/user`).

In order to ameliorate the aforementioned problems, Facebook proposed the GraphQL query language [6], initially being used internally by the company in 2012. GraphQL was released for public use in 2015 and since then has been adopted by companies from various sectors such as technology (GitHub), entertainment (Netflix), finance (PayPal), travel (KLM), among others. Two main components of a GraphQL server are **schema** and **resolvers**. The GraphQL schema specifies the type of an object together with the fields that can be queried. GraphQL resolvers are data extraction functions implemented in a programming language that are responsible to translate GraphQL queries into queries supported by the underlying datasets (e.g. GraphQL to SQL). GraphQL is supported by multiple GraphQL engines for major programming languages (e.g. JavaScript, Python, Java, Golang, Ruby). In addition to the above mentioned frameworks, query planning tools have been developed in order to translate GraphQL queries into other query languages (e.g. dataloader¹, joinmonster²).

¹<https://github.com/facebook/dataloader>

²<https://join-monster.readthedocs.io/en/latest/>

Generating a GraphQL server requires expertise from both domain experts and software developers. Typically, the following tasks need to be done:

- 1) A domain expert will analyse the underlying datasets, propose a unified view schema as a GraphQL schema and how the source datasets would need to be mapped into the GraphQL schema. Note that there is no standard mechanism to represent these mappings (e.g. the domain expert may use a spreadsheet, which is not necessarily easy to understand by another domain expert).
- 2) A software developer then implements those mappings as GraphQL resolvers, a process that takes significant resources. Given that the complexity of any given source code grows faster than the size of the source code, generating GraphQL resolvers is becoming more difficult even for a standard-sized dataset which typically contains more than a handful tables and hundreds of properties. This situation is even worse if the underlying dataset evolves considering that the corresponding resolvers have to be updated as well. GraphQL resolvers may not be easily understood by new developers who were not involved in the initial version thus bringing the possibility of introducing errors.

In this paper we propose the use of W3C R2RML [4] to specify the mapping rules that relate the source datasets and the GraphQL schema. The use of R2RML mappings is based on the idea that the use of a standard mapping language would facilitate better understanding of the mapping from the underlying data source and the exposed GraphQL schema. Furthermore, they also allow for better maintainability as R2RML mappings are declarative and independent from any programming language. Our main contribution in this paper is, taking the advantage that R2RML mappings are declarative, an approach to translate R2RML mappings to JavaScript-based GraphQL resolvers.

The rest of the paper is structured as follows: in section II we review R2RML and GraphQL and in section III we describe our approach on translating R2RML mappings to GraphQL resolvers. In section IV we present the queries, based on the example provided in the reference implementation³, that we use to test our implementations. Finally, related work and conclusion are presented in sections V and VI.

II. BACKGROUND

In this section we provide some background on two of the underlying technologies that we will use: GraphQL and R2RML. We use the example provided in the reference implementation based on the Star Wars movies to explain the background concepts. An overview of its schema in a tabular model and some of the data is shown in Figure 1.

A. GraphQL

GraphQL is a specification that provides a unified view for accessing heterogeneous datasets using its query language.

³<https://github.com/graphql/graphql-js/>

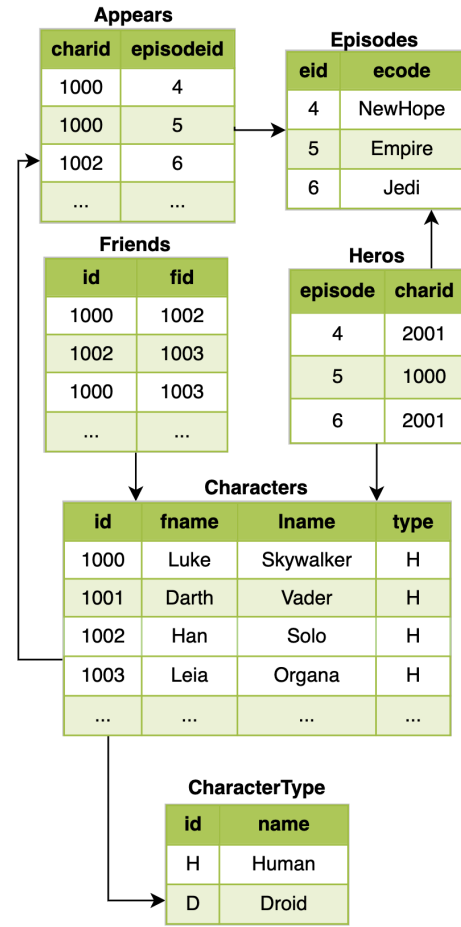

Fig. 1. Tables used in the Star Wars example, inspired by the example provided in the reference implementation

Besides the query language, the specification defines how a GraphQL server may be implemented for allowing the developers to deploy their own implementation in different programming languages. In this section we describe and provide an example of the main components of a GraphQL server: schema and resolvers (query root and type).

```

type Query {
  listEpisode(identifier:String, code:
    String): [Episode]
  ...
}

type Episode {
  identifier:String
  code:String
}

```

Listing 1. GraphQL Schema for type Episode

A GraphQL schema specifies all the available types and their properties. For example, in Listing 1 we can see that the schema for the Episode type together with its two fields: identifier and code.

A GraphQL resolver describes the relationship between the defined GraphQL types/fields and the data sources.

It implements the methods for accessing the data of each field in a specific dataset. For example, given the dataset in Figure 1, a GraphQL resolver may provide queries for retrieving all instances of the defined GraphQL types (e.g., `listAppear`, `listEpisode`, `listCharacter`, `listFriends`, `listHeroes`).

Listing 2 shows a possible JavaScript implementation of the resolver for the Episode type. This part of the code is responsible for filtering out instances based on the fields identifier or code.

```
listEpisode: function({identifier,code}) {
  let sql = `SELECT
    'ex.com/episode/' || eid AS c1
    , ecode AS c2
  FROM episodes
  WHERE
    c1 = ${identifier} AND c2 = ${code}`
  let data = db.all(sql);
  let allInstances = [];
  return data.then(rows => {
    rows.forEach((row) => {
      let instance = new Episode(
        row['c1'], row['c2']
      );
      allInstances.push(instance);
    })
  })
  return allInstances;
};
```

Listing 2. GraphQL Resolver for Type Episode

B. R2RML

The W3C R2RML Recommendation (September 2012) allows users to specify rules for transforming relational database content into an *R2RML output dataset*, the resulting graph from applying R2RML mappings. The transformation rules are defined in an R2RML mapping document that contains a set of Triples Map (`rr:TriplesMap`). Triples Maps are used to generate RDF triples from logical tables. A Triples Map consists of:

- a Logical Table (`rr:LogicalTable`) that specifies the source relational table/view.
- a Subject Map (`rr:SubjectMap`) that specifies the rule for generating the subjects of the triples.
- a set of Predicate Object Maps (`rr:PredicateObjectMap`) that consists of a pair of Predicate Map (`rr:PredicateMap`) and Object Map (`rr:ObjectMap`) that specify rules for generating predicate and object of the triples, respectively. If a join with another Triples Map is needed, a Reference Object Map (`rr:RefObjectMap`) may be specified.

A Term Map (`rr:TermMap`) is either Subject Map, Predicate Map, and Object Map. Term Maps are used to generate RDF terms, either as IRIs (`rr:IRI`), Blank Nodes (`rr:BlankNode`), or literals (`rr:Literal`). The values of the term maps can be specified using a constant-valued map (`rr:constant`), a column-valued map (`rr:column`), or a template-valued map (`rr:template`). Furthermore,

additional information such as datatype (`rr:datatype`) can also be attached to Term Maps.

In Listing 3 we show the R2RML mapping for the table Episode where the subject is defined as a template involving the eid column and a predicate-object pair involving the ecode column.

```
<TMEpisodes>
  rr:logicalTable [
    rr:table "Episodes";
  ];
  rr:subjectMap [
    rr:template "ex.com/episode/{eid}";
    rr:class schema:Episode
  ];
  rr:predicateObjectMap [
    rr:predicate schema:code;
    rr:objectMap [ rr:column "ecode" ]
  ];
.
```

Listing 3. R2RML Mapping for Episode

III. APPROACH

Our approach (Figure 2) generates GraphQL servers from R2RML mappings. Hence, mappings can be created by a domain expert in a declarative language, without the need for programming skills, while benefiting from the wide range of tools available for GraphQL in order to access data stored in tabular format (i.e., RDB or CSV). The approach consists of the following steps: 1) the generation of a SQL query, 2) the generation of schema and 3) the generation of resolvers, from each Triples Map defined in the mapping document.

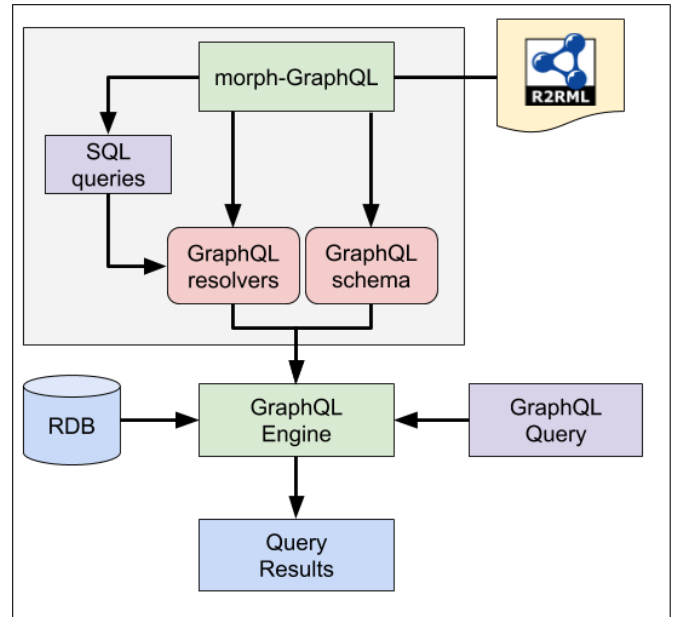

Fig. 2. **morph-GraphQL workflow.** morph-GraphQL receives R2RML mappings and generates SQL queries to be used in GraphQL resolvers. Then, it generates a GraphQL server (schema + resolvers) that can be used by a GraphQL engine to evaluate queries over the RDB data.

Auxiliary Functions. We present here a set of auxiliary functions that will be used in the functions that generate resolvers.

- *getConstant(TermMap)* retrieves the constant *c* in the constant-value term map *TermMap* = *rr:constant "c"*.
- *getColumn(TermMap)* retrieves the column *col* in the column-value term map *TermMap* = *rr:column "col"*.
- *templateToSQL(TemplateValue)* converts a template-value term map into an SQL expression. For example, given the term map *rr:template "ex.com/episode/{eid}"* as the input, this function may return *"ex.com/episode/" || eid* or *CONCAT("ex.com/episode/{eid}", eid)*, depending on the database system being used.
- *transDataType(xsdDataType)* that given an XSD Data Type return the corresponding GraphQL type. For example, *transDataType("xsd : string")* returns String.
- *join(objs, separator)* that joins a collection of objects *objs* into a string with the separator *separator*. For example, *join([1, 2, 3], "AND")* returns *"1 AND 2 AND 3"*.

A. Generating SQL Queries

We present here a set of translation functions that translates a triples map into the corresponding SQL query to be used in GraphQL resolvers. This set of functions is adapted from the work presented in [3], which is used to translate SPARQL queries into SQL queries without the presence of R2RML mappings.

- $\alpha(\text{TriplesMap})$ returns a set of logical tables associated with the triples map *TriplesMap*, which is the logical table associated to the triples map *TriplesMap* and additionally all the parent tables if *TriplesMap* contains Referenced Object Maps.
- $\beta(\text{TermMap})$ that given a term map *TermMap* returns the corresponding SQL expression, that is:
 - *getConstant(TermMap)* if *TermMap* is a constant-value map
 - *getColumn(TermMap)* if *TermMap* is a column-value map
 - *templateToSQL()* if *TermMap* is a template-value map.
- *alias(TermMap)* generates a unique alias to be used in the generation of SQL statement
- *genPRSQL(TriplesMap)* generates a SQL expression which projects the relevant SQL expressions of a triples map *TriplesMap* (i.e., β of Subject Map and all Object Maps) together with their aliases.
- *genCondSQL(TriplesMap)* generates a SQL expression which is evaluated to true if they match the arguments passed in the resolver functions and additionally the join conditions if *TriplesMap* contains Referenced Object Maps.

- finally, $\text{trans}(TM) = \text{"SELECT genPRSQL}(TM) \text{ FROM } \alpha(TM) \text{ WHERE genCondSQL}(TM) \text{"}$ translates a triples map into the corresponding SQL query.

Example Given Listing 3 as the input, *trans* generates the SQL query that can be seen in variable *sql* in Listing 2.

B. Generating Schema

Algorithm 1 generates a GraphQL schema from a Triple Map. It simply generates a GraphQL type *MappedClass*, where *MappedClass* is the class specified in the Subject Map of the Triples Map. The fields of the *MappedClass* are identifier and all the mapped predicates in the Predicate Object Maps of the Triples Map. The datatype of the fields are the results of function *transDataType*, which returns the corresponding GraphQL type from the datatype specified in the Object Maps of the Triples Map.

Algorithm 1 GenerateSchema(TriplesMap)

```

SM = TriplesMap.getSubjectMap()
MappedClass = SM.getMappedClass()
POMS = TriplesMap.getPredicateObjectMaps()
Result = "type MappedClass {"
Result += "identifier:String"
for all POM ← POMS do
    PM = POM.getPredicateMap()
    OM = POM.getObjectMap()
    PMConstant = PM.getConstant()
    DataType = transDataType(OM.getDataType())
    Result += "PMConstant:Datatype"
end for
Result += "}"
return Result

```

Example Given Listing 3 as the input, Algorithm 1 generates GraphQL Type *Episode* that can be seen in Listing 1.

C. Generating Resolvers

Algorithm 2 generates a GraphQL resolver from a TriplesMap. As for the name of the resolver, we opt for *listMappedClass*, that is, a Triples Map whose mapped class is *Episode* will generate a resolver *listEpisode*. This resolver will use the SQL query generated from section III-A, execute the SQL query on the underlying database engine, and then generate the corresponding instances by calling the constructor of Type *MappedClass*.

Example Given Listing 3 as the input, Algorithm 2 generates resolvers that can be seen in Listing 2.

IV. IMPLEMENTATION AND QUERIES

As of the time of writing, we have implemented **morph-GraphQL**⁴, an open source tool to translate R2RML mappings into Javascript-based GraphQL resolvers. Currently, it

⁴<https://github.com/oeg-upm/morph-graphql>, deployed at <http://graphql.morph.oeg-upm.net>

Algorithm 2 GenerateQueryRoot(TriplesMap)

```

SM = TriplesMap.getSubjectMap()
MappedClass = SM.getMappedClass()
POMS = TriplesMap.getPredicateObjectMaps()
PMSConstants = [identifier]
for all POM ← POMS do
    PM = POM.getPredicateMap()
    PMConstant = PM.getConstant()
    PMSConstants.push(PMConstant)
end for
Result = ""
Result += "listMappedClass:
functions(PMSConstants.join(", ")) { "
Result += "sql = trans(TriplesMap)"
Result += "rows = db.all(sql) "
Result += "allInstances = []"
for all row ← rows do
    args = []
    for all POM ← POMS do
        PM ← POM.getPredicateMapping()
        PMConstant ← PM.getConstant()
        args.push(row.[alias(PMConstant)])
    end for
    Result += "instance = new
MappedClass(args) "
    Result += "allInstances.push(instance) "
    Result += "return allInstances"
end for
Result += "}"
return Result

```

is able to generate resolvers for accessing tabular datasets, such as RDB or CSV files. We use the JoinMonster library⁵ to generate efficient SQL queries when joins are needed.

Due to the recent emergence of GraphQL, and as far as we are aware of, there has not been any standard benchmark or test-case proposed for evaluating the conformance and performance of a GraphQL-compliant framework. In order to test our approach, we use a set of GraphQL queries with various degrees of complexity proposed in the example of the reference implementation. First, we serialize the Star Wars instance data in a tabular format (Figure 1) and then generate its corresponding R2RML mapping document. Then we evaluate the queries in Table I. All the information about the dataset, mapping and queries and their results is available online⁶. Additionally, a GraphQL server that is ready to answer those queries has been also deployed⁷.

The initial version of morph-GraphQL presented in this paper shows that an R2RML mapping document can be used to generate automatically GraphQL resolvers. Besides, the implementation of the resolvers is able to cover various levels

TABLE I
STAR WARS QUERIES

No	Description	Tables Involved
Q1	Query the hero of every episode	heroes, episodes, characters
Q2	Query for the id and friends of R2-D2	characters, friends
Q3	Query for Luke Skywalker directly, using his ID	characters
Q4	Query for both Luke and Leia	characters
Q5	Verify that R2-D2 is a droid	characters, types
Q6	Verify that the hero of episode Empire is a human	heroes, characters, types, episodes

of query complexity so that it can be used as a tool for accessing heterogenous datasets via GraphQL queries.

V. RELATED WORK

Several works are at the intersection of GraphQL and Ontology-Based Data Access (OBDA) [9]. In OBDA, ontologies are used as a global view over heterogeneous local datasets and the relationship between them is specified by mappings. R2RML is an example of declarative OBDA mappings whose focus is the generation of ontology instances from relational databases. Other related declarative proposals are: RML [5] (to deal with CSVs, JSON and XML data sources), xR2RML [8] (to deal with MongoDB), KR2RML [12] (to deal with nested data) or RMLC-Iterator (for statistical CSV files) [2]. Two techniques for answering queries over the global schema are: data translation and query translation. In data-translation, a set of mapping rules is used to generate the instances of the global schema and then those instances are materialised in a triple store so that queries posed over the global schema can be evaluated by the triple store. In query-translation, queries over the global schema are translated into queries over the local schema, taking into account the information provided in the mappings, thus eliminating the need of materialisation.

The GraphQL-LD specification is proposed in [14], where the authors include a context to GraphQL queries, similar as it is proposed in JSON-LD [13]. The goal of this work is to translate GraphQL queries to SPARQL queries for querying RDF interfaces and provide a more friendly interface for the developers. Ontop [1] proposed several semantic optimisation techniques to generate efficient SQL queries resulting from the translation of SPARQL queries taking into account R2RML mappings. morph-RDB [10] presented an R2RML-based SPARQL to SQL query translation based on the approached proposed by Chebotko et. al [3]. The approach that we proposed in the paper can be considered as a query translation technique as it allows the answering of GraphQL queries over local datasets without materialising them, by translating R2RML mappings into GraphQL resolvers and delegate the query evaluation to GraphQL engines. Note, however, unlike previous approaches that take a query as their input in their run-time, morph-GraphQL is compile-time, in sense that the generation of SQL and GraphQL resolvers

TABLE II
SUMMARY OF APPROACHES

Proposal	Input	Output	Type
Chebotko et al	SPARQL	SQL	run time
morph-RDB	SPARQL + R2RML	SQL	run time
ontop	SPARQL + R2RML	SQL	run time
GraphQL-LD	GraphQL	SPARQL	run time
morph-GraphQL	R2RML	SQL + GraphQL (Schema & Resolvers)	compile time

are only executed once. We summarise the aforementioned approaches in Table II.

Another relevant work is [7], in which the authors analyse and formalise the semantics and the complexity of GraphQL. Their theoretical study can be used for further analysis of the query language while their technical contributions help GraphQL developers to implement more robust interfaces for the web.

VI. CONCLUSION

In this paper we have presented an approach to generate GraphQL resolvers from R2RML mappings together with its corresponding implementation, morph-GraphQL. Note that we do not aim to replace the traditional approach of generating GraphQL schema/resolvers manually, but we position this approach as supplementary approach. This is to say, this approach allows domain experts to use the generated schema and resolvers as the initial proof of concept that can be used to query datasets without the need for software engineers to develop a full-fledged GraphQL server. Software engineers may also benefit from our approach as they may also use morph-GraphQL to generate the initial version of a GraphQL server instead of building it from scratch. In the future, we plan to support more programming languages (e.g. Java) and more data formats (e.g. JSON) and integrate morph-GraphQL with Mappingpedia [11], a repository for R2RML mappings. We also plan to evaluate our approach comparing the time taken by a domain expert to generate R2RML mappings and a software engineer programming a GraphQL resolver.

ACKNOWLEDGMENT

We are thankful to Nandana Mihindukulasooriya, Anastasia Dimou, Ben de Meester and Pieter Heyvaert, who helped us in the identifying the main contributions of our approach. The work presented in this paper is supported by the Spanish Ministerio de Economía, Industria y Competitividad and EU FEDER funds under the DATOS 4.0: RETOS Y SOLUCIONES - UPM Spanish national project (TIN2016-78011-C4-4-R) and by an FPI grant (BES-2017-082511).

Abstract—Program monitoring aims at making sure the functionalities of the software are always correctly performed during runtime. Semantic Web provides a context enriched framework for data representation and manipulation. This paper proposed the use of ontological rules and reasoning engines to monitor the dynamic behaviours of computer systems in handling of exceptional circumstances, both positive and negative, that occur at runtime within the software processes. A prototype framework was proposed on how to integrate the rule based monitoring technique together with the targeted system. To validate the proposed solution, a light control system case study together with the Unity game engine were used to develop a simulation environment for the evaluation purpose. Compared to existing solutions, the approach outlined can provide an effective software behavioural monitoring outcome.

I. INTRODUCTION

In the past, research has been done into how software program monitors can be used to verify runtime correctness of an application by providing means of identifying errors when they occur. The goal of these monitoring systems is to provide a way to formally verify the correctness of the system in a way like automatic software testing, with the stipulation that this testing is done during the running of the system. Depending on the purpose of the program monitor, such as a debugging tool for developers, a logger or a system-wide message monitor, the exact way that these monitors are implemented changes with their purpose. These monitors can also provide many other features including precise error cause locations, methods to provide alerts about certain errors occurring or ways to recover from errors, e.g., by reverting a database to a previous state. However, these systems all have in common a way to specify what constitutes an error in the program and a way to provide feedback about that error, typically by logging or throwing an exception. Despite the potential application of program monitors in possibly increasing the overall quality of software, software program monitors are not commercially widespread and are not a part of typical software development workflow [1]. Recently, advances in the semantic web and ontologies have opened new possibilities for formal program modelling and verification. Additionally, these semantic web technologies provide powerful means for verifying constraints and conditions using rules and reasoning engines which could be useful for monitoring software program behaviour [2].

Since ontologies are a promising way to model software program data and thus monitor programs, the goal of this project is to investigate whether ontologies can be used in this way, and if they can, how best ontologies may be used for monitoring program data at runtime. Consequently, evaluation of how effective ontology-based monitoring is should be done. Because program monitors provide many different feature sets, levels of correctness and speed, amongst other factors. To determine the effectiveness of ontology-based monitoring, the best way to integrate a reasoning engine to the monitoring system should be explored, since the reasoning engine will be performing the runtime verification. Finally, the proposed system should be easy to use and more useful for developers, providing a possible alternative to conventional software testing methods.

From prior research, the monitoring approach used depends to a large extent on the intended use of the program monitor. Therefore, care must be taken to ensure that the monitor is fit for purpose. Since the intention of this project is to provide a monitor that can allow for error checking at program runtime at a single application level without developer interaction, such a system need not determine the origin of error states, nor does it require the implementation of sophisticated data recovery techniques. Additionally, although there exists within more recent research proposals for systems that integrate hardware into the monitoring of low fault-tolerant applications, to increase monitoring speed and protect against hardware faults [3], such a system would not be suitable for this purpose since the proposed system should be hardware agnostic for ease of use.

Examining past solutions, not all systems provide guaranteed fault detection. The most common cause is not mistakes in the proposed systems themselves, but in poor coverage provided by the predominantly control-flow driven monitoring techniques employed. Note that programs that have stricter runtime requirements with respect to real-time computing have more rigorous speed evaluations than those that do not, implying that for such systems, performance is of a greater concern than for systems where relatively slow human interaction comprises the bulk of the total process. Regarding the use of ontologies for modelling program data, there is evidence that such activity is possible. Other data formats such as XML are already used as intermediates for transferring data between different programs using middleware technology [4]. Since on-

technologies are designed as an expansion of such technology, with more sophisticated and standardised reasoning capabilities, it stands to reason that the functionality of semantic web and ontologies is a superset of the functionality of XML [5].

The objectives of this research are to design a system that can be used by software developers to monitor the runtime behaviour of programs and demonstrate how such a system can be used. To accomplish these objectives, the modelling of program data using ontologies needs to be explored and demonstrated for use in the ontology monitoring system. Also related to the modelling of program data is the way that rules and reasoning engines can be integrated into the system to provide the constraint checking necessary for this type of program monitoring to work. Furthermore, the proposed system should be easy to integrate into monitored programs, allow for specification of many different types of constraints on the data and be fast enough so that it could be realistically used in an actual software system.

This project aimed at achieving a usable, reliable and useful way to allow for integration of any software program into a runtime behavioural monitoring system and ways to verify correctness using many rules and constraints that can be easily and quickly changed to accommodate fluctuating requirements. Since this system focusses on providing a tool for developers and is difficult to evaluate independently of its use, a case study is proposed to test the monitoring system and to show how such monitoring can be extended to any generic program given an ontology structure. It should be noted that although the goal of this system is to simply provide a means for checking errors in programs, there exists the potential to implement some business logic in the defined rules on the ontology such that when reasoned about. These rules can make useful changes in the program data based on these functional requirements. Therefore, in the system demonstration, business logic inferences to maintain data consistency are demonstrated as they show off a superset of the potential uses of ontologies compared to the relatively simplistic logging of error states.

The rest of the paper is organised as follows. Section II presents the design of the system including software architecture decisions, technologies used, and the general methods used to integrate the program monitor with the monitored program and associated ontology. Section III presents the implementation of the system, including the construction of the monitoring system, the use of ontology and reasoners and an exploration of the case study as an example of a possible use case of the proposed system. In section IV, an evaluation of the monitoring system is discussed including the success of the testing methodology, comparison with previous program monitors, discussion of proposed system features, lessons learned and possible improvements. Finally, Section V concludes the contributions and discusses the future work.

II. SYSTEM DESIGN

The system proposed for integrating program monitoring into a piece of software is to create an instance of the program monitor within the monitored program using external APIs,

and then using this monitor instance to update and receive updates from the ontology. This approach allows for easy integration with any monitored program by simply importing the relevant library whilst providing a high degree of control to the monitored program in deciding what properties are important within the monitored program. However, for the program monitor to work, an ontology and externally defined rules must be made available to the program monitor. This can be done within the monitored program by providing the location of these two files to the program monitor instance at construction time. Since updates from the program monitor should not be polled for by the monitored program, an interrupt style listener paradigm is used so that the monitored program can register an interest with the values of properties and provide code that runs when those updates are triggered. An overall data flow of the monitoring system is shown in Figure 1.

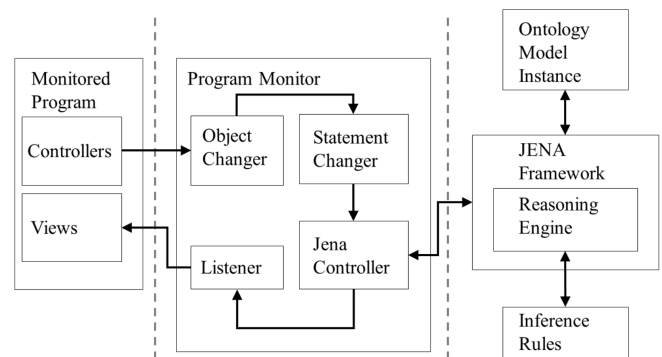

Fig. 1. Data flow through monitoring system

This call-back-like approach is known as the listener pattern and is an easy way to integrate program modules that do not need to be aware of when the other module runs given that updates are received eventually. For triggering updates, controllers are obtained from the program monitor instance to provide means to change property values from within the monitored program. The final part is the ontology model, which is updated firstly from the monitored program, then again by the reasoner if any updates are caused by the rules firing. This overall approach can be summarised as an implementation of the model-view-controller pattern (MVC) [9], which is often used for systems with a high degree of user interaction.

III. IMPLEMENTATION DETAIL

Conceptually, the monitoring system lies between the monitored program and its corresponding ontology; the monitoring itself works by checking the entire ontology against all the rules every time the Jena API is called by a property changer to update the given ontology. The timing of the rules firing is managed by the Jena framework, however, since Jena is open source, the rules engine could be made to run at different times. Since the controller objects in the monitored program use the call-back principle to specify changes, it is easy to change value types and access core Jena functionality with little additional work.

These statement changers or monitor controllers require direct access to the ontology model and must be requested from the program monitor instance rather than be constructed directly. At construction time, the full URL of the resource and property to be updated is supplied by the controller to the program monitor instance to obtain the resource and property Jena objects associated with those URLs. However, since the ontology objects for each entity change values, these property values must be located each time the object pointed to is updated. After an update is made to the ontology, all listeners are notified synchronously of the current value of the property objects that they are listening for. As with the controllers, a reference cannot be kept for a listened object, so each listener supplies URLs for the resource and property to use to retrieve listened for objects each time an update occurs. These updates are then passed to the listeners using the callback-like method, invoking a change in the monitored program somewhere. After all listeners are notified, control is passed back to the monitored program for the next update.

Before the monitoring system should be integrated into the target system, consideration must be made for the construction of the ontology and associated rules. The ontology should be constructed such that all possible conditions that might be reasonably monitored are represented in an externally logical form and such that the ontology can provide an accurate representation of the important data in the program. This means that each object in the program that represents something in the physical world should be represented in the ontology; more specifically, objects that have value outside of necessary software development usage within programs, like array lists or hash tables would only appear in the monitored program. In other words, an ontology should represent the context schema of a program. The classes of the ontology should represent the types of object to be modelled, the entities should represent the instances of those objects within the program and the ontology properties should represent the fields or attributes that are of interest within these entities. From these parts, a complete model of the ontology of a system can be constructed. For this project, OWL [5] ontology reasoning was used. Jena supports OWL DL (Description Logic) specifically, which allows more powerful reasoning than would be provided by a less expressive ontology language such as RDF. Notably, when using the proposed monitoring system, the ontology should be modified by an external tool such as Protege [10] which is designed for easy editing and analysis of ontologies.

IV. CASE STUDY AND EVALUATION

A. The Light Control System

To demonstrate the proposed system, a case study is required that demonstrates how monitored programs can be integrated with the monitoring system and how effective the proposed system is at monitoring programs. A building management system was chosen for the demonstration since building management systems are typically well-defined, contain many complex rules and constraints and are suitable for demonstration in an interactive environment such as a

game engine. Additionally, such a simulation could be feasibly extended to a physical sensor network if the associated simulation is successful at capturing all the necessary functionality in a similar way. The basis for the chosen building management system is provided in [12]. This description provides a high level of detail about a typical smart building complex with constraints related to context-aware features such as the temperature and light intensity controls [13].

Fig. 2. Simplified ontology example.

In this example, there are at least three entities which may be formalised by an ontology, i.e., the motion detector, the light and the room which contains both these objects. Therefore, this interaction can be represented by a SWRL [11] rule which updates the ‘?light on?’ property to false whenever the motion detector in the same room has the ‘?motion detected?’ property evaluate to false. Figure 2 shows a simpler version of this scenario (without the connecting room entity) to illustrate how rules can be used to infer relationships using a reasoning engine. Extending this scenario to every room in the building with a motion detector allows the same rule to be used in each case.

B. Evaluations

For validating the monitoring system, 10 rules of varying complexity and approach were constructed to show that when updates relevant to each rule are received, that rule is fired, producing some change in the system ontology. Of these 10 rules, each was tested within the simulation environment and all rules were found to fire when expected and with the expected results. These rules were constructed such that every rule possible was paired with a rule that fired under opposite conditions and produced the opposite result. The motivation behind this rule construction methodology was to ensure that in a test environment, that the updates and rule changes were repeatable. The rules that did not have an opposite satisfied this condition of repeatability by including the object part of the triple condition within the rules as a wildcard or free variable, using this variable input to compute a variable output. This meant that some rules could contain the same functionality as two rules in the case of a Boolean literal object, or that rules which used integers could contain the same functionality as an infinite number of more specific rules. This behaviour is of interest since assertions are typically static during runtime, and different cases of assertions cannot be compressed into a single assertion. Thus, it seems that rules can sometimes provide more powerful condition checking than assertions.

For the testing environment, rooms were constructed within a simplistic mock building within the game engine so that each rule could be tested in isolation and without interference as many times as desired. This approach is a generalisation of typical testing techniques, with the main differences being that rules could be tested systematically by following a defined path through the different rooms, whilst allowing for rules to be fired at any time and with any frequency, more closely mirroring actual human interaction with a system. Although this style of testing is less automatic than traditional testing means, errors associated with timing and user experience are much easier to identify if each test is run eventually. In addition to the freeform testing provided by the simulation environment, a JUnit test suite was used early in the project lifecycle to evaluate the reasoning engine before the simulation environment had been completed. As with the simulation environment, all rules were fired when expected and produced the expected results.

A benefit of using the system is that ontologies can easily be reused and transferred between multiple formats, this contrasts with other program monitoring approaches which are more specific to each monitored program which may require more redesign work for slightly different applications. Another benefit compared to assertion-based systems is that the code is not cluttered with annotations that obscure the code intent or need extensive work to change if the monitored behaviour changes due to new requirements. This constraint checking work is delegated to the rules file, which provides a more cohesive interface for changing checked behaviour. Compared to the more common control-flow based monitoring, the proposed system is simpler to understand conceptually and easier to reason about from a monitoring perspective. This is because checking the control flow through a conditional or function often assumes some flow higher up in the control of the program, which can make it complicated to get a total view of the system status.

The proposed system can be compared to other program monitoring approaches based on each system's relative feature set. The features of several other program monitors are summarised in this paper. In comparison to systems that require specialised hardware, such as [3], this approach provides guaranteed correctness, given that the rules and ontology are constructed correctly without the hassle of customised hardware. Software only monitors to insert assertions automatically have been proposed [7], however it and other automatic assertion generating programs do not guarantee correctness unlike [3]. Systems that use constraints to monitor program execution also exist [6], however, these systems can be too heavyweight for smaller projects and do not provide the benefits of using ontologies as discussed previously. Assertion based monitors like [8] can also be used, but the main disadvantage of assertions to monitor control flow, is that control flow monitoring can become too complex to easily modify and rules must be changed from within each software module monitored. Although the monitoring system described in this paper solves the previously discussed problems, it is not

without disadvantages, the most notable being the additional work required to make and maintain the ontology and the performance of the system.

V. CONCLUSION

Program monitoring aims at ensuring functionalities of the software system are always correctly performed during run-time. This paper demonstrates not only that semantic ontology and its reasoning engines can be integrated with software applications to allow for rule-based monitoring, but also outlines a method for doing so. Additionally, the effectiveness of such a tool was evaluated with respect to how well a reasoning engine could determine errors in software and how useful the tool would be for software developers. This project has found that it is not only possible to create a powerful and flexible tool to monitor programs using rules and ontologies, but also the tool can be easily integrated with existing applications. These contributions were gathered based on implementing and testing a semi-realistic case study integrated with a game engine simulation environment to provide real-time feedback on ontology updates and rule firing. In addition, comparisons to related work were conducted with useful evaluations. In the future, a feature that would greatly increase usability would be the ability to convert rules from more common languages such as SWRL into the Jena specific rule format.

Abstract— IoT, smart cities, cyber-physical systems and sensor networks are context-aware, highly dynamic and reactive systems. Their implementation should take into account the heterogeneity of their components and make easy the management of events unplanned at design time. According to these requirements, in this paper we propose an ontology-based approach to provide runtime models of the physical entities characterizing context-aware reactive systems. We extend SSN, a W3C standard ontology, to support complex reactive behaviors through the modeling of Logical Sensors and Actuators (LSA ontology); we also present a software architecture in which a knowledge base, structured coherently with this semantic model, is bound to real world entities by grounding (via web services) semantic elements to physical sensors and actuators. To validate the approach we discuss a case study related to smart buildings for cultural heritage preservation.

Index Terms—Context modeling, Context-awareness, Semantic modeling, Semantic Sensor Networks, Ontologies

I. INTRODUCTION

Internet of Things (IoT), smart cities and cyber-physical systems propose several scenarios characterized by a high level of dynamism and heterogeneity. Applications supporting these scenarios should be context-aware since this property has been widely acknowledged as an enabler for software adaptation to dynamic changes [1]. According to [2], context is the state that a system is able to access to or modify. This state is the set of variables that are possibly shared with other systems: they can be read or modified by users, devices or applications other than the one the state is referred to.

Various recent research works take the idea of using models as central artifacts to cope with dynamic aspects of ever-changing software and its environment at runtime. Szvetits et al. [3] comprehensively survey these approaches for adaptive context-aware systems highlighting the common idea of establishing semantic relationships between executed applications and runtime models.

In this paper, we focus on the design and implementation of reactive context-aware systems taking into account the heterogeneity of the physical devices they consist of and the ability to infer high-level context properties from directly measurable

ones. Such systems need both (i) a way to describe the systems and their environments (i.e. to express architectural and state information), and (ii) a mechanism to define the application logic that drives their behaviors.

To meet the first requirement, we exploited the Semantic Sensor Network (SSN) ontology, a recent W3C recommendation [4] that has been designed to describe systems composed of a densely interconnected graph of sensors and actuators along with observations and actuations they produce. To satisfy the second requirement, we propose an extension of SSN called Logical Sensors and Actuators (LSA) ontology, since SSN does not provide mechanisms helping programmers (or reasoners) to close the gap between observations and actuations for programming context-aware reactive systems.

The LSA ontology introduces two main concepts: (software) *logical sensors* and *logical actuators*. A logical sensor (resp. actuator) is a sensor (resp. actuator) that generates observations (resp. actuations) as result of software procedures executions that use other observations as inputs. Logical sensors and actuators are entities that live only in the virtual space (e.g. knowledge base) and are connected to the external world through SSN simple sensors and actuators.

The proposed semantic runtime model is supported by a software architecture centered on a knowledge base which is bound to real world entities by grounding (mainly via web services) semantic elements to physical sensors and actuators. The behavior of the system can be specified by using sensing or actuating procedures tied to logical devices provided by the semantic model. These procedures can act upon the knowledge base by generating new facts or by redefining the structural aspects of the model thanks to the declarative approach adopted.

To clarify our approach, the overall architecture and the proposed ontology, we present a detailed scenario related to a case study in the domain of smart buildings hosting cultural heritage. The example has been implemented and tested with a prototype implementation of the proposed architecture based on Jena, OWL, and SPARQL, for the knowledge base, and RESTful services, for the interaction with the physical world, currently virtualized through an emulator.

The remainder of this paper is organized as follows. Sec-

tion II presents the related work from both research and standardization points of view. Section III introduces the SSN ontology, identifies its limitations with reference to the definition of complex and runnable sensors/actuators behaviors and proposes an extension of SSN. Section IV sketches a general architecture for context-aware applications. Section V validates the proposed ontology extension with a prototype of the infrastructure used to run an application scenario from eCulture domain. Finally, Section VI concludes the paper and highlights future work.

II. RELATED WORK

Several papers have tried to propose approaches and technologies to easily model and handle dynamic context-aware applications especially for ubiquitous and pervasive computing. One of the first ontology-based approaches is SOUPA [5]. It is expressed in OWL and includes modular component vocabularies to represent intelligent agents, time, space, events, user profiles, actions, and policies for security and privacy. However, it does not focus on sensors/actuators and reactive systems but on smart meeting places. In [6], the authors discuss the requirements that context modelling and reasoning should meet, including the modelling of a variety of context information types and their relationships, of high-level context abstractions describing real world situations, and of uncertainty of context information, without defining an ontology.

Paper [7] surveys context awareness from an IoT perspective. IoT researchers are taking into consideration Web technologies (WoTs) to support context-driven system engineering. The goal of the WoT is to extend Web services to devices, allowing a Web client to access devices properties, to request the execution of actions or to subscribe to events representing state changes [8]. The related ontology describes how to model physical or virtual sensors and actuators with the main objective of easing the binding with devices reachable through web protocols (REST, CoAP, etc.).

A different objective is pursued by the Semantic Sensor Network (SSN) ontology [4], an Open Geospatial Consortium (OGC)/World Wide Web Consortium (W3C) standard. It is mainly focused on the SOSA (Sensor, Observation, Sample, Actuator) pattern [9] to model reactive systems. It aims at supporting the definition of simple reactive behaviors that link observations, coming from modeled sensors, with the related reactions, performed by actuators. In order to link observations to physical or virtual properties, the SOSA pattern is extended with some system-oriented features. However, SSN does not directly support complex processing inside the knowledge base than asserting facts due to external sensing activities.

The Semantic Smart Sensor Network (S3N) ontology [10] is an effort that tries to specialize SSN for supporting the modeling of smart sensors. To this end a new class, `s3n:SmartSensor`, has been introduced as a specialization of `ssn:System`. A smart sensor is composed of embedded sensors, microcontrollers and communicating systems. The behavior is expressed by the execution of an algorithm (selected among the existing ones on context basis) by the

microcontroller, which can be thought as a specialization of the `ssn:Actuator`, being able to select algorithms from the current context and to change the state of the whole smart sensor. Therefore, the main purpose of S3N is to support smart sensors modeling and not to close the logical gap between sensors and actuators for fully programming reactive systems.

III. SEMANTIC MODELING OF LOGICAL SENSORS AND ACTUATORS

Semantic Sensor Network ontology: the SSN ontology was specifically designed for supporting interoperability between WoT entities taking into account performance and composition requirements. Web developers, in fact, have their concern about semantic approaches that do not assure near real time data processing. For this reason, its core module is constituted by the lightweight SOSA ontology that defines concepts and properties through schema.org annotations. The SSN main perspective is the system one.

Systems of sensors and/or actuators can be deployed on platforms for particular purposes. Actuators determine changes of the state of the world through the execution of procedures triggered by the observations of properties. SSN does not fix restrictions on the way to implement procedures, allowing to describe any information that is provided to a procedure for its use (`ssn:Input`), and any information that is reported from a procedure (`ssn:Output`). Finally, sensors detect stimuli that originated observations, i.e. events that assign results to observable properties. Stimuli can be proxies for observations of properties related to features of interest. For example, infrared sensors respond to thermal stimuli detected from the environment. The thermal stimulus is a proxy for a live presence in the sensor zone, which represents the observable property related to a feature of interest.

SSN does not allow the definition of software procedures that implement machine actionable system behaviors. To overcome this limitation, we extended SSN introducing software procedures that we mainly exploit with logical sensors and actuators, which are active, composable system components able to generate observations by processing one or more observations asserted into the knowledge base and to generate actuations in a similar way, i.e. by running actionable behaviors tied to software procedures.

Logical Sensors and Actuators ontology: Fig. 1 shows a Graffoo [11] diagram of the core elements of the Logical Sensors and Actuators (LSA) ontology², an extension of the SOSA core of the SSN ontology that allows to describe logical sensors and actuators with a specification of their behavior.

Logical sensors and actuators are modeled with the classes `lsa:LogicalSensor` and `lsa:LogicalActuator`, which are subclasses of `sosa:Sensor` and `sosa:Actuator`, respectively. The behaviors associated to logical sensors/actuators are represented by the `lsa:SoftwareProcedure` class, and the property `ssn:implementedBy` is used to connect software procedures to sensors/actuators and consequently to the logical ones.

²The Logical Sensor and Actuator ontology is available at <https://sites.google.com/site/logicalsensorsactuators>

Fig. 1. Core classes of the Logical Sensors and Actuators (LSA) ontology.

A `sosa:Procedure` is defined in SSN as “a workflow, protocol, plan, algorithm, or computational method specifying how sensors make observations, or actuators make changes to the state of the world”. A `lsa:SoftwareProcedure` is a specific kind of `sosa:Procedure` with an actionable behaviour. Software Procedures may be implemented by Sensors (Actuators) or by Logical Sensors (Actuators). Sensors (Actuators) exploit software procedures for exposing how clients may interact with physical Sensors (Actuators). Through Software Procedures, a System may expose/manage its internal states or trigger an internal process. A `lsa:SoftwareProcedure` behavior is described by executable code (`lsa:hasBehavior` property).

It is important to note that the LSA ontology does not impose constraints on how such behaviors should be represented. For example, they can be modeled as OWL-S [12] processes, BPMN processes described using the BPMN Ontology [13], etc. Another key point of the LSA ontology is that it allows to discern between:

- **procedures specifications:** the algorithm, workflow, protocol, etc. used by a sensor (actuator) to perform observations (actions), along with a declaration of inputs and outputs. E.g. the algorithm used by a logical sensor that measures the perceived humidity (output) by aggregating a temperature and a humidity (input);
- **procedures executions:** the description of a specific execution of a procedure made by a sensor (actuator), which is carried out using a specific set of input values to produce a specific output. E.g. the perceived temperature X (output) of a room computed by using temperature Y and humidity Z as inputs.

In our pattern (which we aim at aligning with the ontology proposed in [14]) a procedure execution is modeled with the `lsa:SoftwareProcedureExecution` class. It is related (via the `lsa:usedProcedure` property) to a `lsa:SoftwareProcedure` and is performed (`lsa:madeBy` property) by `lsa:SoftwareProcedureExecutor`, a software agent able to execute (`lsa:executes`) a `lsa:SoftwareProcedure` that specifies the actionable behaviour (e.g. algorithm, workflow, protocol, etc.) manifested by the execution.

IV. AN ARCHITECTURE FOR SEMANTIC CONTEXT-AWARE REACTIVE SYSTEMS

We propose a reference architecture to design a framework able to host and exploit the semantic model described before for executing context-aware reactive applications. The main

component of this architecture (see Fig. 2) is the Semantic Engine. It extends a knowledge base with the machinery needed to interact with sensors and actuators and execute their software procedures. The knowledge base contains a model of the physical world it interacts with that is enriched and modified with the data coming from the sensors, assuring consistency with the physical elements it represents. This alignment is usually referred to as *causal connection*. When a modification of the model causes the enactment of an actuator to materialize this modification in the physical world we say that the model is *bi-causally connected* [15], a feature that is supported by our architecture.

To exemplify these concepts just think about a simple reactive system immersed in an environment composed by a room with a light bulb, a bulb actuator and a light sensor, all these elements are represented in a virtualized form within the system. In a causally connected system the change of the state of the real-world light bulb (turned on/turned off) is reflected in the model element that represents the bulb within the system. In a bi-causally connected system, the modification of the state of a model element is reflected as a change of state of its real-world counterpart. Thus, if we set the state of the model element representing the light bulb to off while the real-world light bulb is turned on, this triggers an actuator to turn off the bulb.

The key ingredients to actualize a system of this type are: one or more models that describe real-world conceptual classes, a binding mechanism that maps sensor observations to knowledge base updates, logical causal connections that propagate updates throughout the knowledge base, and a binding mechanism that maps updates to actuators activation for preserving the model alignment with real-world situations. It is worth noting that causal connections need some kind of computational support. According to the organization above, our architecture presents: (i) a semantic model built using the previously introduced ontologies hosted by a knowledge base platform (a triple store); (ii) a linking mechanism to report sensor readings to the system, implemented using web services exposed by the system, which is responsible of converting readings into semantic triples to insert into the triple store; (iii) a programmed logic for generating new facts from observations; (iv) an actuation mechanism exploiting actuators Web services, consistently with the WoT approach.

Causal connections are supported by rules that correlate real

Fig. 2. Architecture outline.

world changes observed by sensors with knowledge base updates. We consistently represent these rules in the knowledge base itself: the activation part is modeled as software procedures associated to semantic sensors and actuators whereas the triggering logic is implemented by monitoring changes to the properties that are declared as inputs for these semantic sensors and actuators.

The engine (see Fig. 2) connects to the physical world by exposing a service API used to receive observations from external sensors (that can be real or simulated ones) and by invoking web service endpoints for activating external actuators or for invoking external services (on the right) to increment the capabilities of the software procedures associated to logical sensors and actuators. Whenever an external sensor notifies an observation invoking the engine's API, that observation is transformed in a semantic format and added to the knowledge base. If a logical sensor/actuator is interested in that observation (which means that it is modeled in such a way that its software procedure uses as one of its inputs the property reported by the observation) its related software procedure is executed (by running the actionable items that define the specific Actionable Behavior), producing new facts (observations or actuations) that could trigger external actuators. This approach allows for declarative definitions of reactive behaviors in a bi-causally connected system. In fact, both the model of the context and that of the system (in terms of logical sensors/actuators and their behaviors) is represented in a semantic format (e.g. by RDF triples). This allows to change the overall behavior of the system by manipulating the knowledge base: at runtime new logical sensors can be defined, the behavior of the existing ones can be modified, existing sensors/actuators can be deleted. A further advantage of this architecture is that self-adaptive behaviors can easily be implemented by simply allowing the software procedure of a sensor/actuator to work as described in [16], [17]. For example a software procedure can be activated by the detection of a failure in an external sensor to compose observations produced by other sensors in order to collect the expected events related to a feature of interest.

V. A CASE STUDY

We consider a running example derived from a larger system for Cultural Heritage preservation [18]. In a museum a new temporary exhibition is arranged. In a room of this exhibition a multimedia content has to be played. The organizers of the exhibition express the desire that the content starts playing when visitors enter the room, and stops when the room is

empty. Museum rooms have no specific detectors for knowing the number of people inside them but are equipped with Bluetooth beacons (one per room) and Infrared (IR) sensors close to the doors (used as part of the anti-theft system). Beacons notify their presence to users' personal devices equipped with a specific App turning these devices into location detectors.

We can define a logical sensor for observing the number of people in a room with two different implementations: one based on beacons and personal devices and another one based on IR sensors. If the former is faulty, the declarative approach eases the selection of another (logical) sensor able to observe the same property. In the following, we assume the first is faulty and describe the IR-based logical sensor for clarifying the overall approach and the LSA ontology.

Multimedia playback control based on a logical presence sensor:

1. a tourist crosses the door of the museum, and the two physical infrared sensors on the door sides produce two observations about the presence of a person in their detection areas;
2. a logical sensor aggregating such observations produces another observation updating the number of persons present in the rooms;
3. if the tourist enters an empty room, an actuator starts to play a multimedia flow on the room monitor; if the tourist is the last person that leaves a room before the end of the playback, an actuator will stop the multimedia flow. In both cases, the information about the new actuation is inserted into the triple store.

1. Observations made by physical sensors: Fig. 3 shows the RDF statements that are added to the triplestore by the semantic engine when a person crosses a door. Whenever this occurs, the infrared sensors placed on the two sides of the door detects the presence of a person and invokes the engine REST API in sequence (providing their ids and the instants of time when the observations occurred as request parameters).

Two observations (i.e. `gmus:observation/ir1/1` and `gmus:observation/ir2/1`) made by sensors `gmus:ir1` and `gmus:ir2` are produced, which relate to the same feature of interest (i.e. `gmus:door1`). Each observation concerns a distinct observable property (i.e. the presence in the detection area of each sensor: `gmus:presence/room1/ir1/zoneDoorInside` and `gmus:presence/room2/ir2/zoneDoorOutside`), and keeps track of the time in which the observations were performed.

In these examples we make use of punning³, an OWL metamodeling capability that allows to treat model elements as classes and individual as the same time. Elements with this double nature are represented as light blue squares in the diagram. This has been used in Fig. 3, for instance, to model the concept of infrared sensor (`gmus:IRSensor`), which is at the same time a class (i.e. a specific subclass of sensors representing infrared sensors) and an individual (since it is connected with

³See https://www.w3.org/TR/owl2-new-features/#F12:_Punning

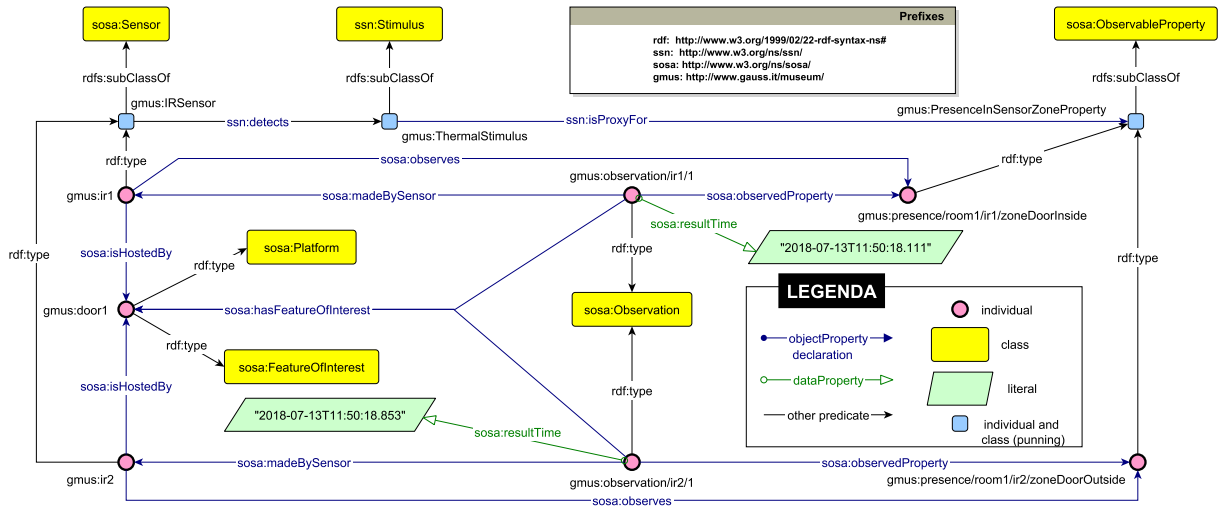

Fig. 3. Observations made by two infrared sensors.

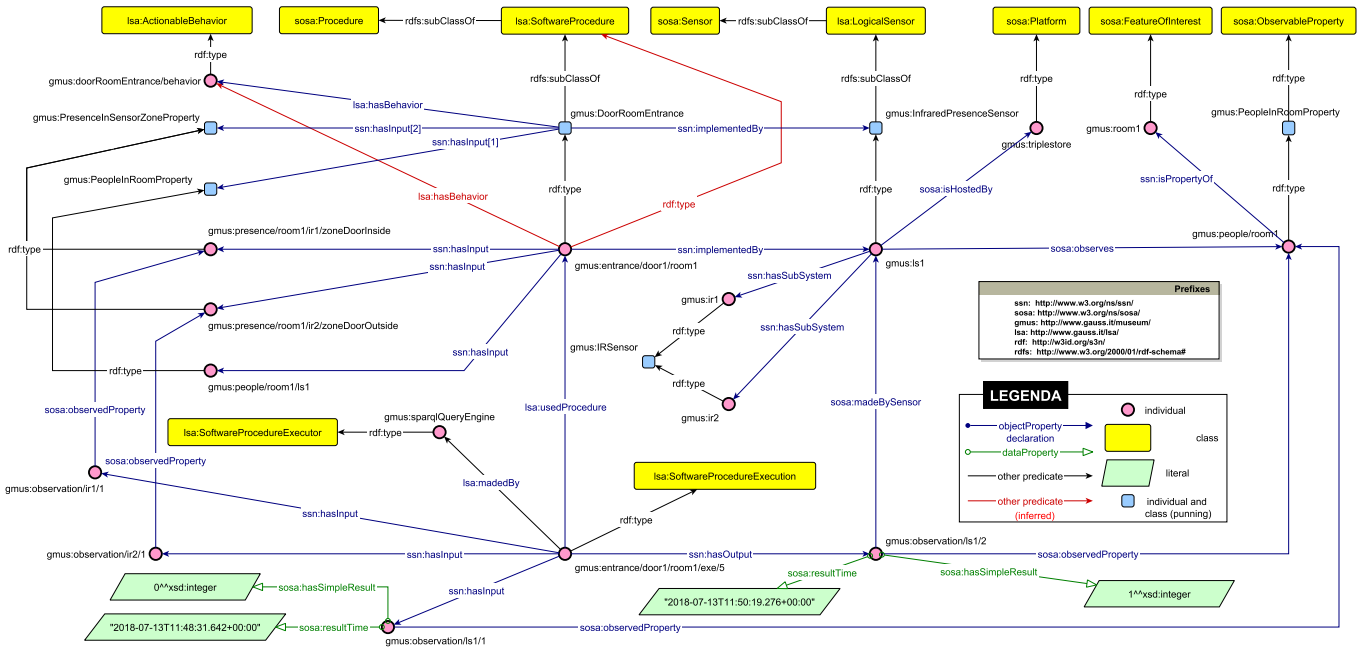

Fig. 4. Observations made by the logical presence sensor. Square brackets are used to specify property cardinality restrictions.

gmus:ThermalStimulus by the ssn:detects property). In the same way, gmus:PresenceInSensorZoneProperty is a type of observable property (i.e. subclass of sosa:ObservableProperty) and an individual (connected to gmus:ThermalStimulus by the ssn:isProxyFor property). This approach is also useful to model logical sensors behaviors, as described in the rest of this section.

2. Observations made by logical sensors: whenever a modification occurs in the triplestore (e.g. the insertion of a new observation), the semantic engine checks if one or more procedures specifying the behaviors of logical components (i.e. logical sensors and actuators) should be executed. To do so,

the engine checks if the properties related to the new observations (e.g. gmus:presence/room1/ir1/zoneDoorInside and gmus:presence/room2/ir2/zoneDoorOutside in the previous example) are specified as inputs of one or more software procedures. Since these properties (see Fig. 4) are inputs of the gmus:entrance/door1/room1 procedure (as specified by ssn:hasInput), the semantic engine identifies the procedure, which is tied to the logical sensor gmus:ls1, a specific instance of gmus:infraredPresenceSensor (the class representing logical presence sensors) hosted by the triplestore (gmus:triplestore), and executes it by observing the presence of people in the specific room (gmus:people/room1).

A mechanism is adopted by the semantic engine to retrieve behavioral information (e.g. a sequence of activities to perform) pertaining logical sensors. Since behavioral information is shared by all logical sensors of a type, the engine identifies the related software procedure (gmus:DoorRoomEntrance in our case) and retrieves the behavioral specification (gmus:doorRoomEntrance/behavior) by navigating the lsa:hasBehavior property.

Such behavioral specification in this case is composed of two actions, i.e. two SPARQL CONSTRUCT queries checking the entrance/exit in/from the room, respectively. Each of these queries retrieve the new observations made by the two infrared sensors, and if they have been performed in a short time interval - e.g. one second - produces:

- 1) a new software procedure execution (gmus:entrance/door1/room1/exe/5), connected to the software procedure (gmus:entrance/door1/room1/) by the lsa:usedProcedure property, and to the observations used as input (those made by the two infrared sensors and those pertaining the number of persons in the rooms connected by the door⁴) and the software procedure executor (gmus:sparqlQueryEngine) by the ssn:hasInput and lsa:madeBy property, respectively;
- 2) two observations as output of the procedure execution represented using the ssn:hasOutput property. For instance, the number of people in the first room has been updated from zero (in gmus:observation/lsl/1) to one (in gmus:observation/lsl/2) since a person entered the room.

3. Actuations made by logical actuators: the newly added statements (i.e. those about the observations produced by the logical sensor gmus:lsl and the relative procedure executions) trigger another control performed by the semantic engine to check logical sensors/actuators interested to those observations. In our example, the logical actuators controlling the video playback on the monitor in the room is activated, and the related software procedures is retrieved and executed, triggering the final actuation (REST invocation) of the physical device that starts the video playback on the monitor.

VI. CONCLUSIONS AND FUTURE WORK

In this paper, we presented a proposal for an extension of the SSN ontology to support modeling of logical sensors and actuators, and their behaviors. The extension enables reactive behaviors of context-aware applications by defining the decision logic that exploits sensor observations to trigger actions. The ontology is accompanied by a an architecture that supports behaviors definition and the interaction with the real devices in the physical world. A prototype of the architecture has been implemented by using Jena, SPARQL and RESTful APIs for the interaction with the external environment, currently emulated with Freedomotic. We discussed and validated the

⁴Because of space limitations in the diagram we depicted only the observations about a room (i.e. we omitted the observations about the number of people in gmus:room2)

proposed ontology extension and the supporting architecture with the help of a case study in the domain of smart buildings for cultural heritage. The ontology extension and the related architecture represent the first step towards the definition of a more complex platform for context-awareness able to take into account failures and adaptation policies.

Enhancing Semantic Search of Crowdsourcing IT Services using Knowledge Graph

Duankang Fu, Zhou Shufan, Beijun Shen*, Yuting Chen

School of Electronics, Information and Electrical Engineering, Shanghai Jiao Tong University, Shanghai, China
{duankangfu, sfzhou, bjshen, chenyt}@sjtu.edu.cn

Abstract—Mining search intents in vertical websites like IT service crowdsourcing platform relies heavily on domain knowledge. Meanwhile, it still remains a difficulty of searching services in crowdsourcing platforms, as these platforms do contain much insufficient information, for example, users tend to use images describing IT services for the purpose of advertisements. To solve these problems, we build and leverage a knowledge graph to enhance searching of crowdsourcing IT services. The key idea is to (1) build an IT service knowledge graph from StackOverflow tag synonym system, Wikipedia, StuQ and data in IT service crowdsourcing platforms, (2) plug two activities into the basic search process – term expansion and service re-ranking, (3) use superordinates, hypernyms, synonyms, descriptions and relations of entities in the knowledge graph to expand user query and service information, and (4) apply a learning-to-rank model with four features to re-rank the search results, enforcing those more relevant services have the higher-ranking position. We have conducted several experiments to evaluate our approach. The results show that our approach achieves an MRR 34.9% higher and a Recall@15 11% higher than those of a basic search approach.

Keywords – IT Service Crowdsourcing; Knowledge Graph; Semantic Search; Learning-to-rank

I. INTRODUCTION

Recently, crowdsourcing has been widely used in many fields such as image recognition, taxonomy construction and entity resolution [1-2], etc. Those tasks are simple and straightforward, and people can deal with them with common knowledge. However, due to the strong professionalism and specialization, IT crowdsourcing is more complicated [3]. In a typical IT crowdsourcing platform, developers provide various types of IT services, and users search for target services according to their own requirements. The appropriate matching between user query and service information is one of the key values offered by IT crowdsourcing platforms.

Currently, almost all crowdsourcing platforms provide search function following the basic search process as shown in Figure 1. The services data are used to create the reverse index, and the user queries are segmented. And then Elasticsearch performs text matching between the queries and the reverse index. This approach adopts pure text matching technology,

which means users have to describe their requirements precisely, or, it can't identify the latent intents of users. We also find that developers tend to use images to describe their services for the purpose of advertisements in most IT crowdsourcing platforms, and thus there are not enough available textual description for services. All these lead to low performance of semantic search in IT crowdsourcing – it is difficult for users to find their target services.

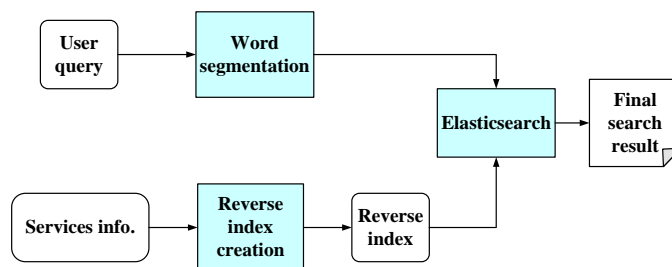

Figure 1. Basic Search Approach for Crowdsourced IT Services

As searching for crowdsourced IT services, how to understand user queries accurately? And how to complete the information of services? To address these challenges, a domain-specific knowledge graph, ITServiceKG, is constructed to enhance user query understanding. ITServiceKG mainly consists of three parts: IT service categories, IT skills and IT service instances. We insert two pluggable activities in the basic search process: term expansion and service re-ranking. After word segmentation, we use superordinates, hypernyms, synonyms, descriptions and relations of entities in ITServiceKG to expand user queries and service information. And then we get the preliminary search results from Elasticsearch, use learning-to-rank model to re-rank these results, and make the more relevant service have the higher-ranking position. We conducted several experiments to evaluate our approach. The results show that compared with the basic approach, the MRR (mean reciprocal rank) is increased by 34.871% and the Recall@15 is increased by 10.976% in our approach.

Our main contributions are summarized as follows:

1) We construct a knowledge graph of IT crowdsourcing services, which represents a complex network among IT service categories, IT skills and IT service instances.

2) We utilize ITServiceKG to expand both user queries and service information, which helps alleviate the problem that the

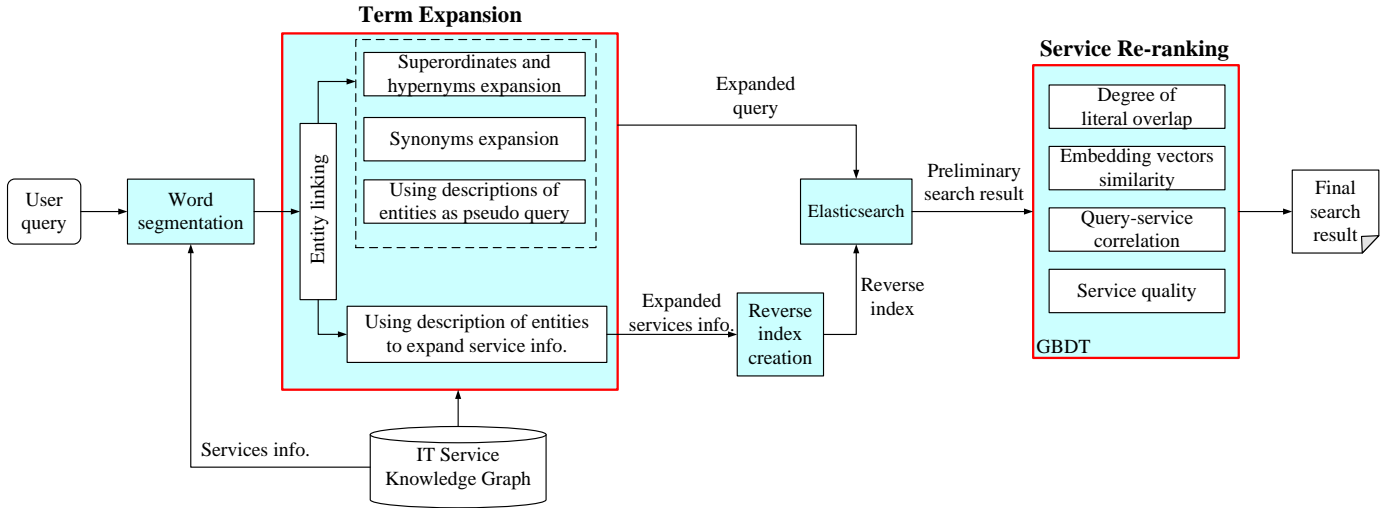

Figure 2. Overview of Our Approach

user queries are not precise and the services lack enough textual descriptions.

3) We propose a learning-to-rank model to obtain the more appropriate results. Four ranking features are designed to boost the ranking position of the more relevant services.

The rest of the paper is organized as follows. In the next section, we review some related works. The details of our approach are presented in Section III. We conduct a series of experiments to evaluate the effectiveness of our approach in Section IV. Finally, we conclude our work in Section V.

II. RELATED WORK

A. Semantic Search

Semantic search is a broad field, with many different aspects, ranging from query understanding, to answer retrieval, and result representation. In this paper, we focus on query understanding and answer retrieval. In previous research, people use query word expansion and retrieval model to obtain relevant results. They use synonyms as word expansion, extract word stems and obtain their different tenses [4], or use acronyms [5] and relevant words [6] to expand queries. The state-of-art retrieval model is learning-to-rank model applying machine learning methods, like LambdaRank, DSSM, CDSSM, etc. [7].

B. Knowledge Graph and its Application

There exists a wide range of general-purpose encyclopedic knowledge graphs, like WikiData, Freebase, DBPedia, and some domain-specific knowledge bases, such as WordNet, ConceptNet, etc. general-purpose knowledge graphs are not suitable for domain search, since these knowledge graphs are too general and could introduce redundant or unnecessary information, which leads to irrelevant search results. Some researchers construct an in-domain knowledge graph by extract related entities from a general domain knowledge graph [8]. However, this only extract a subset of a general knowledge graph, not optimized for in-domain specific purposes.

Knowledge graphs have been utilized in text information retrieval and made certain achievements [9]. Alexander Kotov, ChengXiang Zhai [10] used path finding and random walk to find related entities in ConceptNet as an expansion for queries. It mainly utilized the graph construction but neglected the text resources of entities. Jeffrey Dalton, Laura Dietz [11] proposed an Entity Query Feature Expansion (EQFE) model to make some improvement to the pseudo-relevance feedback model. Chenyan Xiong [12] proposed an EsdRank model, which treats extracted external words, terms and entities as objects in a latent space of queries and documents. Xiangling Zhang, et al. [13] proposed a concept called common semantic feature, to address the problem of entity set expansion by using KGs. Chenyan Xiong [14] proposed a word-entity duet representation model via combing traditional retrieval model and knowledge graph embedding, to describe the common features shared by the seed entities. Wen Zhang, et al. [15] proposed a new knowledge graph embedding method to learn distributed representations for entities and relations, which explicitly simulates crossover interactions. However, seldom researchers focus on the scenarios where documents lack enough text resources and the domain knowledge is not fully exploited.

III. OUR APPROACH

A. Approach Overview

To address the challenges of semantic search in IT service crowdsourcing, we propose a knowledge graph-based approach as shown in Figure 2. Our approach leverages an IT service knowledge graph (ITServiceKG) to enhance query and service understanding, and then seamlessly plugs two additional activities in the basic search process to provide precise IT service search: term expansion and service re-ranking.

- 1) *Term expansion*: After word segmentation, we apply entity linking to locate the entities of ITServiceKG in both queries and service information. Then we expand those using superordinates, hypernyms, synonyms, descriptions and relations of these entities in ITServiceKG. Thus our

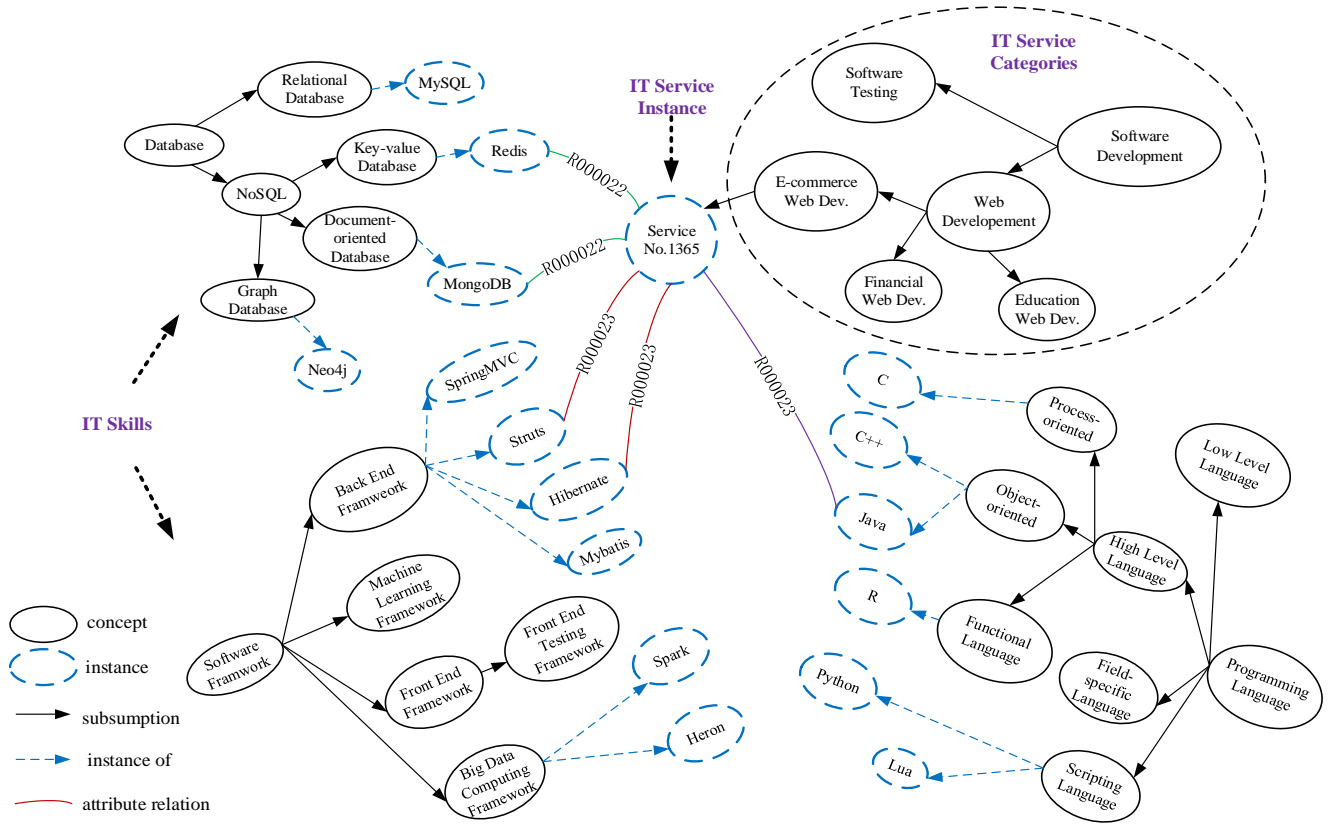

Figure 3. One fragment of IT Service Knowledge Graph

approach boosts query understanding, and alleviates the problem that service information lacks enough text resources.

- 2) *Service re-ranking*: After the preliminary search results are returned by the Elasticsearch engine, a learning-to-rank model is applied to re-rank the results and obtain the top-N IT services. Our approach designs several novel features, including degree of literal overlap, embedding vector similarity, query-service correlation, and service quality. Thus, it makes the more relevant service have the higher-ranking position.

Next explains the details of IT service knowledge base, term expansion and service re-ranking.

B. Building IT Service Knowledge Graph

A domain knowledge graph in IT crowdsourcing should include the information of IT services and the knowledge in IT service implementation. Therefore, we design ITServiceKG from three aspects: IT service categories, IT skills and IT service instances. In ITServiceKG, each entity (i.e. concept or instance) has following attributes: name, synonym, cooccurrence, and

description; and relations between entities includes subsumption, instance-of, and attribute relations. One fragment of ITServiceKG is shown in Figure 3.

1) *IT service categories*: IT service categories record the hierarchical structure of service categories. These data are provided by the real-world IT crowdsourcing platform—*JointForce*¹. It holds a three-layer structure. The first layer contains various types of software services, including those for software development, software testing, architecture design, DevOps deployment, logo design, etc. The second layer collects sub-types of specific IT services. Let "software development" be an example. Its child services include software services such as "web development", "App development", "embed system development", and so on. And the third layer places domain-oriented IT services.

2) *IT skills*: IT skills contain the technologies that IT services adopt, such as programming languages, frameworks and database. Every skill holds a multi-layer structure. Take "Database" as an example, it can be divided into "Relational Database" and "NoSQL Database", and MySQL is an instance of "Relational Database". IT skills data are collected mainly from StackOverflow tag synonym system², Wikipedia³ and StuQ skill map⁴. And the cooccurrence data is processed from search logs.

3) *IT service instances*: IT service instances are to-be-crowdsourced IT services in the platform. They are connected to IT service categories and IT skills. Taking an example in Figure

¹<https://www.jointforce.com>

²<http://stackoverflow.com/tags/synonyms>

³<https://www.wikipedia.org>

⁴<https://github.com/TeamStuQ/skill-map>

3, Service No.1365 is an instance of e-commerce website development, with Redis and MangoDB as databases, Java as programming language, and Struts and Hibernate as frameworks.

C. Term Expansion

Term expansion is a common technique in information retrieval (IR), but we reach two conclusions that implies space for improvement: a) in previous research, the query expansion resources are from synonyms and cooccurrence words. The relations of superordinates and hyponyms are neglected; b) most researchers only pay attention to the query expansion but neglect the document expansion. In IT service crowdsourcing platforms, there are not enough textual description for services, which impedes the performance of semantic search. Therefore, the expansion of both user queries and service information is indispensable, and we leverage ITServiceKG to expand them along the following four channels.

1) *Synonym and cooccurrence expansion.* The entities in the ITServiceKG have attributes "synonym" and "cooccurrence", and we use synonym and cooccurrence terms of the linked entity to expand the queries.

2) *Superordinates and hyponyms expansion.* The IT service categories in ITServiceKG have a hierarchical structure. For example, in Fig. 3, the entity "Software Framework" has a hyponym "Back End Framework", the latter has a hyponym "Hibernate", and "Hibernate" as a relation with Service No.1365. We expand both for queries and services information with superordinates and hyponyms of the linked entity in ITServiceKG. For example, if a user wants to search for IT services with back-end frameworks, but does not know any concrete name of it, we can expand this query by adding the hyponyms of back-end framework: "Struts", "Hibernate", etc. For another example, Service No.1365 has a relation with entity "Struts", we can expand the information of Service No.1365 by adding the superordinate of "Struts" - "Back End Framework".

3) *Using the descriptions of entities as pseudo query.* ITServiceKG contains rich textual descriptions about entities. Given an entity e , we use its name and description as pseudo query. This makes sense because the query is usually short and concise, only including two or three keywords usually. So we use the descriptions of entities as the pseudo query, without worrying that the expanded query is too long or introduces too many irrelevant information.

4) *Using the description of entities to expand service information.* It makes sense that the extra information of entities in ITServiceKG can help us understand the meaning of the service information. It is like a process of looking up words in the dictionary. When we read an article and find a new word, we may look up the word in the dictionary. The meaning of the new word will help us understand the article. The domain knowledge graph behaves in the similar way. The description of entities can be helpful for users who do not have the background knowledge about the entities.

D. Service Re-Ranking

After the term expansion, the expanded query and service information are obtained. We build the reverse index in the

Elastic search engine, and get the preliminary results. Then, we apply machine learning techniques to re-rank the list of the search results and make the more relevant result have the higher-ranking position. This rank model can be viewed as a supervised learning problem. The input is the query and all to-be-crowdsourced IT services, the output is the top-N IT services, each of which has a relevant score of 0-1.

We adopt Gradient Decision Tree (GBDT) as our learning-to-rank model. It is a point wise ranking model. We design four features for this rank model, shown as below:

1) *The degree of literal overlap.* If the query and the service's name and description have more common characters, they are more relevant.

$$d = \frac{S_q \cap S_t}{|S_q \cup S_t|},$$

where S_q denotes the character set of a query and S_t denotes the character set of a service name.

2) *Embedding vector similarity.* We embed the query and the service's name and description into vectors by TD-IDF. The cosine similarity of the vectors between the query and the service indicates the relevance.

$$sim = \cos(v_q, v_t),$$

where v_q denotes the query vector and v_t denotes the vector of the service.

3) *Query-service correlation.* In IT service crowdsourcing platform, we record user service clicking events on search results as $\langle \text{query}, \text{service}, \text{timestamp} \rangle$ triples in the log. More clicking times indicates higher relevance.

4) *Service quality.* User quality evaluation on crowdsourced services are also recorded in IT service crowdsourcing platform. People tend to search for services with good quality, so it makes sense that we give them higher relevance score.

$$quality = w_p \cdot p + w_s \cdot s + w_t \cdot t,$$

where t denotes the score of service on-time delivery, and s denotes the product quality score, t denotes the technical support score, and w is the corresponding weight.

We transfer the query-service pair to feature vectors and use them as the input of the GBDT model. Then a point wise ranking model is learned through model training on historical data, and re-ranks the current search results.

IV. EXPERIMENTS

We implemented our semantic search approach, and conducted evaluations to explore the following research questions:

(RQ1): What is the effectiveness of our approach compared with the baseline?

(RQ2): How much does each expansion channel contribute to IT service search?

TABLE I. THE OVERALL PERFORMANCE COMPARISON

Methods	P@10(%)	Δ	R@10(%)	Δ	P@15(%)	Δ	R@15(%)	Δ	MRR	Δ
TF-IDF	13.096	—	49.563	—	9.856	—	56.396	—	0.542	—
BM25	13.107	+0.084	51.872	+4.659	9.905	+0.497	57.197	+1.420	0.553	+2.030
term expansion	13.053	-0.328	52.369	+5.661	9.996	+1.420	61.263	+8.630	0.695	+28.229
term expansion + service re-ranking	13.298	+1.542	52.965	+6.864	10.236	+3.856	62.586	+10.976	0.731	+34.871

(RQ3): How much does each feature contribute to IT service re-ranking?

A. Experiment Setup

1) *Dataset*. Experimental data is offered by JointForce, the biggest IT crowdsourcing platform in China. There are 8753 services and 18025 search records. Each record in search logs contains a query (q), top k service list returned by search engine ($Sq@k$), and service list clicked by user (Iq). We split the dataset into training (80%) and testing (20%).

2) *Evaluation Metrics*. We use precision (P@ k), recall (R@ k) and MRR (Mean Reciprocal Rank) to measure the performance of our approach. For query sets Q , these metrics are defined as follows:

Precision (P@ k): It is the percentage of correctly discovered services in all discovered k services.

$$P@k = \frac{1}{|Q|} \sum_{q \in Q} \frac{|Sq@k \cap Iq|}{|Sq@k|}$$

Recall (R@ k): It is the percentage of correctly discovered services in all correct services.

$$R@k = \frac{1}{|Q|} \sum_{q \in Q} \frac{|Sq@k \cap Iq|}{|Iq|}$$

MRR: The reciprocal rank of a query response is the multiplicative inverse of the rank of the first correct answer: 1 for first place, 1/2 for second place, 1/3 for third place and so on. The MRR is the average of the reciprocal ranks of results for a sample of the query sets Q :

$$MRR = \frac{1}{|Q|} \sum_{q \in Q} \frac{1}{rank_q},$$

where $rank_q$ refers to the rank position of the first relevant service for the query q .

B. RQ1. Overall Performance

Basic search approaches with BM25 and TD-IDF are selected for overall performance comparison. The experimental result is shown in the Table I. We can observe that the performance of BM25 is better than TD-IDF, therefore, we choose BM25 as the reference in the subsequent experiments. Moreover, we can observe that when applying term expansion, the recall is enhanced more prominently than the precision. It makes sense because the term expansion introduces more useful relevant terms and can find more correct services which cannot be retrieved before. After further applying ranking model, the precision is enhanced, because we make the more relevant services have higher ranking position. The performance of @15

is better than @10, which means @15 is a balanced metric for both precision and recall.

The experiment demonstrates that our approach (i.e. basic search with BM25 + term expansion + service re-ranking) outperforms the baselines. The precision is improved by 3.856%, the recall is improved by 9.912%, and the MRR is improved by 34.871%. This is because we introduce extra domain knowledge and retrieve some results that are neglected in the baseline approaches.

C. RQ2. Expansion Channel Contribution Analysis

During term expansion, our approach adopts four expansion channels: synonym and cooccurrence expansion (SCQ), superordinates and hyponyms expansion (SHQ), descriptions of entities as pseudo query (DQ), and descriptions of entities to expand service information (DS). In this experiment, we perform an analysis to evaluate each channel's contribution to the performance of IT service search.

We choose basic search approach with BM25 as the baseline, and add each expansion channel one by one. Recall@15 is chosen as the evaluation metric, because term expansion mainly enhances the recall.

Figure 4. Expansion Channel Contribution Analysis

The impact of each expansion channel on the overall performance in this experiment is shown in Figure 4. We can observe that the performance is improved greatly when introducing "Superordinates and hyponyms expansion" and "Using description of entities to expand service information". We take following two examples to illustrate why superordinates and hyponyms can improve the performance.

The first query example is "ERP web service that uses Struts and Hibernate". Before term expansion, we find some related services, all of them relying on exact match. But Struts is not as popular as Spring now, so the services using Struts are rare. When we introduce the superordinates of entity "Struts"-

"Back End Framework" and add it to the query, we can find some services with back-end framework, such as using SpringMVC and Mybatis.

The second query example is "student management system that uses NoSQL". Before applying term expansion, we cannot find services with keyword "NoSQL", because "NoSQL" does not appear in the name or description of any service, since more detailed words are used to describe their techniques, such as "Redis", "MongoDB" rather than the general word "NoSQL". Therefore, we introduce the hyponyms of the entity "NoSQL", and then we can find services use Neo4j and MongoDB, which are both NoSQL databases.

We can also observe that when we use the description of entities to expand service information, the performance is improved greatly. The reason is that there are not enough available textual descriptions for services, and after we use description of entities to expand them, this problem is alleviated, and thus the performance becomes better.

D. RQ3. Ranking Feature Contribution Analysis

Our approach adopts four features for the learning-to-ranking model: degree of literal overlap (DLV), embedding vectors similarity (EVS), query-service correlation (QSC) and service quality (SQ). In this experiment, we perform an analysis to evaluate each feature's contribution to the performance of ranking model.

The baseline is the basic approach with term expansion. The metric is Recall@15. We add the features one by one and the impact of each feature on the performance is shown in Figure 5.

Figure 5. Ranking Feature Contribution Analysis

From Figure 5 we can see that all the features take effect. The embedding vectors similarity and the query-service correlation contribute most in the four features. The embedding vectors similarity mainly represents the similarity between the queries and the name of services. This implies the name of service plays an important role in the model. The query-service correlation implies how correlated a query and a service is in the history of previous crowdsourcing, so it can give advice to the search in the present.

V. CONCLUSION AND FUTURE WORK

In this paper, we propose a knowledge graph approach to enhancing semantic search for crowdsourced IT services. Compared with the traditional search approach, the MRR of our approach increases 34.871% and the Recall@15 increases

10.976%. The key to success comes from two aspects: (1) an IT service knowledge graph is built and utilized to expand both user queries and service information; (2) a learning-to-rank model with four features is designed to re-rank the preliminary search results.

As for future work, we will employ neural networks and learn latent representations of words, entities, and their relations in the knowledge base. These latent representations can be learnt in an unsupervised manner to be subsequently leveraged in a ranking model.

ACKNOWLEDGMENT

Abstract—Maintaining large complex software is one of the major challenges faced by today's software industry. Refactoring is one way to do so. It is the process of changing internal structure of project code or software design without altering functionality. It improves software quality and reduces software entropy. This paper presents the preliminary results of an explanatory survey targeted at investigating refactoring practices by IT professionals. 221 participants helped to reveal important facts about refactoring risks, benefits, limitations of tools, and how a team manages consistency between different artefacts while practising refactoring. Findings reveal that refactoring tools are under-used as they have availability, usability and trust issues. An automated system is the need of the hour to manage change consistencies, visualizing code structures, detecting code, and design smells, and performing refactorings. This study will enable researchers and developers to understand their role in a better way as prevailing issues with current state-of-art are exposed and challenges are reported.

Keywords: *Refactoring; code smells; refactoring tools; survey; empirical study.*

I. INTRODUCTION

Code smells are design flaws, though are free of syntax errors, but can lead to future bugs and errors [1]. They are a violation of basic design principles and are also known as anti-patterns [2]. They contribute to financial debts and make software complex, hard to understand and maintain, and make changes difficult to embed. Thus, detection of such designs flaws and their correction is an absolute necessity [3]. Refactoring is one of the techniques to remove these anomalies. Refactoring is a well-organized practice for the reorganization of the present body of code, changing its internal structure without changing its external conduct. It is a sequence of little functionality preserving transformations. It is done while adding a feature, fixing a bug, and during code review [4].

Refactoring is mainly done to improve the internal structure and readability of the software. It increases flexibility, maintainability and reduces inter-modular couplings [5, 18]. It

can be done by a specialist or stakeholders like software designer, developer, tester or maintenance team. It can be done either manually or with the help of a tool. The scope can be system-wide or small scale, depending on the aim of applying refactorings. Refactoring is a time-consuming process that does not reflect immediate benefits like new features or bug fixes [6]. Incomplete and incorrect refactorings can lead to bugs [7] and it has been found that a high proportion of refactorings often led to an increase in the number of errors [8, 17].

The refactoring process [9] consists of following activities: (1) identify code smells; (2) determine which refactorings are best suitable for application; (3) make sure that applied refactoring preserves behaviour; (4) apply refactorings; (5) calculate the impact of refactorings on software quality features; (6) maintain uniformity between refactored program code and other software relics (test data, documents etc.).

Murphy-Hill [10] mentioned four different ways to collect research data for refactoring. They are:

- Mining the Commit Log – Look for mention of the word “refactor” in the commit logs of versioned repositories. Commit logs are updated when a programmer commits a change to the repository.
- Analyse Code Histories - Analyze an order of versions of the source code by manual comparison or by automating the comparison using a software tool.
- Observing Programmers - Observe developers in the field, working on software development and illustrate their refactoring behaviour. Such observation can be direct observation which comes under the category of a controlled experiment. Another is indirect observation which can be a survey or a project post-mortem.
- Logging Refactoring Tools - Some programming environments automatically record the programmer's activity in a log file. Such an environment is specialized to collect refactoring tool events.

DOI reference number: 10.18293/SEKE2019-038

In this study, the third method i.e. indirect observation has been implemented and data has been collected through a survey.

In this study, the following research questions have been addressed:

RQ1: How do programmers ensure that code has been refactored correctly and what are the measures taken to manage consistency between software artefacts?

RQ2: What are the reasons that prompt the refactoring process?

RQ3: What are the common refactoring practices followed by developers?

RQ4: Which are the most desirable features and barriers in the adoption of refactoring tools?

RQ5: What are the risks and benefits associated with refactoring?

To find answers to these burning questions, a survey was conducted and 221 software engineers participated in the study. Responses were collected online and analyzed quantitatively. The results were presented pictorially through graphs.

This study will make the following contributions:

- Study will assist researchers to identify research areas in the field of refactoring and to focus on issues to be solved in refactoring process. It will support the developers to develop the tools keeping in mind the shortcoming of the available tools. And will help IT professionals to understand the importance of refactoring and make it a part of their development process in various projects.
- Learning limitations of refactoring tools will guide researchers to focus on grey areas and what are prominent research areas, for example validation and verification of applied refactorings, maintaining change consistency in between artefacts, and development of better algorithms for detection of code smells etc. Developers can build easy to understand tools with better GUI and work on availability issues as well by creating awareness among development community.

II. RELATED WORK

G. H. Pinto and F. Kamei [11] did a qualitative and quantitative study to find out answers to following research questions: Which are the most desirable features in refactoring tools? What are the factors that prevent developers to adopt refactoring tools? Does interest in refactoring tools increase over the years? To uncover the number of issues regarding these tools, more than 1,400 messages – 324 questions and 1,115 answers to those questions were analyzed from more than 1,200 users. Major findings of this study are: refactorings tools are in demand for dynamic languages, databases and multi-language

refactorings. Users reported that a lack of trust and usability problems in tools still prevails. Interest in refactoring tools over the years has not increased as expected.

M. Kim, T. Zimmermann and N. Nagappan [12] conducted a survey at Microsoft, followed by a semi-structured interview and quantitative analysis of version history data of Windows 7 to reveal refactoring benefits and challenges. Survey finds that the refactoring definition in practice is not restricted to a standard definition of behaviour-preserving code alterations and developers observed that refactoring involves considerable cost and risks. The quantitative analysis of Windows 7 version history finds refactoring top 5% of modules led to a reduction in modular couplings and many complexity measures but increases the size more than the bottom 95%.

N. Singh and P. Singh [16] performed a comprehensive sentiments analysis on 3,171 GitHub comments during refactoring 60 open Java source projects by mining relevant commit messages. Research Question – “Does a refactoring task allocated during the implementation of a software feature following a strict deadline invoke positive or negative sentiments in the developer?” was answered. Tool RefTypeExtractor for automatically linking commit messages to their respective refactoring techniques was developed and dataset SentiRef, which stores the identified developer’s sentiments linked to each of 3,171 commit messages was created. The research concluded that in general software developers express more negative sentiments than positive sentiments while performing refactoring tasks which reveals the substandard state of the refactoring process.

Arcoverde, Roberta, Alessandro Garcia, and Eduardo Figueiredo [13] presented the results of a survey with the purpose of understanding the longevity of code smells in software projects. They concluded that (i) there is a probability of breaking APIs before refactorings by developers of widely-scoped reusable code; (ii) developers of standalone applications consider contract breaking changes easier to apply than developers of reusable assets; (iii) refactoring tools are more frequently used by developers that apply Test-Driven Development; (iv) refactoring tools are commonly used, and (v) reusable assets and standalone applications have different refactoring prioritization.

Our study intends to foster such previous investigations by revealing current challenges faced by developers and how they maintain consistency between different artefacts. We designed a questionnaire in order to understand the gap that subsists between the interpretation of refactoring practices by developers and researchers. The questionnaire was made available as an online survey and 221 software engineers filled it.

III. SURVEY SETTINGS

In order to understand the refactoring practices, a questionnaire was created and sent to 10 experts (well learned software engineers in the IT industry with more than 12 years

of experience in companies like Amazon, Adobe, Flipkart, TCS, Walmart etc.) and based on their feedback, the questionnaire was refined regarding the clarity and objectivity of the questions. It consisted of 14 multiple choice questions and 6 free-form questions. Few multiple choice questions had an option where participants could write answers of their choice as well. A glossary was included at the beginning explaining terms and acronyms used, for disambiguation. To collect information online survey was conducted and 221 engineers participated. Participants belonged to different companies and various designations. Majorly, they were developers (i.e. 90.5%) including requirement engineers, software designers, testers, researchers, full stack developers, and software architects etc. having a maximum of 20 years of experience, minimum of a year and an average of 3.2 years. The survey was divided into four sections and is described in Table 1.

The questions were formulated to identify how often and when refactorings are performed, what is the main purpose behind it and how consistency is managed between different artefacts while performing refactorings. Another section was focused on the most popular tools and what are the desirable features and barriers in the adoption of refactoring tools. Further, investigation on benefits, risks, and challenges regarding refactoring is explored. After the collection of responses, data was analyzed and categorized pictorially. Results that were revealed were both interesting and useful in understanding the roles and responsibility of researchers and developers in the field of refactoring. It revealed major challenges that still prevail and scope in the research area.

IV. RESULTS

The survey was made online and 221 IT professionals participated. 90.5% of them were developers from different companies and having experience in various languages like Java, Python, .NET etc. 23.4% of participants performed refactoring daily, 34.9% weekly and 21.1% daily. Software engineers from diverse and virtuous companies like Amazon, HCL, Infosys, Flipkart, Oracle, TCS, Expedia, Snapdeal, IBM, Paytm, ISRO, and ICAR etc. contributed to our findings. Participants had an average experience of 3.2 years with a maximum of 20 years and working in various nations like India, USA, Australia, Germany, and China.

The following section organizes the results in terms of the research questions.

RQ1: How do programmers ensure that code has been refactored correctly and what are the measures taken to manage consistency between software artefacts?

Results show that 78% of participants perform some kind of testing after refactoring code. Most of them prefer simple unit or functional testing but some of them prefer regression, integration, smoke, sanity or boundary value testing. Few of them make their peers to do code review. To maintain consistency, teams use version control platforms like Git, communicate to the team through a pre-defined channel or by

adding comments, maintain an excel file of changes. Test code and documents are changed manually after refactorings. Some of the remarks are as follows:

- *“Version control helps to keep a track of changes made, which once are completed successfully are documented.”*
- *“Rewrite/Update Unit Test, Update Documentation, Add relevant comments”*
- *“Code and test cases must go hand in hand. To ensure this I follow test based approach with unit test cases written before the code has to be refactored.”*
- *“We use XML notation for commenting code which reduces the need for separate documentation to a very large extent, code coverage tools for maintaining test cases.”*

Some of the good practices followed by engineers after performing refactorings are doing code reviews, compiling the code, running test cases, running bug detectors and modifying test cases according to the refactored code.

RQ2: What are the reasons that prompt the refactoring process?

Refactoring software is only beneficial when it is done with a purpose like reducing coupling between modules. Results revealed some of the reasons that prompt software engineers. 79% and 83% of professionals refactor when code gets hard to understand and maintain respectively. 50% agreed that slow performance and wide dependencies between modules are the main reason behind their refactoring actions. Logical mismatch, difficulty in debugging and testing, readability, re-usability and duplicity were also the main causes to initiate refactoring as depicted in Fig 1.

Figure 1. Reasons that prompt team to refactor code

Majority of the participants agreed that refactoring increases program flexibility, improves readability, reduces coupling, improves the internal structure of the code and makes it easier to add new features. Apart from these, honourable mentions were to reduce bugs, to increase consistency of an application, to reduce compiling time, to optimize and improve software performance, to enhance scalability and robustness of applications.

TABLE I. Summary of Survey Questions

Background	Which best describes your primary work area (developer, tester, manager etc.)? (open answer)
	How many years of work experience do you have in the software industry? (open answer)
	Name of Current Company and Country (open answer)
Refactoring Practices	How often do you perform refactoring (Daily, Weekly, Monthly, Yearly, Seldom, Never)? (multiple choice)
	Which keywords do you use or have you seen being used to mark refactoring activities in change commit messages? (multiple choice)
	How do you ensure that you have refactored program correctly? (open answer)
	How do you manage consistency between different software artefacts (e.g. documents, code and test cases) during refactoring? (open answer)
	What is the purpose of your refactorings? (multiple choice with the open answer)
	Which of these reasons prompts you to initiate the refactoring process? (multiple choice with the open answer)
	Select following options for refactorings [multiple choice: (a) manually and with a tool (b) manually, (c) using automated tools, (d) know this but don't use it, (e) don't know this refactoring.]
	• Rename, Extract Method, Encapsulate Field, Extract Interface, Remove Parameters, ... [From Fowler's catalogue]
	How do you strongly agree, agree, neither agree or disagree, disagree, strongly disagree with each of the following statements?
	• I perform refactorings with other functional changes. • Refactorings I want to perform are different from what supported by tools. • Tools do not support higher level refactorings. • How do you validate code refactorings?
Refactoring Tools	Few statements are shown in this table for presentation purposes.
	What tools do you use during refactoring? (open answer)
	How do you perform most of your refactorings? (multiple choice with the open answer)
	What are the barriers to adoption of refactoring tools? (multiple choice with the open answer)
Risks and Benefits	What are the features in refactoring tools you would like to have? (multiple choice with the open answer)
	How do you strongly agree, agree, neither agree or disagree, disagree, strongly disagree with each of the following statements?
	• Refactorings advance code readability • Refactorings introduce subtle errors • Refactorings disrupt other programmer's code • Refactorings advance performance • Refactorings make it debugging easy.
	What are the challenges associated with performing refactorings? (open answer)
	Based on your own experience, what are the risks involved in refactoring? (multiple choice with the open answer)
	What benefits have you observed from refactoring? (multiple choice with the open answer)
	Only some of the questions are mentioned for representation purpose.

RQ3: What are the common refactoring practices followed by developers?

Great proportion strongly agreed on the following practices:

- Refactorings are carried out in batches and changes in associated test cases and documents are reflected.
- Refactorings are done with other types of changes which modifies program behaviour externally. Pure refactorings are hardly done. This observation is consistent with R. Johnson's study [14].
- Refactorings that are done manually differ from what tools offer.
- Refactorings that are applied are higher level changes which are not supported by tools. This informs about the need for tools for higher level refactorings, for example dealing with generalization refactorings.
- Majority of the refactorings (60.6%) are done manually. This practice proves the urgent need for good quality, available and easy to use tools.
- Renaming, Extract Method and Remove Parameters are the most common refactorings performed manually or with the help of a tool. The same observation was made by M. Kim [15].

RQ4: Which are the most desirable features and barriers in the adoption of refactoring tools?

Participants listed a wide variety of tools that are used to perform common refactorings. Most commonly used tools are Jenkins, ReSharper, CodeRush, JS Refactor, Visual Assist X, TSLint, DPack, JetBrains etc. Refactorings like renaming and move method are simply done in IDEs like Eclipse, IntelliJ, Visual Studio etc.

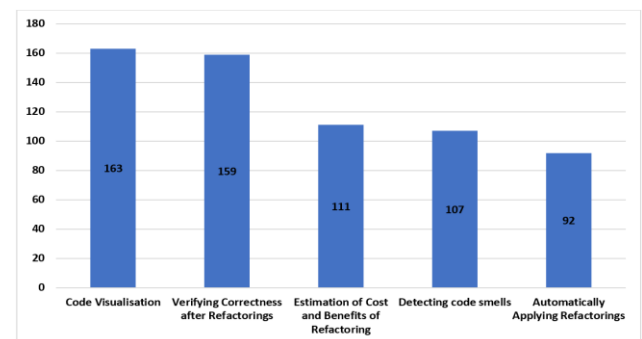

Figure 2. Most desirable features of refactoring tools

Most desirable features, developers want in refactoring tools are code smell detection feature, 74% want code visualization applicability. 72% of professionals would like to verify correctness feature after they are done performing refactorings, estimation of cost and benefits of refactoring are another requirement that participants mentioned. Automatically applying refactorings was only suggested by 42%. Fig 2 represents data in graphical form.

65% stated barriers that cease developers in adopting tools are less or no knowledge about the availability of tools. Around 29% participants mentioned difficult to understand/learn tools and unknown or not able to understand the debugging process is their reason that prevents them to use refactoring tools. Tools are not trustworthy and have bad GUI. Fig 3 represents same. Other mentions were:

- *“Company support”*
- *“Languages like Python and CSS have limited support for refactoring tools.”*
- *“They sometimes don't understand that “why I do, what I do” such as if I declare something in multiple lines, I mean it to be so, but formatting online size makes it hard to understand.”*

Figure 3. Barriers in the adoption of refactoring tools

RQ5: What are the risks and benefits associated with refactoring?

Refactoring risks are quantitatively presented through the graph in Fig 4. Key causes are identifying code smells. It is one of the major research areas in the field of refactoring. Many automatic, semi-automatic, and metric-based code smell detection techniques have and are being developed. Managing consistency between artefacts is a long and regressive process. Managing time is challenging as developers avoid refactoring code before major releases. Refactorings might introduce bugs or break existing code. Preserving behaviour, understanding legacy code, and convincing management team are considerable challenges.

Refactoring though is time-consuming procedure but it definitely yields promising benefits such as improved maintainability and readability which was further supported by more than 80% of the participants in this empirical study. More than 60% acknowledged improved performance, reduction in code size as well as duplicate code are perks of

refactoring code. Other advantages are the reduction in release time and bugs, software becomes easy to test and add the new features. Fig 5 represents the benefits of refactoring pictorially through a bar graph.

Figure 4. Risks involved in the refactoring process

Figure 5. Benefits of performing refactorings

V. THREATS TO VALIDITY

Some points to be considered are:

Participants of survey conducted were IT professionals not refactoring specialists and with the assumption that people who filled the survey know what “Refactor” means. Survey made no inquiry about the type of projects (e.g. Web applications, Embedded systems, Information systems, etc.) participants had experience in. A number of participants were low to generalize the results and few of them had the experience below 5 years. Most of the questions were closed-ended which might lead to biasing.

VI. CONCLUSIONS AND FUTURE WORK

Large scale survey was conducted and a wide range of IT professionals was engaged. The main purpose of the survey was to understand the trends followed by developers and what are the research opportunities in the field of refactorings and developmental challenges. The study also answers the questions like what sort of tools should be built to better or automate the whole process and limitations of currently available tools. Survey responses were collected and analyzed to conclude the following results:

The refactoring process needs automated tools to maintain changes between different artefacts of software.

Some companies use version control systems but a system that updates the design, test cases, documentation automatically after refactoring is in demand. Software companies can invest their efforts in this sector.

Refactoring without purpose will not yield any benefits. Some of the factors that prompt refactorings are - hard to understand and maintain program code, wide inter-modular dependencies, difficulty in debugging and testing, readability issues etc. Software development teams should devote their time in refactoring process to overcome such issues.

Refactoring increases program flexibility, reduces coupling, improves the internal structure of the code and makes it easier to add new features. These points were supported by the majority of participants. Benefits associated with the refactoring process are improved maintainability, performance, modularity and readability, reduction in code size, duplicate code, release time and bugs, and easy to test. They are the motivations for teams to invest more time and effort in the refactoring process.

Common practices in refactoring are that they are carried out in batches, done with other types of changes that modify external program behaviour. Majority of the refactorings (60.6%) are done manually. Renaming, Extract Method, and Remove Parameters are the most common refactoring performed manually or with the help of a tool.

The reason that prevents software engineers to adopt refactoring tools is - less or no knowledge about the availability of tools, difficult to understand/learn, unknown or not able to understand debugging process, trust issues, and bad GUI. So, developers and researchers should investigate the reasons behind such an inappropriate condition of refactoring tools and try diminishing them. Tools for many dynamic languages are still unavailable. Code structure visualization, code smell detection, cost and effort estimation tools are coveted. Tools to validate and verify refactorings need to be developed.

Most desirable features, developers want in refactoring tools are automatic code smell detection, code visualization aspect, verifying correctness after refactoring edits, estimation of cost, efforts and benefits of refactoring, automatically applying refactorings. This provides research areas that should be explored by researchers and developers working in the field of refactoring.

Refactoring challenges faced by professionals are identifying code smells, managing consistency between artefacts, time management, excessive couplings between modules, refactorings might introduce bugs or break existing code, behaviour preservation, understanding legacy code, and convincing management team. Researchers can work in these domains to ease up the refactoring process. Companies and teams should realize the importance of refactoring code

and refactoring activities needs to be further encouraged to reduce maintenance time, money, and effort.

For future work, personal interview with professionals can be conducted on a large scale and further conclusions can be made by observing refactorings patterns and behaviour of IT teams in the field.

Abstract—Just-in-time software defect prediction (JIT-SDP) is an active topic in the field of software engineering, and many methods have been proposed to solve this problem. State-of-the-art method MULTI applies multi-objective optimization algorithm to the effort-aware JIT-SDP problem, and obtains good average performance. Although the average performance of the MULTI method is high, there are many optimal solutions with poor performance. If an optimal solution is randomly selected, a poor prediction model may be obtained. In order to further improve the performance of the MULTI method, we propose three optimal solutions selection strategies: benefit priority (BP), cost priority (CP), and a compromise between cost and benefit (CCB). In order to compare and validate the effectiveness of the strategies, we conduct a large-scale empirical study on data sets of six open source projects. The experimental results show that, compared with the average performance of MULTI, the optimal solutions selection strategy based on BP has a significant improvement in ACC and P_{opt} indicators. Therefore, we recommend using the BP-based optimal solutions selection strategy to improve the performance of MULTI when using the MULTI method to solve the effort-aware JIT-SDP problem.

Index Terms—software defect prediction, empirical software engineering, multi-objective optimization algorithm, just-in-time, effort-aware

I. INTRODUCTION

Software defect prediction [1] [2] is an active research topic in the domain of software engineering. As software scales increase, it becomes very difficult to release a high-quality software system. In the case of limited software testing resources, it is critical for the enterprise to find and fix defects in the software as early as possible.

Software defect prediction is an effective method. By using defect prediction models, developers can accurately estimate whether a program module is likely to have defects, thereby allocating more test resources to modules that are more likely to have defects, which help to improve the quality of the software [3].

Traditional software defect predictions have shortcomings in practical applications [4]. First, because the prediction

granularity is coarse (i.e., class, file, or package), it is time consuming to locate risky code regions. Second, a module is usually completed by many developers, so it is difficult to find the suitable developer to code checking for the defect-prone module. Finally, because the defect prediction is made in the later stages of software development, it is difficult for developers to come up with thoughts for software development.

Just-in-time software defect prediction (JIT-SDP) can well overcome the above deficiencies. JIT-SDP is made at change-level rather than module-level. Once the developer submits the modified code, the defect prediction will be executed. Developers can quickly know whether the change is defect-inducing or not.

Nowadays, many supervised and unsupervised methods have been proposed to solve the JIT-SDP problem. Yang et al. [5] compared the performance of supervised learning methods and unsupervised learning methods in the context of effort-aware JIT-SDP through a large-scale empirical study. The experimental results show that some unsupervised learning methods are even better than supervised learning methods, which contradicts people's experience, because supervised learning methods can learn knowledge from data sets and should have better performance than unsupervised learning methods.

Therefore, in order to improve the performance of supervised learning methods, Chen et al. [6] proposed a new method called MULTI, which formalized the effort-aware JIT-SDP problem into a multi-objective optimization problem. The optimal solution set is obtained by using the classical multi-objective optimization algorithm (MOA) NSGA-II. The experimental results show that the average performance of the MULTI method is better than the state-of-the-art supervised learning methods and unsupervised learning methods. However, Chen et al. [6] used the median of the performance of the optimal solution set to represent the average performance of the MULTI method. In the actual use of the MULTI method, if an optimal solution is randomly selected, a poor performance prediction model may be obtained. Therefore, in order to improve the stability and performance of the MULTI

Corresponding Authors: Huiqun Yu (yhq@ecust.edu.cn), Guisheng Fan (gsfan@ecust.edu.cn) DOI reference number: 10.18293/SEKE2019-174

method, we design three optimal solutions selection strategies: benefit priority (BP), cost priority (CP), and a compromise between cost and benefit (CCB). Empirical results show that the optimal solutions selection strategy based on BP can significantly improve the performance of MULTI. Therefore, we recommend using the BP strategy to obtain a higher performance prediction model when using the MULTI method to solve the effort-aware JIT-SDP problem.

The contributions of this paper are summarized as follows:

- In view of the shortcomings of the MULTI method, we propose three optimal solutions selection strategies BP, CP, and CCB, aiming to improve the effort-aware prediction performance of the MULTI method.
- Through large-scale empirical research, we compare the performance of three optimal solutions selection strategies and the average performance of MULTI on the data sets of six open source projects. Experimental results demonstrate that BP-based optimal solutions selection strategy can significantly improve the performance of the MULTI method in ACC and P_{opt} indicators.

The rest of this article is as follows. Section II introduces related work of software defect prediction. Section III introduces the principle of MULTI and our proposed optimal solutions selection strategies. Case study is introduced in section IV. Experimental results and discussion are presented in section V. Section VI describes the threats to validity. The conclusion and future work are presented in section VII.

II. RELATED WORK

A. Just-in-time Software Defect Prediction

Mockus and Weiss [7] firstly applied JIT-SDP to 5ESS updates by designing a series of change metrics. Experimental results show that JIT-SDP can be effectively used in many commercial software projects. Kamei et al. [4] conducted a large-scale empirical study of 11 projects, including 6 open source projects and 5 commercial projects, and they shared data sets of 6 open source projects. Empirical results reveal that the model based on logistic regression can achieve 68% accuracy and an average recall rate of 64%.

Subsequently, many methods were proposed to improve the performance of the JIT-SDP models. Yang et al. [8] proposed a novel method called TLEL, which leverages decision tree and ensemble learning. Experimental results indicate that their method can significantly improve the performance of JIT-SDP. McIntosh et al. [3] explored the impact of data validity on the performance of the JIT-SDP models. Empirical results demonstrate that in order to ensure the performance of the prediction models, the defect data sets used should be within the last three months.

B. Effort-aware Defect Prediction

When building a defect prediction model, in addition to considering the precision, recall, accuracy, etc., it is also necessary to consider the effort required to code checking for defect-prone models. Kamei et al. [4] applied effort-aware defect prediction to JIT-SDT. They proposed a new method EALR,

which can identify 35% buggy changes while 20% effort is used. Yang et al. [5] compared unsupervised models with supervised models for effort-aware JIT-SDP. Experimental results show that some unsupervised models outperform state-of-the-art supervised models for effort-aware JIT-SDP. Later, Fu and Menzies [9] repeated the experiment of Yang et al. [5] and proved that although supervised models are better than unsupervised models in project-by-project-based verification, supervised models are not superior to unsupervised models in general.

III. OPTIMAL SOLUTIONS SELECTION STRATEGIES

In order to improve the prediction performance of supervised methods in effort-aware JIT-SDP, Chen et al. [6] proposed a novel method MULTI, which applies multi-objective optimization algorithms (MOAs) to JIT-SDP. Their experimental results show that the average performance of MULTI is significantly better than the 43 state-of-the-art methods including 31 supervised methods and 12 unsupervised methods.

However, we find that the Pareto optimal set derived from MULTI has many optimal solutions with poor performance, which affects the performance of the MULTI method. Therefore, we propose three optimal solutions selection strategies designed to improve the performance of the MULTI method.

A. MULTI

Inspired by search based software engineering (SBSE) [10], Chen et al. [6] first formalized the effort-aware JIT-SDP problem into a multi-objective optimization problem. SBSE aims to solve complex problems with large-scale search space in software engineering by using search technology.

1) *The Design of Objectives*: MULTI uses logistic regression for defect prediction, which is widely used in previous studies [4] [11]. Assuming that a change $c = \langle m_1, m_2, \dots, m_n \rangle$ has n metrics, the prediction process of the logistic regression models can be denoted by the formula 1, where $w = \langle w_0, \dots, w_n \rangle$ is the coefficient vector of the logistic regression model. The output value of $y(c)$ represents the probability that a change c is buggy.

$$y(c) = \frac{1}{1 + e^{-(w_0 + w_1 m_1 + \dots + w_n m_n)}} \quad (1)$$

Since JIT-SDP is a bi-classification problem, we convert the output value of $y(c)$. The rule is as in formula 2. When the y value is greater than 0.5, the change c is classified as buggy, otherwise it is classified as clean.

$$Y(c) = \begin{cases} 1 & \text{if } y(c) > 0.5 \\ 0 & \text{if } y(c) \leq 0.5 \end{cases} \quad (2)$$

For the effort-aware JIT-SDP problem, MULTI mainly considers two optimization objectives based on cost-benefit analysis [6]. The first objective is designed from the perspective of benefit and to identify as many buggy changes as possible. For a set of changes C , the benefit of a model can be calculated by formula 3, which represents the number of buggy changes identified by the model.

$$benefit(C) = \sum_{c_i \in C} Y(c_i) \times buggy(c_i) \quad (3)$$

The return value of the function $buggy(c_i)$ indicates whether the change c_i is defect-inducing. When the change is buggy, the return value is 1 otherwise it returns 0.

The second objective is designed from the cost of the model and is to minimize the effort used for code checking. Once a change is predicted to be buggy by the defect prediction model, the software quality assurance (SQA) team will invest a lot of effort in code checking and test case design. For a set of changes C , the cost value can be calculated by formula 4. Here the function $SQA(c_i)$ represents the effort required to code checking for the change c_i . According to the suggestion of Kamei et al. [4], the value of $SQA(c_i)$ can be set to the lines of code(LOC) modified by the change c_i .

$$cost(C) = \sum_{c_i \in C} Y(c_i) \times SQA(c_i) \quad (4)$$

2) *The Generation of Optimal Solutions:* Obviously, the above two objectives are usually conflicting. If a model wants to identify more buggy changes, it will lead to more effort. Conversely, if the model wants to reduce the effort for code checking, it will miss many buggy changes. MULTI is designed based on NSGA-II [12], which is one of classical MOAs. Before introducing the coding scheme of chromosomes of MULTI, we give some definitions of MOAs.

- **Pareto dominance.** Suppose w_i and w_j are two feasible solutions of the JIT-SDP problem. If and only if $benefit(w_i) > benefit(w_j)$ and $cost(w_i) \leq cost(w_j)$ or $benefit(w_i) \geq benefit(w_j)$ and $cost(w_i) < cost(w_j)$, w_i is Pareto dominance on w_j .
- **Pareto optimal solution.** For a feasible solution w , w is a Pareto optimal solution if and only if there is no feasible solution w^* which is dominance on w . Pareto optimal set is composed by all the Pareto optimal solutions.

The process of MULTI can be summarized into the following four steps.

- 1) **Population initialization.** For the effort-aware JIT-SDP problem, a chromosome can be encoded as a coefficient vector, denoting the coefficients of a logistic regression model. During the population initialization process, N chromosomes are randomly generated, and the values of the elements of each chromosome are randomly generated.
- 2) **Evolution.** After population initialization, classical evolutionary operations are performed to generate new chromosomes. General evolutionary operators include crossover operator, mutation operator, etc.
- 3) **Selection.** Choose the optimal chromosomes from the parent and offspring populations. The selection operator of NSGA-II is based on non-dominated sorting algorithm and the concept of crowding distance [12]. Repeat steps 2 and 3.

- 4) **Termination.** Once the evolutionary process satisfies the termination condition, the iteration process terminates and returns to the final optimal chromosomes.

B. Optimal Solutions Selection Strategies

MULTI designs two optimization objectives and generates a set of optimal solutions based on NSGA-II. In previous studies, Chen et al. [6] use MULTI-B to indicate the best performance of MULTI, and use MULTI-M to indicate the average performance of MULTI. Although the average performance of the MULTI method is good in the context of effort-aware JIT-SDP, randomly selecting an optimal solution from the optimal solution set may result in poor prediction performance.

Fig. 1 shows the values of ACC indicator generated from a run results on six subject systems based on 10 times 10-fold cross-validation. It can be seen from the Fig. 1 that although the median of indicator ACC in optimal solution set can obtain a high performance, there are a large number of poor performance solutions in the optimal solution set. Therefore, randomly selecting an optimal solution may result in obtaining a prediction model with poor performance. Therefore, it is necessary to design a suitable optimal solutions selection strategy to improve the stability of MULTI.

Fig. 1. values of ACC indicator for six subject systems

Since MULTI considers two optimization objectives, we design three optimal solutions selection strategies, as follows:

- **Benefit priority (BP).** BP strategy returns the optimal solution with maximum benefits in the optimal solution set.
- **Cost priority (CP).** CP strategy returns the optimal solution with minimal cost in the optimal solution set.
- **A compromise between cost and benefit (CCB).** CCB strategy considers cost and benefit simultaneously, and returns the optimal solution with middle cost or benefits in the optimal solution set.

To better describe the three strategies, we use the pseudo code to further describe them, as shown in Algorithm 1.

IV. CASE STUDY

Our case study aims to solve following research question.

Algorithm 1: Three optimal solutions selection strategies**Input:** training set: $D = \{(\mathbf{x}_1, y_1), (\mathbf{x}_2, y_2), \dots, (\mathbf{x}_n, y_n)\}$;**Output:** optimal solutions: $solution_BP, solution_CP, solution_CCB$

```

1 begin
2   // Generate optimal solution based on MULTI method
3    $solutions = MULTI(D)$ 
4   // Sort optimal solutions in ascending order based on
   benefit values
5    $solutions = order\_by\_benefit(solutions)$ 
6   // Return solutions according to three strategies
7    $solution\_BP = solutions[solutions.length - 1]$ 
8    $solution\_CP = solutions[0]$ 
9    $solution\_CCB =$ 
    $solutions[(solutions.length - 1)/2]$ 
10 end

```

- Which optimal solutions selection strategy is appropriate for solving the effort-aware JIT-SDP problem?

The experimental hardware environment is *Intel(R) Core(TM) i7-7700 CPU@ 3.60GHz; RAM 8.00GB*. The experimental code is written in python.

This section introduces data sets, performance indicators, data analysis method, and experimental design.

A. Data Sets

The experiment considers the data sets of six open source projects shared by Kamei et al. [4], which have been widely used in previous studies [5] [6]. These six data sets include Bugzilla (BUG), Columba (COL), Eclipse JDT (JDT), Eclipse Platform (PLA), Mozilla (MOZ), and PostgreSQL (POS), and come from different domains with different scales. The basic information is shown in the Table I.

In order to better solve the JIT-SDP problem, 14 change metrics are designed for these data sets, as shown in Table II. These metrics can be divided into five dimensions: diffusion, size, purpose, history, and experience. More details can be found in reference [4].

TABLE I
THE BASIC INFORMATION OF DATA SETS

Project	Period	#defective changes	#changes	%defect rate
BUG	1998/08/26~2006/12/16	1696	4620	36.71%
COL	2002/11/25~2006/07/27	1361	4455	30.55%
JDT	2001/05/02~2007/12/31	5089	35386	14.38%
MOZ	2000/01/01~2006/12/17	5149	98275	5.24%
PLA	2001/05/02~2007/12/31	9452	64250	14.71%
POS	1996/07/09~2010/05/15	5119	20431	25.06%

B. Performance Indicators

Effort-aware JIT-SDP primarily considers effort for code inspection of defect-prone changes. According to the suggestion of Kamei et al. [4], the effort used to check changes

TABLE II
THE DESCRIPTION OF METRICS

Dimension	Metric	Description
Diffusion	NS	Number of modified subsystems
	ND	Number of modified directories
	NF	Number of modified files
	Entropy	Distribution of modified code across each file
Size	LA	Lines of code added
	LD	Lines of code deleted
	LT	Lines of code in a file before the change
Purpose	FIX	Whether or not the change is a defect fix
	NDEV	Number of developers that changed the files
History	AGE	Average time interval between the last and the current change
	NUC	Number of unique last changes to the files
	EXP	Developer experience
Experience	REXP	Recent developer experience
	SEXP	Developer experience on a subsystem

can be obtained by calculating their code churn (i.e., the total number of lines added and deleted by the change). Similar to previous studies [4] [5] [6], our experiment use ACC and P_{opt} to evaluate the effort-aware prediction performance for prediction models. ACC indicates the recall of bug changes when using 20% of effort. P_{opt} is the normalized version of effort-aware performance indicator proposed by Mende and Koschke [13]. Specific information on these two performance indicators can be found in the literature [4] [5].

C. Data Analysis Method

The experiment uses 10 times 10-fold cross-validation technique to evaluate the performance of prediction models. 10 times 10-fold cross-validation technique is performed within the same project. First, the data set of one project is randomly divided into 10 sets of the same scale, nine of which are used to train the model and produce the optimal solution set, and the other one is to test the performance of the optimal solution set. This step will be repeated 10 times. In our case study, the optimal solutions selection strategies only select one solution from optimal solution set. Therefore, 10 times 10-fold cross-validation can ultimately return 100 solutions for each strategy.

In order to test the degree of performance difference between different optimal solutions selection strategies, the experiment uses Wilcoxon signed-rank test and Cliff's δ to further analyze the experimental results. Wilcoxon signed-rank test is a commonly used non-parametric statistical hypothesis test method. In particular, we use corresponding p-values to exam whether two optimal solutions selection strategies have significant difference at the significance level of 0.05. Meanwhile, we use Cliff's δ to determine the magnitude of difference in practical application [14]. Traditionally, the magnitude of the difference is considered trivial ($|\delta| < 0.147$), small ($0.147 \leq |\delta| < 0.33$), moderate ($0.33 \leq |\delta| < 0.474$), or large ($|\delta| \geq 0.474$).

D. Experimental Design

- **Data preprocessing.** In order to obtain a better prediction model, according to the suggestion of Kamei et al. [4], we preprocess the experimental data sets as following steps.

- 1) ND and REXP metrics are excluded since NF and ND, REXP and EXP are highly correlated. LA and LD metrics are normalized by dividing by LT metric since LA and LD are highly correlated. LT and NUC metrics are also normalized by dividing NF since LT and NUC have highly correlation with NF.
- 2) Each metric (except FIX) is executed with logarithmic transformation, since these metrics are highly skewed.
- 3) Due to class imbalance in the defect data sets, we perform random undersampling and keep the number of clean changes same as the number of buggy changes by deleting clean changes randomly.

Our optimal solutions selection strategies are based on the MULTI method, which uses NSGA-II, so some parameters need to be set.

• **Parameter settings.**

- 1) Population size: 200.
- 2) The range of coefficient vector: [-10000, 10000].
- 3) The interval of population initialization: [-10, 10].
- 4) Crossover operation: simulated binary crossover.
- 5) Mutation operation: polynomial mutation.
- 6) The number of generations: 800.

V. EXPERIMENTAL RESULTS AND DISCUSSION

A. Experimental Results

The experiment uses ACC and P_{opt} to evaluate the performance of different optimal solutions selection strategies. The results are shown in the Table III and Table IV. In Table III and Table IV, the first column indicates the names of projects. The second column MULTI-M is the median value of all optimal solutions, representing the average performance of the MULTI method. The third to fifth columns represent the performance of the models based on strategies BP, CP, and CCB, respectively. Since the experiment uses 10 times 10-fold cross validation technology, each strategy will get 100 result values. All the values in the Table III and Table IV reflect the median of the 100 result values.

As we can see from Table III and Table IV, the performance of strategy BP is far superior to the performance of MULTI-M in the ACC and P_{opt} on six data sets. In addition, compared to MULTI-M, the performance of strategy CP is even worse, and the performance of strategy CCB is equivalent. Finally, we use Wilcoxon signed-rank test and Cliff's δ determine the significant difference between different optimal solutions selection strategies and MULTI-M. If and only if p-value is less than 0.5 and Cliff's δ is greater than or equal to 0.147, the performance of our strategy is significantly different from MULTI-M, otherwise the difference is negligible. We have bolded the values that have significant differences.

Conclusion. Compared with MULTI-M, the performance of strategy BP is significantly better than MULTI-M, the average performance can be increased by 12% on indicator ACC, and the average performance on indicator P_{opt} can be increased by 15%. In addition, the performance of strategy CCB is comparable to MULTI-M, and the performance of strategy

TABLE III
COMPARISON OF THREE STRATEGIES AND MULTI-M USING ACC

project	MULTI-M	BP	CP	CCB
BUG	0.633	0.774	0.251	0.636
COL	0.723	0.804	0.344	0.721
JDT	0.658	0.723	0.371	0.653
MOZ	0.577	0.606	0.213	0.579
PLA	0.682	0.746	0.179	0.683
POS	0.612	0.703	0.252	0.613
Average	0.648	0.726	0.268	0.648

TABLE IV
COMPARISON OF THREE STRATEGIES AND MULTI-M USING P_{opt}

project	MULTI-M	BP	CP	CCB
BUG	0.771	0.930	0.492	0.773
COL	0.842	0.936	0.547	0.841
JDT	0.764	0.880	0.557	0.767
MOZ	0.731	0.812	0.473	0.731
PLA	0.792	0.887	0.528	0.790
POS	0.747	0.900	0.441	0.749
Average	0.775	0.891	0.506	0.775

CP is worse than MULTI-M. Therefore, we advise to use BP-based optimal solutions selection strategy to improve the performance of the MULTI method in the effort-aware JIT-SDP problem.

B. Discussion

The experimental results show that the performance of our optimal solutions selection strategies have the following characteristics.

$$BP > CCB > CP$$

In order to explain this phenomenon, we further analyze the experimental results. Take data sets BUG as an example, the experiment uses 10 times 10-fold cross validation to perform model evaluation, so a total of 100 runs will be produced. The results of one run of the experiment is shown in the Fig.2 and Fig.3. As we can see from Fig.2 and Fig.3, each graph contains 200 red dots, each representing an optimal solution. In the Fig.2 and Fig.3, the horizontal axis represents the value of the benefit, and the vertical axis represents the value of the performance indicators (i.e., ACC and P_{opt}).

It is obvious that in an optimal solution set, the benefit values of optimal solutions are positively correlated with the performance indicators including ACC and P_{opt} . Our experimental results show that this feature is also present on five other data sets. Therefore, BP-based optimal solutions selection strategy can significantly improve the performance of MULTI.

VI. THREATS TO VALIDITY

External validity. Although the data sets used in the experiment are widely used in the field of JIT-SDP [6] [5] [4], we still cannot guarantee that the findings of the experiment will apply to all other defect data sets. Therefore, more data sets in different fields have yet to be mined and shared to verify the generalization of experimental conclusions.

Fig. 2. ACC values in an optimal solution set

Fig. 3. P_{opt} values in an optimal solution set

Construct validity. Threats to construct validity are mainly considered whether the evaluation indicators can accurately reflect effort-aware prediction performance of models. Our experiment uses ACC and P_{opt} to evaluate effort-aware prediction performance of models, which are widely used in previous JIT-SDP studies [6] [5] [4].

Internal validity. The threats to internal validity are mainly about the accuracy of experimental code. Previous research code is mainly written in R language [5] [4], while our experimental code is written in python. In order to reduce the errors in the code, we check all the code and use the mature python libraries.

VII. CONCLUSIONS AND FUTURE WORK

In this paper, in order to improve the performance of the MULTI method, we propose three optimal solutions selection strategies BP, CP, and CCB. In order to verify the effectiveness of the strategies, we conduct a large-scale empirical study on data sets of six open source projects. Experimental results show that compared with the average performance of MULTI,

BP-based optimal solutions selection strategy can effectively improve the performance of MULTI.

In the future, we hope to further expand our work. First, since the experiment only uses data sets from open source projects, we will collect data sets from commercial projects to further verify the generalization of experimental conclusions. Secondly, we only consider the cross-validation scenario when evaluating the performance of prediction models. In the future, we will extend the work to cross-project-validation and timewise-cross-validation scenarios to further verify the generalization of the experimental conclusions.

Abstract — Business process models help understand the organizational process and the software that supports it. BPMN (Business Process Modeling and Notation) is the standard notation for business process modeling, and it is widely accepted in industry. BPMN models can elucidate the activities carried out by a software during its construction and maintenance. However, during the maintenance of the software that supports an organizational process, usually only the source code of the software undergoes modifications, even when inserting new features. The software design models, including the BPMN models, often become outdated over time and, in future maintenance, they will not help understand the business process in which the software is inserted and which the software aims to support. Such scenario highlights the importance of supporting the maintenance of BPMN models. However, what has been experimentally investigated regarding the maintenance of BPMN models? To answer this question, we performed a systematic mapping, which showed experimental studies, factors and technologies that influence the maintenance of BPMN models. These results present conclusions about the state of the art and gaps that can be explored in this field of research.

Keywords - *Business Process Model and Notation; BPMN; Software Maintenance; Model Maintenance; Systematic mapping.*

I. INTRODUCTION

Business process modeling is an essential activity for the success of business process management (BPM) [1]. The BPMN (Business Process Modeling and Notation) is the standard notation maintained by OMG [2] for business process modeling and is widely accepted in industry [3]. Researchers and practitioners recognize that understanding the business processes is key to identifying the users' needs that a software should support [4]. Martinez et al. [5] emphasize that the focus on software development from business processes can increase the software's compliance with the needs of its users. BPMN models can help in understanding the activities carried out by the software and better support software maintenance.

Maintenance is one of the most crucial phases of the software life cycle. It is usually divided into two steps: understanding the software artifact and modifying the software artifact [6]. In fact, a software artifact should be well understood before being modified, because developers need to know what impact modifications will have on the software and, possibly, on the underlying business processes. In the maintenance stage, process

models are of great relevance in understanding the software being developed [7] or modified. Thus, it is important that they are consistent with the current version of the software, so that it is understood correctly.

However, during the software maintenance process, usually only the source code is modified, even when inserting new features. Over time, development team turnovers mean that new members may not know the software functionalities, since they did not participate in its design and development [8]. It is in this scenario that software models prove to be of great value, because developers first seek to understand the software functionalities through the models built during its project. However, the documentation is almost always outdated and inconsistent [9]. When the models are not maintained together with the software, the information in these models will be inconsistent with the current version of the software, which hinders new professionals' understanding and activities during software maintenance.

As we realize the importance of supporting the maintenance of BPMN models, it is important to know what has been experimentally investigated on the maintenance of BPMN models. The goal of this paper is to describe a systematic mapping of studies related to the maintenance of BPMN models in order to identify what has been done in the literature to support and facilitate the maintenance of such models. The systematic mapping revealed factors and technologies related to the context of maintenance of BPMN models. With this work we present conclusions about the state of the art and gaps that can be explored in this field of research.

The remainder of this paper is organized as follows: Section 2 presents the related works. Section 3 describes the methodology applied to conduct the systematic mapping. Section 4 presents the results of the mapping study. Section 5 discusses the threats to the validity of this work. Finally, Section 6 presents the conclusions of the systematic mapping.

II. RELATED WORKS

In this section, we present some related works to our work. Pourmirza et al. [10] present a systematic literature review of Business Process Management Systems (BPMS) architectures. BPMS are information systems that interpret business processes to ensure that the activities specified therein are properly

executed and monitored by an organization. In this work, BPMS architectures that served as primary studies were compared with respect to the reference architecture that they are based on, the level of detail at which they are described, the architectural styles that they use, the means with which they are evaluated, and the functionality that they support. The resulting comparison provides an overview of and insights into the current body of knowledge on BPMS architectures.

Valença et al. [11] present a systematic mapping study of business process variability approaches, which is an emergent field in BPM with many of its proposals inspired by theories from Software Product Line to handle process variability. According to the authors, variability in business processes is necessary for organizations dealing with environmental changes. The results show that a significant number of approaches is available, but most of them lack empirical studies.

Although these works deal with BPM, they do not exploit the research done on the maintenance of BPMN models. Our work investigates the maintenance of BPMN models in the literature.

III. RESEARCH METHOD

A systematic mapping is a broad review of primary studies in a specific topic area, aiming to identify what evidence is available on the topic [12]. We followed the guidelines proposed by Kitchenham and Charters [12]. The following subsections detail our systematic mapping protocol.

A. Goal

We had the following goals for the systematic mapping:

- To investigate the maintenance of BPMN models and whether the models are understandable and modifiable to allow them to be modified while maintaining the source code.
- To gather experimental evidence on the use of BPMN models in their maintenance or use during the maintenance of the software source code.

B. Research Question

This mapping aimed to answer the following research question: ***“What has been experimentally investigated regarding the maintenance of BPMN models?”***. In order to answer this question, we divided the systematic mapping into specific sub-questions about the maintenance of BPMN models (see Table I).

TABLE I. RESEARCH SUBQUESTS

Subquestion	Description of Ssubquestion
SQ1	What is the state of the art in experimental studies on maintenance of BPMN models or source code maintenance when using BPMN models?
SQ2	Which dependent variables are investigated in the experimental studies?
SQ3 ¹	Which of the factors studied influence the software maintenance capability (source code or model)?
SQ4	What technologies support the maintenance of BPMN models?

¹ We considered as factors the results of the publications selected in the systematic mapping that influence the maintenance of BPMN models.

² <http://www.scopus.com>

C. Search strategy

To construct the search string, we defined the search terms based on the procedure described by Kitchenham and Charters [12], who suggested defining the parameters for Population, Intervention, Comparison, Result, and Context (PICOC). The population was the specific field of research on BPMN - Business Process Modeling and Notation; the intervention was composed of maintenance phases or types; the result was the types of experimental studies; comparison and context were not applicable because our goal is to characterize what is done in relation to the maintenance of BPMN models, so there is no comparison to determine the context. We have identified the terms of the research through the publication of Fernandez-Saez et al. [6], which we used as the basis for this work. They investigated the maintenance of UML models, so we adapted this work by bringing it into the context of BPMN models. Table II shows the terms used in the search string and the groups of synonyms used in its construction. We used the boolean operator OR between the alternative terms and synonyms, and the Boolean operator AND to join the groups.

We used the search string in the Scopus², Engineering Village³ and ACM⁴ digital libraries. We have included the Scopus and Engineering Village libraries because they are meta libraries and index publications from several reputable publishers in Software Engineering, such as ACM, IEEE, Springer and Elsevier, and they allow defining filters by type of document, language and area of knowledge. Although the ACM library is indexed by Scopus, we included this library to ensure that there were no excluded publications in the Scopus indexing and because ACM indexes some Springer Link and Science Direct publications as well.

TABLE II. SEARCH STRING TERMS AND SYNONYMS

Term of PICOC	Main Term	Synonyms
Population	BPMN	business process model and notation OR business process modeling and notation
Intervention	Maintenance	evolution OR comprehension OR maintainability OR evolvability OR understandability OR modularity OR modification OR understanding OR reusability OR stability OR misinterpretation OR analyzability OR testability OR changeability OR comprehensibility
Results	Empirical	survey OR action research OR experiment OR case study

D. Selection Criteria

The selection process comprised three steps (first filter, second filter and process of extracting data). In the first filter, two researchers only read the title and the abstract. They have selected the publications applying the inclusion and exclusion criteria (see Table III). The reliability of the inclusion and

³ <http://www.engineeringvillage.com>

⁴ <http://dl.acm.org>

exclusion criteria of a publication in the systematic mapping was assessed by applying Fleiss' Kappa [13]. Fleiss' Kappa is a statistical measure for assessing the reliability of agreement between a fixed number of raters when classifying items.

TABLE III. INCLUSION AND EXCLUSION CRITERIA

#	Selection Criteria
IC1	Papers with experimental studies using BPMN model during the maintenance of the diagram or source code
IC2	Papers with experimental studies with BPMN models helping in the process of understanding the software
IC3	Papers that evaluate the comprehensibility or maintainability of BPMN diagrams
#	Exclusion Criteria
EC1	Papers proposing BPMN extensions;
EC2	Papers that do not report experimental studies;
EC3	Papers that mention BPMN or maintenance only as general introductory terms in the abstract and nowhere else;
EC4	Papers that are not written in English or Portuguese;
EC5	Papers unavailable for reading or data collection (paid publications, broken links in the search engine and not made available by the authors after an attempt to contact);
EC6	Duplicate papers

Initially, we asked two researchers to classify, individually, a random sample of 20 publications to analyze the degree of agreement in the selection process through the Fleiss' Kappa [13]. The selected sample was the set of the publications returned by Scopus. The result of the degree of agreement showed a substantial level of agreement between the two researchers ($Kappa = 0.653$).

In the second filter, the researchers fully read the selected publications, selecting them according to the same criteria used in the first filter. After completing the selection process, we started the process of extracting data.

We used an extraction form to standardize the data collected. According to Fernandez et al. [6], this ensures that the same criteria will be used, thus facilitating their classification. We extracted the data according to each subquestion. The complete protocol and the publications obtained in the second filter are available in a technical report [14].

IV. RESULTS

Figure 1. depicts the publications selection process carried out in the conduction of the systematic mapping. The search string returned 89 publications in Scopus library, 80 in Engineering Village, and 19 in ACM. After eliminating duplicates, we had 88 publications in Scopus, 7 in Engineering Village and 15 in ACM, resulting in 110 publications. During the first filter, we rejected 81 publications that did not meet the inclusion criteria. We read the remaining 29 publications in full and classified them in the second filter. At that stage we selected 18 publications that proceeded to the extraction process.

Figure 1. Article selection process.

The selected papers were published between 2008 and 2018. There was no criterion to limit the year of publications. Figure 2. shows that most publications are recent, which leads us to believe that the maintenance of BPMN models is a timely research issue.

Figure 2. Overview of the publications per year.

The answers we found for each research sub-question are the following:

1) *SQ1: What is the state of the art in experimental studies on maintenance of BPMN models or source code maintenance when using BPMN models?*

This subsection presents several items related to the state of the art of experimental studies regarding the maintenance of BPMN models. We present these items next:

Experimental Study Type: Figure 3. shows the number of publications with each type of experimental study. Even when a publication reported more than one controlled experiment, i.e., replications of the experiment in other institutions or with other artifacts, Figure 3. only counts it once.

Figure 3. Types of experimental studies reported in the publications.

Experimental studies: When counting the number of experimental studies reported in the 18 publications, according to each type of experiment. If one publication reported two

controlled experiments, we counted the two experiments. In total, the 18 publications presented 39 experimental studies: 35 controlled experiments, 2 case studies, and 2 surveys.

Context: We classified the context of the studies as laboratory, industry or online. Most publications (72.22%) reported experiments that were conducted in a laboratory within academic environment. Two publications (11.11%) reported experiments carried out in industry (in companies that use BPMN models). Three publications (16.67%) reported experiments performed online, where a task was made available online and the participant had a deadline to do it (e.g., a week). **We can see that the amount of experiments performed in industry is low**, which corroborates the result already obtained in the previous section, about the need to perform experiments in real environments.

Characterization of the participants: Most publications have presented experimental studies conducted with undergraduate or graduate students, which is not necessarily inappropriate, since student skills are considered similar to the skills of novice practitioners [15][16]. Some publications have conducted experiments with more than one participant profile. **Among the 39 experiments presented in the publications, 29 were experiments with only students as subjects**, 5 were experiments with only professionals, 3 were experiments with students and professionals, 1 experiment with students, professionals and academic professionals, and 1 experiment in which the participant was the author of the technique. In the latter, the author applied the technique proposed by himself, to reduce the complexity of BPMN models.

Maintenance focus object: Software maintenance tasks usually require some modification in the source code, and should be accompanied by modifications in the corresponding BPMN model. **We did not find experimental studies that reported the use of BPMN models during source code maintenance.** We only found publications where the maintenance was done only in the BPMN model, consisting mostly of experimental studies that evaluate the comprehensibility of BPMN models.

Treatments in experimental studies: Figure 4. shows the different treatments used in the experimental studies. We divided the treatments into six categories: (i) complexity of the model, (ii) model representation, (iii) model characteristics, (iv) type of model representation, (v) model representation method, and (vi) characteristics of the model maintainers and defects in the models.

Figure 4. Types of treatment in experiments, by publication.

We highlight the category *complexity of the model* with the highest number of publications. **Some publications presented experiments with more than one type of treatment**, thus the bars add up to 22 publications. The types of treatment of each publication are more detailed in a technical report [14].

According to the data obtained, we can conclude the following about the state of the art of research on the maintenance of BPMN models:

Most of the **experimental studies carried out** were controlled experiments, carried out in the laboratory, with the participation of students. Various **types of treatment** were applied such as: the complexity of the models, the form of representation, the characteristics of the models, among others. The **focus of the maintenance** was always the model itself – not coupled with source code maintenance.

2) *SQ2: Which dependent variables are investigated in the experimental studies?*

The dependent variables we investigated in the experimental studies are represented in Figure 5. We identified four dependent variables: model understanding, model modifiability, model complexity, and model completeness (i.e., to what extent the model represented the functionalities of a specific process). We can see that the great majority of publications sought to evaluate the comprehension of BPMN models (17), some publications evaluated the modifiability (4) and complexity (4) of the models and only one publication evaluated the completeness of the BPMN models. Some papers investigated both the comprehension and the modifiability or complexity of BMPN models in the same experiment, so the bars add up to 26.

Figure 5. Dependent variables investigated.

3) *SQ3: Which of the factors studied influence the software maintenance capability (source code or model)?*

As we have already mentioned, we have not found experimental studies that dealt with the maintenance of the source code and BPMN together. This research subquestion will therefore focus only on the model. Figure 6. shows the factors that influence, either positively or negatively, the maintenance of BPMN models, according to the results obtained in the experiments of the selected publications (publications are called PB#, such as PB1 for the first publication in the report [14]).

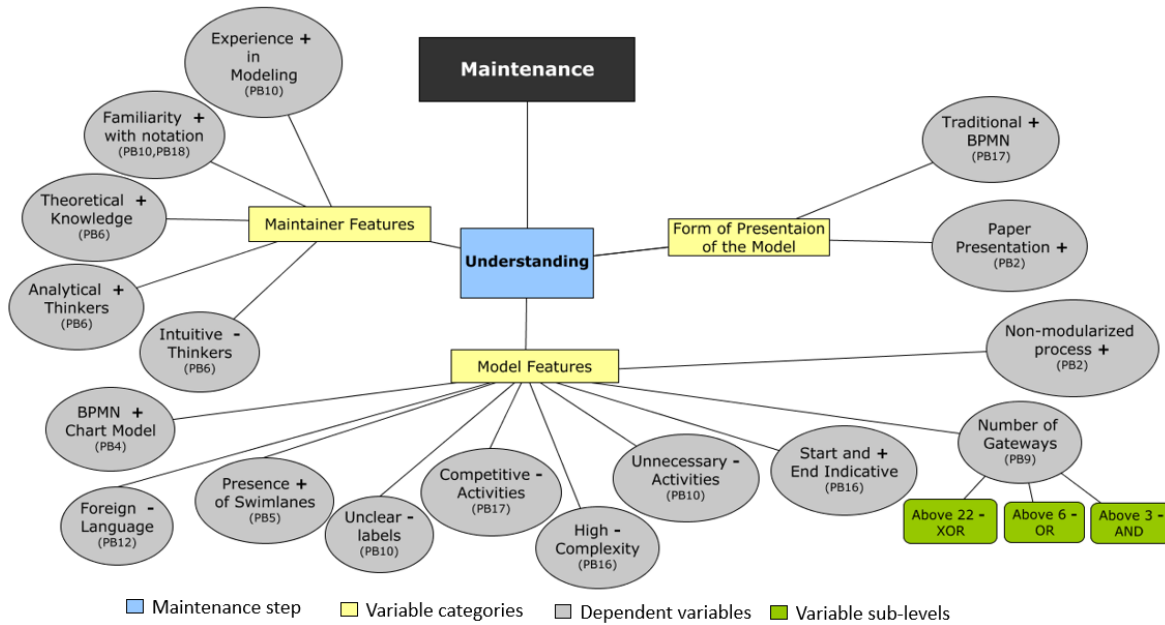

Figure 6. Dependent variables per publication.

It is important to remember that the maintenance activity is divided into two tasks [6]: artifact understanding and artifact modification. Considering these two types of maintenance tasks, the factors identified in the results of the experiments were related to *understanding* (see Figure 6.). The experiments that dealt with modifying the models actually had some kind of technology to support the modification and were therefore fitted as a response to SQ4. Factors that did not present significant results (if the study could not determine whether a factor influenced or not the understanding of a BPMN model) were omitted. We classified as positive (+) the factors that facilitate the understanding of the model and as negative (–) the factors that undermine the understanding of the model.

4) SQ4: What technologies support the maintenance of BPMN models?

We divided the technologies that support the maintenance of models according to the two types of maintenance tasks: understanding and modification. We then evaluated whether the proposed technology supported understanding or modifying the model during maintenance. Figure 7. shows the technologies identified to support the maintenance of BPMN models.

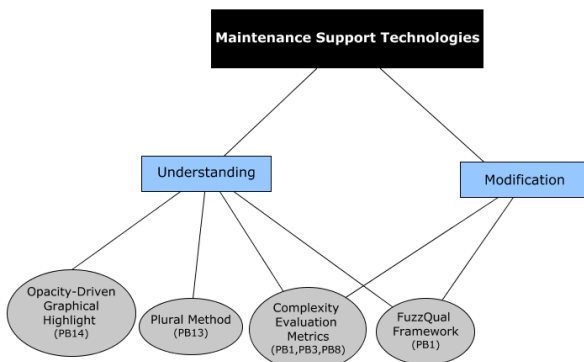

Figure 7. Technologies that support the maintenance of BPMN models

Technologies aimed at supporting the maintenance of BPMN models that focused on understanding were as follows:

- **Opacity-Driven Graphical Highlights Technique:** Jost and Hericko's approach [17] makes business process models less complex without changing the notation. The technique consists of working on the opacity of the models, highlighting only the relevant parts of the model according to the context in which it is used.
- **Plural Method:** decentralized method for creating BPMN models, in which the sources of model construction are also participants in the process. The method aims to involve process participants in modeling, since they are well aware of the problem domain.

Technologies to support the maintenance of BPMN models that focused on understanding and modification were as follows:

- **Complexity measurement metrics:** measures that may be useful in forecasting different aspects of understanding and modifying business process models in future model maintenance. The goal is to make models easier to understand and modify for all stakeholders.
- **FuzzQual Framework:** approach that evaluates BPMN models with regard to comprehensibility and modifiability. A framework/system built in JAVA evaluates the model based on the complexity metrics chosen, among several metrics that were evaluated. Through fuzzy logic, the framework evaluates the model with classifications of the type: "Moderately difficult to understand with a degree of certainty of 63%", "Moderately difficult to modify with a degree of certainty of 100%". This framework is an implementation of the complexity metrics to evaluate BPMN models.

V. THREATS TO VALIDITY

Although we conducted this research under a systematic mapping methodology by defining a research protocol, some

threats to validity can be identified: (i) the researchers' bias regarding the analysis of the primary studies; (ii) the university's limited access to some scientific databases, which can prevent some publications from being accessed; (iii) the limitation of the scope of this research to the selected databases. These threats were minimized by taking some actions. For the first threat, we reviewed the review protocol and performed the Kohen's Kappa statistical test in order to reduce the researchers' bias. Additionally, another experienced researcher reviewed the execution process. For the second threat, we had two publications that fit that threat. We requested the authors for the full publication whenever possible and included those that have been made available. Regarding the third threat, although the research was conducted in only three databases, they index publications from a large number of well-known publishers, journals and conferences.

VI. CONCLUSIONS

This work describes the results of the systematic mapping of the literature that we carried out to identify what has been experimentally investigated on the maintenance of BPMN models. The main conclusions we have reached with the systematic mapping can be summarized as follows:

- Most studies were carried out in academic environments, which is explained by the fact that they are the most accessible environment for researchers. The difficulty to perform research in real environments, within industry/companies, is well known. However, there is a need for further experiments in real environments.
- Most studies performed are controlled experiments. This demonstrates a need for more case studies to confirm the results obtained in real environments.
- We have not identified studies that explored the maintenance of BPMN models together with maintenance of the software itself. We have also not identified studies that investigate the impact of updated or outdated BPMN models during software maintenance.
- The focus of the experimental studies is almost entirely on the *understanding* of BPMN models. However, understanding is only one of the tasks of maintenance, and it is necessary to focus also on *modifying* the models themselves.
- The technologies that we have found focus mostly on the initial construction of the model and how it will be easily understood or modified when it is necessary to use it or modify it. The proposed technologies seek to measure in advance whether the model created will be easy to maintain in the future. However, it is also necessary to create technologies that directly support the maintenance phase of the model.

The results indicate that there is a lack of maintenance of BPMN models, especially the maintenance of these models in conjunction with maintenance of the software source code. In relation to the technologies proposed, most of the research identified focuses on understanding the models, which is the initial task of maintenance, highlighting the need for technologies that support the modification of BPMN models.

This shows research opportunities to be explored in this field of research in future work.

Abstract—Multistep flow prediction is an essential task for the car-sharing systems. An accurate flow prediction model can help system operators to pre-allocate the cars to meet the demand of users. However, this task is challenging due to the complex spatial and temporal relations among stations. Existing works only considered temporal relations (e.g., using LSTM) or spatial relations (e.g., using CNN) independently. In this paper, we propose an attention multi-graph convolutional sequence-to-sequence model (AMGC-Seq2Seq), which is a novel deep learning model for multistep flow prediction. The proposed model uses the encoder-decoder architecture, wherein the encoder part, spatial and temporal relations are encoded simultaneously. Then the encoded information is passed to the decoder to generate multistep outputs. In this work, specific multiple graphs are constructed to reflect spatial relations from different aspects, and we model them by using the proposed multi-graph convolution. Attention mechanism is also used to capture the important relations from previous information. Experiments on a large-scale real-world car-sharing dataset demonstrate the effectiveness of our approach over state-of-the-art methods.

Index Terms—Car-sharing systems, Multistep flow prediction, Graph convolution network

I. INTRODUCTION

In recent years, car-sharing systems have been introduced to a number of cities as a means of increasing mobility, reducing congestion, and pollution [1]. Car-sharing systems involve a small to medium fleet of cars, which are available at several stations, to be used by a relatively large group of users. Users can pick up a car in a station and drop off it at another station, which is called the one-way system [2]. The key to success of the car-sharing systems is an accurate flow prediction model, which plays a vital role in various tasks such as car rebalancing [3]. Furthermore, instead of predicting only for the next step (e.g., next day), the multistep flow prediction is more attractive to the system operators since it offers information on a long-term trend.

Traditional time series prediction methods like ARIMA have been widely used for traffic prediction problem [4, 5]. However, these approaches are often applied to a single station

separately and ignore the spatial relations with each other. For example, if a station near a railway station has high flow, another one close to it may also have high flow. Furthermore, building a separate prediction model for each station is time-consuming and impractical if there are hundreds of stations. Hence, the key challenge for this problem lies in how to model complex spatial relations and temporal dynamics. To tackle the above challenges, we propose a novel deep learning model, named attention multi-graph convolutional sequence-to-sequence model (AMGC-Seq2Seq), which captures spatial-temporal relations effectively for station-level flow prediction.

In this work, a new multistep flow prediction model for car-sharing systems is designed. Multiple graphs among stations are defined to represent their heterogeneous spatial relations. Then we employ the proposed multi-graph convolution to model these spatial correlations. Furthermore, a novel deep learning framework, named AMGC-Seq2Seq, is proposed to capture the spatial and temporal relations simultaneously by incorporating the encoder-decoder architecture with graph convolution networks. The proposed method is validated on a large-scale real-world car-sharing dataset from EVCARD. The dataset contains car orders through EVCARD service in the city of Shanghai in China over three months, with about 480,000 orders per month on average. We conducted extensive experiments to compare with state-of-the-art methods and have demonstrated the superior performance of our proposed method.

The rest of this paper is organized as follows: Section II reviews the existing works. Section III first formulates the multistep flow prediction problem and then describes the details of the proposed AMGC-Seq2Seq model. Section IV presents the experiment settings and discusses the obtained results. Section V concludes this work.

II. RELATED WORK

The problem of car-sharing system flow prediction is similar to traffic prediction problem, of which the goal is to predict the traffic-related value (e.g., traffic flow or traffic speed) for a period of time through historical data. A number of studies

^{*}These authors contributed equally to this work

have investigated traffic prediction for decades. In this section, we discuss the related work on traffic prediction problem.

The early research on traffic prediction focused on the prediction of the individual station using classical empirical statistical methods. Among all the traditional methods, the autoregressive integrated moving average (ARIMA) and its variants are the most widely used [6]. Based on this time series model, recent studies also consider adding external context data, such as weather, wind speed and event information [7]. Besides, various techniques have been used to model spatial interactions. Deng et al. [8] apply non-negative matrix factorization on road networks to capture correlations between roads. Tong et al. [9] mainly adopt POI data as the spatial features. However, all of these methods are based on the time series model and ignore complex spatial-temporal relations.

With the success in deep learning, more and more researchers attempt to use deep learning techniques on traffic prediction problem. Zhao et al. [10] use the long short-term memory (LSTM) networks to capture non-linear temporal relations. Wang et al. [11] propose the DeepSD, which utilizes multiple data sources and predict the gap between the car-hailing supply and demand. These methods focus on temporal features extraction but do not model the spatial-temporal relations.

To effectively model the complex spatial relations, some researchers use convolutional neural network (CNN) to capture adjacent relations among the traffic networks. Yao et al. [12] propose the DMVST-NET, which models both spatial and temporal relations by local CNN and LSTM. Since the traffic networks are naturally non-Euclidean as the data format is no longer a matrix and CNN becomes less helpful, some researchers turn to use graph convolutional network (GCN) to model this non-Euclidean structures. Chai et al. [13] propose a multi-graph convolutional network to catch heterogeneous inter-station spatial correlations. However, all of these methods are proposed for one-step prediction. Specifically, for multistep prediction, the output from the previous step is taken as the input to the current step, which usually leads to error accumulation and poor prediction performance.

Several researchers have recently attempted to investigate multistep prediction. Cai et al. [14] propose an improved KNN model to achieve multistep forecasting. They describe the traffic state of a road segment by a spatial-temporal state matrix and use the Gaussian weighted Euclidean distance to measure the similarity. Park et al. [15] propose the AGC-Seq2Seq for multistep speed prediction, which learns the spatial-temporal relations simultaneously by integrating LSTM and GCN. They utilize encoder-decoder to model the multistep prediction problem. However, they use only one graph to model the spatial relations, which may not be enough to reflect the complex spatial relations, and they have not capture the local temporal relations for the individual station.

Inspired by those research accomplishments and the real-world problem observations, a potential solution for more accurate and practical prediction should be an integrated analysis for both spatial and temporal relations of stations.

III. PROPOSED MODEL

In this section, we first formulate the problem and then describe how to model the spatial and temporal relations using the proposed attention multi-graph convolutional sequence-to-sequence model (AMGC-Seq2Seq).

A. Problem Formulation

In car-sharing systems, there are two types of flows: outflow and inflow. The outflow of station i is defined as the pick-up frequency at the time slot t (e.g. one day), which is denoted by $y_{i,t}^{out}$. The inflow of station i is defined as the drop-off frequency at the time slot t , which is denoted by $y_{i,t}^{in}$.

Suppose we have N stations, then the outflow of all stations at time slot t can be denoted as $Y_t^{out} = [y_{1,t}^{out}, y_{2,t}^{out}, \dots, y_{N,t}^{out}]$, and inflow of all stations at time slot t can be denoted as $Y_t^{in} = [y_{1,t}^{in}, y_{2,t}^{in}, \dots, y_{N,t}^{in}]$.

Suppose the current time slot is t , and we have the historical data $[(Y_1^{in}, Y_1^{out}), (Y_2^{in}, Y_2^{out}), \dots, (Y_t^{in}, Y_t^{out})]$, the problem considered in this work is to predict the flow at next T steps $[(\hat{Y}_{t+1}^{in}, \hat{Y}_{t+1}^{out}), (\hat{Y}_{t+2}^{in}, \hat{Y}_{t+2}^{out}), \dots, (\hat{Y}_{t+T}^{in}, \hat{Y}_{t+T}^{out})]$, aiming to:

$$\min \sum_{k=1}^T \left\| \hat{Y}_{t+k}^{in} - Y_{t+k}^{in} \right\|_2^2, \min \sum_{k=1}^T \left\| \hat{Y}_{t+k}^{out} - Y_{t+k}^{out} \right\|_2^2 \quad (1)$$

B. Framework Overview

Figure 1 shows the architecture of our proposed model. Generally, our model uses the encoder-decoder architecture. In the encoder, we form a "hamburger" structure with two LSTMs and one multi-graph convolution layer (M-GCN) in between to model the spatial and temporal relations. First, LSTM is used to model local temporal information for each station. After that, multi-graph convolution is used to model heterogeneous spatial relations among stations. Finally, another LSTM is used to aggregate spatial-temporal relations together. Then the encoded information is passed to the decoder and incorporated with attention mechanism to generate multistep outputs. The details of each module are described as follows.

C. Encoder

1) *Temporal relations modeling*: Since the flow pattern for each station varies a lot, we adopt Long Short-Term Memory (LSTM) network [16] to model this local temporal relation. At each time step t , LSTM takes two inputs: memory of the last time step h_{t-1} and the related information at current time step x_t . Based on these inputs, LSTM learns to remove or add new information to the memory, and finally generates a new memory state h_t which accumulates all the previous information. This process is controlled by three gates: forget gate, input gate, and the output gate, which can be formulated as follows:

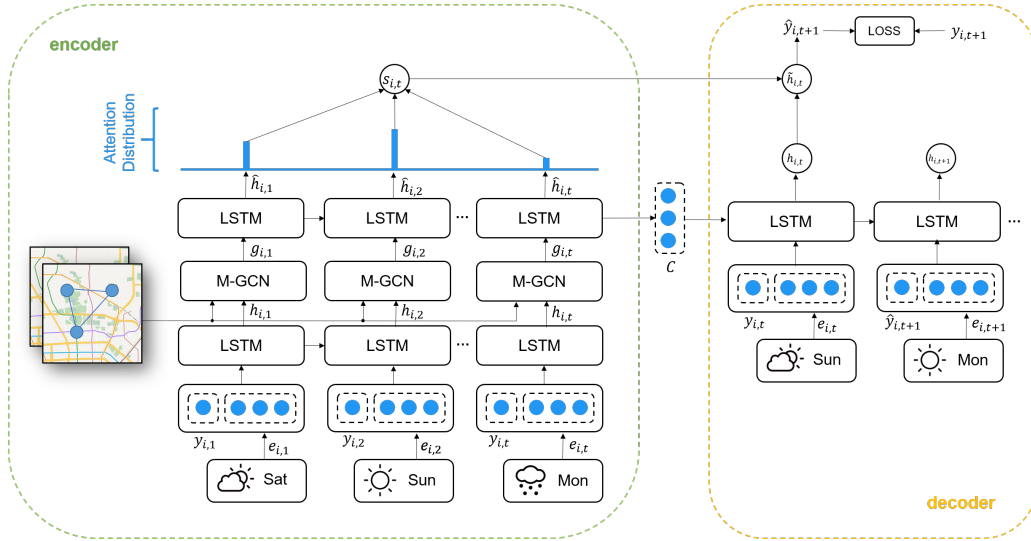

Fig. 1. The architecture of AMGC-Seq2Seq.

$$f_{i,t} = \sigma(W_f[h_{i,t-1}, x_{i,t}] + b_f) \quad (2)$$

$$i_{i,t} = \sigma(W_i[h_{i,t-1}, x_{i,t}] + b_i) \quad (3)$$

$$\tilde{C}_{i,t} = \tanh(W_C[h_{i,t-1}, x_{i,t}] + b_c) \quad (4)$$

$$C_{i,t} = f_{i,t} \circ C_{i,t-1} + i_{i,t} \circ \tilde{C}_{i,t} \quad (5)$$

$$o_{i,t} = \sigma(W_o[h_{i,t-1}, x_{i,t}] + b_o) \quad (6)$$

$$h_{i,t} = o_{i,t} \circ \tanh(C_{i,t}) \quad (7)$$

Where \circ denotes the Hadamard product. $f_{i,t}$, $i_{i,t}$ and $o_{i,t}$ are the forget gate, the input gate and the output gate respectively. σ and \tanh are the nonlinear activation functions. W_f , W_i and W_o are all trainable parameters, while b_f , b_i and b_o are the corresponding bias vectors.

As for the inputs of step t , we concatenate flow $y_{i,t}$ with external features $e_{i,t}$ (e.g., weather, weekday/weekend) together:

$$x_{i,t} = y_{i,t} \oplus e_{i,t} \quad (8)$$

It should be noted that all stations share the same weights of LSTM in the proposed model. The reason is that sharing LSTM among all stations may encourage the desired model becomes more general and reduce complexity.

2) *Spatial relations modeling*: To capture the spatial relations between stations, we propose a multi-graph convolution layer. The goal of the multi-graph convolution layer is to learn a function of features on graphs. Here we define the graphs which will be used later.

The car-sharing systems can be modeled as a weighted undirected graph, of which a node represents one station and an edge represents the relation between two stations. Usually, the large the weight of an edge is, the strong correlations there are between two stations. The simplest graph is the distance

graph, where the weight of an edge is defined as the reciprocal of the distance. In addition to the distance graph, there can be more graphs used to model the relation of stations. In this work, we propose and define the following two graphs: distance graph and POI graph.

Distance Graph: According to our observation, stations in the same area are likely to have similar flows. Therefore, the edge in the distance graph between two stations is defined to be the reciprocal of the distance.

$$A_{dis,i,j} = \begin{cases} d_{i,j}^{-1}, & i \neq j \\ 0, & i = j \end{cases} \quad (9)$$

Where $d_{i,j}$ is the distance between station i and j .

POI Graph: Intuitively, stations sharing similar functionality may have similar flows. For example, stations in the commercial area usually have more flows on weekends, and stations in the office area are expected to have more flows on weekdays. Point of interest, or POI, is a specific point location that someone may find useful or interesting (e.g., schools, shops, post offices are all POIs). Therefore, we can use POIs around a station to represent its functionality. Accordingly, we define the edge in a POI graph between two stations as the cosine similarity of POIs.

$$A_{dis,i,j} = \begin{cases} \frac{P_i \cdot P_j}{\|P_i\| \|P_j\|}, & i \neq j \\ 0, & i = j \end{cases} \quad (10)$$

Here P_i and P_j are the POI vectors of station i and j respectively. The dimension of the vector is the category of POIs, and the value in the vector is the number of the specific POI category around the station.

Recall that in the temporal modeling, we have the hidden state $h_{i,t}$, which contains the temporal information of station i at t time step. Here we define $H_t = [h_t^1, h_t^2, \dots, h_t^N]$, which

represents the temporal information of all stations at the time t . Then with the above graphs constructed, we propose the multi-graph convolution to model the spatial relations as defined in eq.(11).

$$G_t = \sigma\left(\sum_{A \in \mathcal{A}} A * H_t * W\right) \quad (11)$$

Where \mathcal{A} is the set of graphs, H is the feature matrix of all stations, and W is a trainable matrix which will be updated during the training. Here σ is a non-linear activation function, which is ReLU in our model.

Eq.(11) indicates that for each station, we update its feature by a weighted sum of the features of all the other stations. The larger the weight of the edge is between two stations, the more the feature of that station contributes. However, there are some problems need to be resolved.

First of all, according to the definition of the graph, the diagonal of the graph matrix contains all zeros. As a result, if we multiply it with the feature matrix, the vector of itself contributes nothing, which loses a lot of important information of itself. We fix this by adding an identity matrix to A .

Another problem is that since we combine multiple graphs by adding the transformed feature matrices together, the obtained graph matrices may vary a lot. Hence, we normalize A by dividing each value by the row sum such that all rows sum to one.

Therefore, we modify the eq.(11) as follows:

$$D_{i,j} = \begin{cases} \sum_{k=1}^N A_{i,k}, & i = j \\ 0, & i \neq j \end{cases} \quad (12)$$

$$\hat{A} = D^{-1}A + I \quad (13)$$

$$G_t = \sigma\left(\sum_{\hat{A} \in \hat{\mathcal{A}}} \hat{A} * H_t * W\right) \quad (14)$$

Where D is a diagonal matrix of which the value in the main diagonal is the row sum of A . Multiplying D^{-1} with A makes all rows of A sum to one. Finally, we add it with the identity matrix I to ensure self-loops in the graph.

Finally, another LSTM is applied to each station to aggregate both temporal and spatial relations for station i . The final hidden state $h_{i,t}$ is selected as the context vector c_i for station i which stores all the information of the encoding, and then this vector is passed to the decoder as the initial state to be decoded as shown below.

$$\hat{h}_{i,t} = LSTM(\hat{h}_{i,t-1}, g_{i,t}) \quad (15)$$

$$c_i = \hat{h}_{i,T'} \quad (16)$$

D. Decoder

In the decoder, a separate LSTM is used to decode context vector c_i to obtain the multistep outputs. The LSTM part is the same as the equations (2)-(7), while the initial state is set as

the context vector which stores all the information of previous time steps.

$$h_{i,0} = c_i, \quad (17)$$

$$h_{i,t} = LSTM(\hat{h}_{i,t-1}, x_{i,t}) \quad t > 0 \quad (18)$$

Furthermore, we employ the attention mechanism which is widely used in most of NLP scenarios [17]. At a high-level, an attention mechanism enables our neural network to focus on relevant parts of the inputs more than the irrelevant parts when performing a prediction task. For example, if the current time step is Sunday then the information of the Sunday before a week are considered as much help to predict the current output. Let t and t' denote the time step at decoder and encoder respectively, and the attention mechanism works as follows:

$$u_{i,t}^{t'} = q_a^T \tanh(W_a[h_{i,t} + \hat{h}_{i,t'}]) \quad (19)$$

$$a_{i,t}^{t'} = \frac{\exp(u_{i,t}^{t'})}{\sum_{t'=1}^{T'} \exp(u_{i,t}^{t'})} \quad (20)$$

$$s_{i,t} = \sum_{t'=1}^{T'} a_{i,t}^{t'} \hat{h}_{i,t'} \quad (21)$$

Where the weight $a_{i,t}^{t'}$ measures the importance of the time step t' in t . Here $a_{i,t}^{t'}$ is derived by comparing the current hidden state $h_{i,t}$ with the previous spatial-temporal hidden state $\hat{h}_{i,t'}$. The attention vector $s_{i,t}$ is a weighted sum of hidden states in each previous time step t' .

Finally, we concatenate attention vector s_i with current hidden state h_i as h_i' . Then we feed h_i' to a fully connected layer and get the final prediction. Noted that in this work, we predict inflow and outflow simultaneously.

$$\tilde{h}_{i,t} = h_{i,t} \oplus s_{i,t} \quad (22)$$

$$[\hat{y}_{i,t}^{in}, \hat{y}_{i,t}^{out}] = W_y \tilde{h}_{i,t} + b_y \quad (23)$$

Since this is a multistep problem, the loss function is defined as the mean squared error:

$$loss = \frac{1}{T} \sum_{t=1}^T (y_{i,t}^{in} - \hat{y}_{i,t}^{in})^2 + (y_{i,t}^{out} - \hat{y}_{i,t}^{out})^2 \quad (24)$$

IV. EXPERIMENT

A. Dataset

We use a large-scale car-sharing dataset provided by EV-CARD, which is one of the biggest hourly rental operators in China. The dataset contains the orders from 5/1/2017 to 7/31/2017 in Shanghai, and there are about 15,000 orders per day. The order includes pick-up station, drop-off station, pick-up time and drop-off time. Weather data is collected from JUHE¹ website. POI data is collected through AMap API²,

¹<https://www.juhe.cn/docs/api/id/277>

²<https://lbs.amap.com/>

which contains 15 primary categories. For each station, we collected POIs within 1km around it and represented them in a vector, whose entry is the number of a specific POI category. We summarize the statistics of the dataset in Table I.

The data from 5/1/2017 to 6/30/2017 are used for training (61 days), and the data from 7/1/2017 to 7/31/2017 are used for testing (31 days).

TABLE I
DATASET STATISTICS

Data Source		EVCARD	
Time from	5/1/17	7/1/17	
to	6/30/17	7/31/17	
#days	61	31	
#stations	1433	1433	
#orders	964,531	498,856	

Data Source		AMap API	
POI type	number	POI type	number
food	520,779	shopping	1,065,138

enterprises	455,720		

B. Experiment settings

In the experiment, we use the past 14-day historical data to predict the flow in the next 7 days. The number of hidden layers for LSTM is two with 64 hidden units. The dimension of graph convolution is set to 64. Adam [18] is selected as the optimization algorithm, and the initial learning rate is set to 0.001. Here 10% of the training data were selected as the validation set for parameter tuning, and early stopping is used. To speed up convergence, teacher forcing [19] is applied, which means we feed the actual flow to the decoder at the training stage. We perform Xavier initialization to initialize all the trainable parameters. The training process takes about 8 hours on a single TITAN XP GPU.

C. Baseline & Metric

We compare the proposed model (AMGC-Seq2Seq) with the following methods:

- **Historical Average (HA):** The historical average model predicts the flow by using the average value of history. In our experiment, the prediction is the average from the same time in previous weeks.
- **Autoregressive Integrated Moving Average (ARIMA):** ARIMA is a widely used time series prediction model. There are three parameters (p, d, q) need to be set for the model. The degree of differencing is set as $d = 1$. Here p and q are determined by grid search on the training set.
- **Seq2Seq:** Sequence to sequence model has been proved to be effective for time series prediction problem. Same as our model, Seq2Seq model is trained on all stations.
- **AGC-Seq2Seq [15]:** AGC-Seq2Seq is a graph based seq2seq model to predict traffic speeds. The encoder of

that model is different from ours in two aspects: (1) They employ only one graph while we combine multi-graphs, and (2) we have one more LSTM which is used to capture the local temporal relations for each station.

We use Mean Average Percentage Error (MAPE) and Rooted Mean Square Error (RMSE) to evaluate the proposed model, which are defined as follows:

$$MAPE = \frac{1}{NT} \sum_{i=1}^N \sum_{j=1}^T \frac{|\hat{y}_{t+j}^i - y_{t+j}^i|}{y_{t+j}^i} \quad (25)$$

$$RMSE = \sqrt{\frac{1}{NT} \sum_{i=1}^N \sum_{j=1}^T (\hat{y}_{t+j}^i - y_{t+j}^i)^2} \quad (26)$$

D. Performance comparison

Table II shows the performance of the proposed model compared to all other competing models. AMGC-Seq2Seq achieves the lowest RMSE (6.15) and the lowest MAPE (23.66) among all the methods. More specifically, HA and ARIMA perform poorly, as they rely on only historical data for prediction. Deep learning methods, including Seq2Seq, AGC-Seq2Seq, and AMGC-Seq2Seq, which are able to model the spatial-temporal relations, generally outperform the traditional methods. Compared with AGC-Seq2Seq, the proposed model further utilizes multi-graph convolution and one more LSTM to capture the local temporal relation for the individual station, which results the lowest RMSE and MAPE.

TABLE II
PERFORMANCE OF DIFFERENT METHODS

Method	RMSE	MAPE(%)
HA	8.03	30.23
ARIMA	7.54	27.89
Seq2Seq	6.73	25.93
AGC-Seq2Seq	6.48	24.82
AMGC-Seq2Seq	6.15	23.66

E. Effect of multi-graph convolution

Here we study the effect of multi-graph convolution. Table III shows the results when we only use a single graph (distance or POI graph) for prediction. According to the results, we observe that a single graph can be worse than the baseline method(e.g., the model of POI graph yields a result which is worse than Seq2Seq model). However, by combining them, our model beats the AGC-Seq2Seq with the lowest RMSE and MAPE, which proves the effectiveness of the proposed multi-graph convolution.

TABLE III
PERFORMANCE OF DIFFERENT GRAPH

Method	RMSE	MAPE
AGC-Seq2Seq + POI Graph	7.46	30.26
AGC-Seq2Seq + Distance Graph	6.52	25.35
AMGC-Seq2Seq	6.15	23.66

F. Effect of attention

Figure 2 shows the prediction of station 1 from 7/6 to 7/26, where the data from 7/6 to 7/19 are used as the historical data, and the flow from 7/20 to 7/26 are predicted by our model. In the attention mechanism, $a_{i,t}^t$ in eq.(20) measures the relevance of the historical information in the predicted state. The corresponding attention heatmap of station 1 is depicted in Figure 3, where the darker the color is, the more the relevance there are between two dates. One interesting finding is that when predicting flows on weekdays, the model tends to look at the latest history. However, when predicting flows on weekends (7/22 and 7/23 in this example), the model tends to look at the information on weekends from the history (7/15, 7/16, 7/8 and 7/9 in this example). These results confirm that our model can automatically capture the relevant information to make a more robust prediction.

Fig. 2. Outflow of station 1

Fig. 3. Attention heatmap of station 1

V. CONCLUSION

In this paper, we propose a novel deep learning model AMGC-Seq2Seq for flow prediction in a car-sharing system. There are two novelties of the proposed model. The first is that we utilize multi-graph convolution to model the spatial relations from different aspects. The second is that we incorporate LSTMs with a graph convolution network in a "hamburger" structure which capture both spatial and temporal relations effectively. We evaluated the model on a large-scale real-world car-sharing dataset from EVCARD. The experiment results show that the proposed model achieved better results than state-of-the-art baselines. In future, we plan to investigate the following aspects: (1) evaluate the proposed model on other datasets. (2) incorporate more diverse features (e.g., road network) in a car-sharing system.

Abstract—Recently, deep learning models have emerged as powerful tools for relation extraction. However, little work has been done on relation extraction for the Chinese language. One major challenge for relation extraction in Chinese texts is that Chinese sentences have no obvious word segmentation. This ambiguity increases the possibility of word segmentation errors. Another challenge is the lack of broad-scale Chinese text datasets. In this paper, we propose an attention-based multi-instance multi-label bidirectional long short-term memory network for distantly supervised Chinese relation extraction. Our model takes Chinese character embeddings and position embeddings as input without Chinese word segmentation errors. Then, the attention mechanism is used to extract richer Chinese character and sentence features. Finally, we handle the multi-label nature of relation extraction by using multi-label loss functions in the neural network classifier. Based on the idea of distant supervision, we constructed a new dataset for relation extraction in Chinese texts. Experiments on this dataset show that our method has achieved relatively high performance, and that the proposed network architecture is suitable for Chinese relation extraction. Furthermore, we also ran experiments on a popular English benchmark dataset, and the results show that our method is superior to some existing methods.

Index Terms—Chinese relation extraction, distant supervision, attention, bidirectional long short-term memory network (BLSTM).

I. INTRODUCTION

Relation extraction is the detection and identification of semantic relations between natural language text entities [1]. The relation extraction problem can be formally described as follows. Given a sentence s and two entities, e_1 and e_2 , in s , predict the relationship type r of e_1 and e_2 in the sentence s . The candidate set of r is a predefined relation set R , and the output is usually a triple (e_1, e_2, r) [2]. As one of the key tasks of natural language processing (NLP), relation extraction has high significance for many applications of NLP, such as question answering and knowledge graphs [3].

Distant supervision is proposed to automatically generate labeled training data by aligning knowledge bases and text for relation extraction [4]. The main idea of distant supervision is that if two entities have a relationship in the knowledge base, then all sentences containing the two entities will represent this relationship. Distant supervision solves

the problem of constructing labeled training data and saves human resources needed for manually labeling data. However, since a sentence containing two entities does not necessarily represent a corresponding relationship, a large amount of noise data is inevitably introduced. Therefore, distant supervision is modeled as a multi-instance multi-label classification problem [5]- [7]. In recent years, deep learning models have been applied in relation extraction [8]. The most commonly used models for relation extraction tasks include recursive neural networks (RecNN) [9], convolutional neural networks (CNN) [10], recurrent neural networks (RNN) [11]. Moreover, LSTM network is an improved variant of RNN that has been widely applied to natural language processing tasks and has achieved good performance [12]. Adding an attention mechanism to the model and weighting the data sequence can effectively improve sequence learning and boost the system performance [13] [14].

The research on relation extraction for Chinese texts is relatively less common than that for English ones [15]. This scarcity can be ascribed to three main difficulties of Chinese relation extraction. Firstly, there is no obvious separation between Chinese words; Chinese words are composed of characters whose combinations are highly complex and ambiguous. Secondly, current Chinese word segmentation systems still have considerable errors that introduce noise into the relation extraction task. Finally, there is a lack of a Chinese corpus for relation extraction.

In this paper, we propose an attention-based multi-instance multi-label bidirectional long short-term memory network (ATT+MIML+BLSTM) for distantly supervised Chinese texts relation extraction. It is sufficient to use raw Chinese sentences as input. The BLSTM and character-level attention modules are used to obtain the important semantic information in each sentence, and then the final sentence vector representation is obtained through sentence-level attention. Also, the multi-label loss function is used in the network model to deal with overlapping relations. In view of the lack of a Chinese dataset, and based on the distant supervision concept, we used CN-DBpedia of Fudan Knowledge Factory ¹ to obtain the identified entity pairs, and aligned them in the SogouCS2012

news text corpus ² to construct a large Chinese character relationship dataset. The model proposed in this paper is evaluated on this constructed dataset as well as on an English benchmark dataset. The results show that the proposed model is suitable for relation extraction in Chinese texts and achieves good performance.

The contributions of this paper are summarized as follows:

- Proposing a deep learning model for distantly supervised relation extraction in Chinese texts.
- Using Chinese character vectors as model inputs to avoid introducing Chinese word segmentation noise into the relation extraction process.
- Making full use of the information of each word in the sentence and all the sentence information with the same entity pair, and handling the overlapping relationships of entity pairs.
- Performing extensive experiments on Chinese and English benchmark datasets showing the suitability and good performance of our model for relation extraction in both languages.

II. RELATE WORK

Over the years, many methods for relation extraction have been proposed. These methods can be mainly divided into three categories: supervised, semi-supervised and unsupervised approaches. Supervised approaches treat relation extraction as a classification task and typically exhibit better performance in comparison to other approaches. However, supervised methods are very time consuming and labor intensive since they require a lot of labeled data. Distant supervision can solve this problem through automatic data labeling. However, distant supervision can cause false labeling problems. Riedel et al. [5] models distant supervision as a multi-instance single-label problem and selects for each entity pair. Furthermore, Hoffmann et al. [6] and Surdeanu et al. [7] noted that there might be multiple relations between entities and hence they cast relation extraction as a multi-instance multi-label learning problem.

Recently, with the emergence of deep learning, many scholars have begun to use deep learning to automatically learn features. In NLP, deep learning methods are mainly based on learning the distributed representation of each word, which is also called a word embedding [16]. Zeng et al. [17] proposed a convolutional neural network for relational classification. Furthermore, Zeng et al. [18] combined at least one multi-instance learning scheme with a neural network model to extract relationships using distant supervision. Zhou et al. [19] used a neural attention mechanism combined with a bidirectional long-term memory network (BLSTM) to obtain important semantic information in sentences. Lin et al. [14] showed that the establishment of a sentence-level attention mechanism for dynamically calculating the weights of multiple instances can be very effective in distantly supervised data. Jiang et al. [20] used the maximum pool across sentences

to select features in different sentences, then aggregated the most important features into the vector representation of each entity pair. In addition, they addressed relation extraction as a multi-label problem. Jat et al. [21] combined multiple complementary models to improve relational extraction, and introduced a new distantly supervised dataset that eliminated the test data noise present in all previous benchmark datasets. Feng et al. [22] applied reinforcement learning to distantly supervised relationship extraction. Relevant side information from KB has been utilized for relation extraction [23] [24].

In the study of Chinese texts relation extraction, lexical and syntactic features are usually used to extract feature vectors, and the classifier SVM can be used for Chinese texts relation extraction [25]. The performance of Chinese relation extraction has been improved by clustering and pattern matching the feature vectors extracted by dependence relationship and parts of speech labeled in relational schema [26]. In the works of [27] and [28], all can reveal that performance of Chinese relation extraction based on kernel function has obtained significant improvement. However, The need for amounts of manually annotated corpora hinders the application of deep learning methods in Chinese texts relation extraction.

At present, relation extraction research and experiments are mainly focused on English. This paper focuses on distant supervision for relation extraction in Chinese texts. Based on the advantages of previous models, this paper proposes a multi-instance multi-label BLSTM model equipped with an attention mechanism. This model can obtain the rich semantic information of the Chinese sentences and handle overlapping relations.

III. MODEL

As shown in Fig.1, the proposed ATT+MIML+BLSTM model consists of three main parts:

- **Sentence Representation:** Enter raw characters of the input sentence into the BLSTM model, and use the character-level attention mechanism to weight the output of each time step of the BLSTM network. Merge the character-level features of each time step into a sentence-level feature vector.
- **Entity-pair Representation:** Use sentence-level attention to give different weights to different statements, implicitly discarding some noise statements.
- **Multi-label Classification:** Multi-label classification is performed by using multiple binary classifiers corresponding to a class of relationships.

A. Sentence Representation

Sentence-level features are designed to construct a distributed representation for each sentence. As shown in Fig.2, we first convert the Chinese characters in the sentence into real-valued vectors. The higher features of the sentence are then extracted by BLSTM. The final character-level attention weights the output of each time step of the BLSTM. The character-level features of each time step are then merged into a sentence-level feature vector.

²<http://www.sogou.com/labs/>

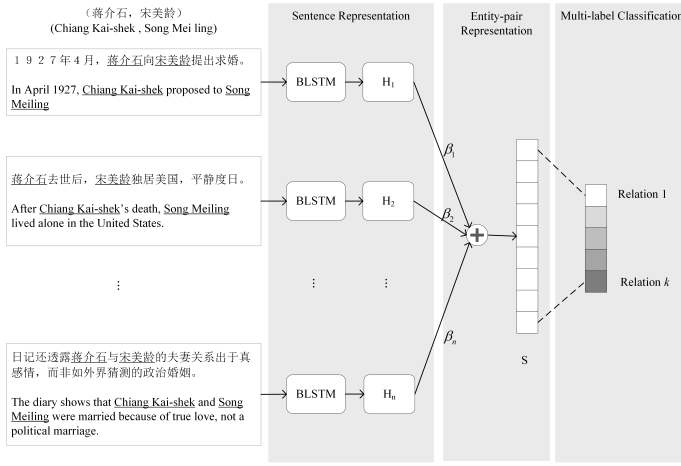

Fig. 1. The architecture of ATT+MIML+BLSTM used for distant supervised relation extraction.

Input Representation Layer. The input for each sentence consists of two embeddings:

Character Embedding: Chinese words are composed of characters, the combinations of which are very complicated. As well, there is no obvious separation between Chinese words. Chen et al. [29] observed experimentally that character features are more suitable for Chinese relation extraction tasks than word features. Based on this observation, we use character embeddings to avoid introducing word segmentation errors into the relation extraction process. The model takes as an input each raw Chinese character in a Chinese sentence s . Therefore, given a sentence $s = \{x_1, x_2, \dots, x_m\}$ consisting of m Chinese characters, we convert each Chinese character into a real-value vector by looking up the pre-trained embedded matrix $V \in \mathbb{R}^{d_w \times |V|}$ (where d_w is the dimension of the character embedding and $|V|$ is vocabulary size).

Position Embedding: Position embeddings are used to represent the structural information of sentences, and two different dimensional position vectors are constructed by the relative distances between each Chinese character and the two entities $e1$ and $e2$.

We concatenate all the character embeddings and position embeddings to get a sequence of vectors $w = \{w_1, w_2, \dots, w_m\}$ (where $w_i \in \mathbb{R}^d$, $d = d_w + 2 \times d_p$ and d_p is the dimension of the position embedding) and set such a sequence as the model input.

BLSTM Layer. The LSTM model can effectively alleviate the long-distance dependence problem of RNN and CNN, and it has been improved and promoted recently by Graves [30]. In many problems, LSTM has achieved considerable success and has been widely used.

In LSTM, the forget gate f_t determines how much information is discarded in the cell state. The gate has three inputs: x_t is the input of the current time step, h_{t-1} is the output of the previous LSTM cell, and c_{t-1} is the memory of the previous cell.

$$f_t = \sigma(W_{xf}x_t + W_{hf}h_{t-1} + W_{cf}c_{t-1} + b_f) \quad (1)$$

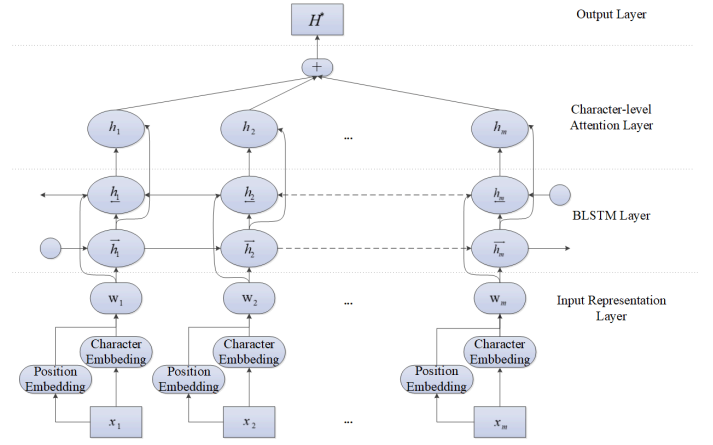

Fig. 2. Detailed structure of the sentence representation.

where, W_{xf} , W_{hf} , W_{cf} , and b_f are weight matrices.

The input gate i_t determines what information will be updated and has the same input as the forget gate f_t :

$$i_t = \sigma(W_{xi}x_t + W_{hi}h_{t-1} + W_{ci}c_{t-1} + b_i) \quad (2)$$

where, W_{xi} , W_{hi} , W_{ci} , and b_i are weight matrices.

Then create a new candidate value vector \tilde{c}_t that will be added to the state:

$$\tilde{c}_t = \tanh(W_{xc}x_t + W_{hc}h_{t-1} + W_{cc}c_{t-1} + b_c) \quad (3)$$

where, W_{xc} , W_{hc} , W_{cc} , and b_c are weight matrices.

Update current cell status c_t :

$$c_t = i_t \tilde{c}_t + f_t c_{t-1} \quad (4)$$

Finally, how much information is controlled by output gate o_t should be entered into the next LSTM cell.

$$o_t = \sigma(W_{xo}x_t + W_{ho}h_{t-1} + W_{co}c_{t-1} + b_o) \quad (5)$$

$$h_t = o_t \tanh(c_t) \quad (6)$$

where, W_{xo} , W_{ho} , W_{co} , and b_o are weight matrices.

As can be seen from Figure 2, the BLSTM layer contains forward and reverse LSTM networks. The output for the i^{th} Chinese character from the BLSTM layer is combined by the forward and reverse outputs by element-wise summation:

$$h_i = [\vec{h}_i \oplus \overleftarrow{h}_i] \quad (7)$$

Character-level Attention Layer. Following the approach of [20], we use character-level attention to capture important information in sentences and improve the accuracy of sentence representation. The vector sequence $H = \{h_1, h_2, \dots, h_m\}$ output by the BLSTM layer is weighted to obtain the final representation of the sentence.

First apply a non-linear activation function on h_i :

$$N_i = \tanh(h_i) \quad (8)$$

Then calculate the weight of the Chinese characters in the sentence:

$$\alpha_i = \text{softmax}(W^T N_i) \quad (9)$$

where, W^T is the training parameter.

The vector representation r of the sentence is obtained by weighting the N_i :

$$r = \sum_{i=1}^m \alpha_i N_i \quad (10)$$

Finally, a non-linear activation function is applied to r to get the final representation of the sentence H^* .

$$H^* = \tanh(r) \quad (11)$$

B. Entity-pair Representation

Distant supervision produces a lot of noise or mislabeled data, and direct use of supervised methods to classify relationships is very ineffective. In order to solve the problem of mislabeling, this paper proposes the construction of sentence-level relational attention on multiple instances by using the selective attention mechanism to weigh sentence vectors and weaken the weight of noisy instances dynamically [14]. Suppose there is a set S containing n sentences of the same entity pair, and the set S is represented as having a real-valued vector, i.e. $S = \{H_1^*, H_2^*, \dots, H_n^*\}$, where H_i^* is the representation of the sentence obtained in the subsection A.

First, calculate the degree to which a sentence H_i^* matches the corresponding relationship.

$$D_i = H_i^* \cdot A \cdot l \quad (12)$$

where A is a weighted diagonal matrix and l is the vector representing the relationship. Therefore, the size of D_i depends on the size of the mapping of H_i^* on l , and sentences that are more closely related to the entity relationship can achieve larger values. Then, we can get the weight β_i :

$$\beta_i = \text{softmax}(D_i) \quad (13)$$

Then for the sentence set S , it can be calculated as the weighted sum of all the sentences in the set:

$$S = \sum_i \beta_i H_i^* \quad (14)$$

C. Multi-label Classification

In this paper, we formalize distant supervision as a multi-instance multi-label learning problem. In this section, we will handle the overlapping relationship of entity pairs. The sentence set vector S obtained in the subsection B, and then get o through a layer of network:

$$o = MS + b \quad (15)$$

where M is the weight matrix of all relational vectors and b is a bias. Thus o represents the confidence score for each relation label.

Then, we use multiple binary functions to do multi-label classification. In particular, we calculate the probability of each relationship. The relationship label is considered accurate if the relationship probability exceeds a certain threshold.

$$p_i = \text{sigmoid}(o_i), i = \{1, 2, \dots, k\} \quad (16)$$

where k is the number of relation labels.

We set the binary label vector y to represent the set of true relationships between pairs of entities, where 1 represents a relation in the set and 0 otherwise. Finally, we use the cross entropy of the sigmoid function as the loss function:

$$\text{loss} = - \sum_{i=1}^k y_i \log(p_i) + (1 - y_i) \log(1 - p_i) \quad (17)$$

where $y_i \in \{0, 1\}$ is the true value on label i .

We train the model in an end-to-end manner. We use Adam to optimize the loss function [31]. In the training phase, we used a dropout mechanism in the BLSTM layer to prevent overfitting [32]. For the testing phase, our method selects a relation with a probability of more than 0.5 as a predicted label.

IV. EXPERIMENTS

A. Experiments on Chinese Character Relationship Dataset

Building Chinese datasets. Using distant supervision, we can automatically construct a Chinese dataset, which avoids labor intensive of manually labeling data. The details of these steps are as follows.

Step 1: Obtain entity pairs with a defined relationship. The large-scale structured encyclopedia CN-DBpedia, developed and maintained by the Fudan University Knowledge Factory Laboratory, is the earliest and the largest open Chinese knowledge extraction system. We set up a list of seed names, use the free API provided by the Fudan Knowledge Factory to obtain the corresponding personal relationships, and then add the character entities not included in the entity list to the list, and iterate over and over again.

Step 2: Align the entity pairs with certain relationships with the Chinese text corpus. The Chinese text corpus uses SogouC-S from Sogou Lab, which is one of the most comprehensive Chinese text corpus resources. Pure text is obtained by data preprocessing through the corpus. The text corpus is aligned with the entity pairs of the first step to get the statements containing the entity pairs.

Finally, the dataset contains eight kinds of relationships (cooperation, friends, couples, parenthood, lovers, faculty-student, brother and sister, others). We divide the training set and the test set according to a ratio of 9:1. The training set contains 220,160 sentences and the test set contains 24,463 sentences.

Experimental settings and evaluation metrics. Chinese character embeddings are trained on the Chinese Wikipedia corpus by the word2vec tool³. We set the dimension of character embedding to 100 and the dimension of position embedding to 5. Position embeddings are randomly initialized with uniform distribution between $[-1, 1]$. At BLSTM layer,

TABLE I
COMPARISON OF P@N RESULTS BETWEEN OUR MODEL AND OTHER MODELS.

	PCNN	BGWA	ATT+CNN	ATT+MIML+BLSTM
P@100	0.87	0.91	0.95	0.97
P@200	0.845	0.885	0.93	0.955
P@300	0.817	0.85	0.923	0.946
Mean	0.844	0.882	0.934	0.957

the number of LSTM hidden units is set to 230. Meanwhile, we use a batch of 64 entity pairs, set learning rate to 0.001 and dropout keep probability to 0.5.

Following previous work [14] [18], We compare the performance of each model with the aggregate curves Precision/Recall(PR) curves and Precision@N(P@N).

We choose the following three deep learning models as baselines: (1) **PCNN**: A piecewise max-pooling over CNN based relation extraction model. (2) **ATT+CNN**: A CNN based model with sentence-level attention. (3) **BGWA**: A piecewise max-pooling over bidirectional gated recurrent unit based model with word-level attention. They are all superior to traditional methods and are also significant works for relation extraction.

Experimental results. The curves in Fig.3 show that our model has a relatively high accuracy and recall rate compared to other models when we perform Chinese relation extraction. In other words, under the same recall rate, the accuracy of Chinese relation extraction using ATT+MIML+BLSTM is higher than other models. We observed that the PR curve of the neural network method (ATT+CNN, BGWA, ATT+MIML+BLSTM) that introduces the attention mechanism is significantly higher than the ordinary neural network method PCNN. It can be seen that the attention mechanism can improve the performance of the model. In addition, our model is superior to the CNN model which also adopts sentence-level attention, which shows that BLSTM combined with word attention can obtain richer semantic information, and considering multi-label problem can

Fig. 4. Performance comparison of our method with five popular methods for English benchmark dataset.

TABLE II
STATISTICS OF THE NYT10 DATASET.

	Sentences	Entity Pairs	Relations
Training	522611	281270	53
Testing	172448	96678	53

improve model performance. Table I shows the results using the P @ N metric. Similar to Figure 4, our approach is superior to other methods overall. And when N is smaller, our method accuracy is marginally higher than others.

B. Experiments on the English Benchmark Dataset

In order to evaluate the performance of our model on other languages, we conducted a comparative experiment on the English dataset proposed by Riedel in 2010 [5]. The dataset is generated by the heuristic matching of Freebase and the New York Times(NYT), and is a popular benchmark dataset. As shown in Table II, the dataset contains 53 relationships (including "NA", indicating that there is no relationship between entity pairs). We used sentences from 2005 to 2006 as training data and sentences from 2007 as test data.

The parameter settings for the English experiments are like those of the Chinese ones, except that the input is word embedding, the word embedding dimension is 50, and the batch size is 50.

We compare our model with three traditional methods(Mintz [4], Multir [6] and MIML [7]) and two popular neural-based methods(ATT+CNN and BGWA). They are major works for English relation extraction based on distant supervision.

Fig.4 clearly shows that the PR curve of our model (ATT+MIML+BLSTM) is above those of the other models, so our model is not only superior to traditional methods but also neural-based methods. Since the size of the Chinese dataset we constructed is smaller than the English benchmark dataset and the amount of noise data is different, there is a small error in the experimental results on the two datasets. However, we

can still conclude that our model is superior to other models, especially for Chinese relation extraction.

V. CONCLUSION

In this paper, we propose a multi-instance multi-label neural network model based on the attention mechanism for Chinese relation extraction. It can not only obtain the rich semantic information of the sentence, but also consider the multi-relationship problem of the entity pair. Experiments on a Chinese dataset based on distant supervision prove that the neural network model combining attention mechanism and multi-label learning can achieve good results, and the proposed method has better performance than most existing methods on the benchmark English dataset. In the future, we hope to build a large-scale and standardized Chinese corpus, and further study how different loss functions affect the performance of the model.

Abstract—Pruning effectively reduces the size of neural networks, which facilitates deployment of neural networks in production environment, especially in embedded systems with limited computing resources. In this paper, we propose a convolutional neural network pruning method based on attention mechanism. We add an attention module to model to generate scaling factors for channels. The scaling factors are considered as channels' importance score, thus filters and convolution kernels corresponding to channels with lower importance score are removed. Our method has the ability to learn importance of channels during training, instead of considering only the direct impact of parameters like existing methods. Moreover, it does not depend on any dedicated libraries, so could be combined with other compression methods for better performance. In experiments, we prune about 90% parameters in VGGNet with 0.67% accuracy drop and prune about 50% parameters in ResNet-56 with 1.02% accuracy drop.

Index Terms—convolutional neural network; pruning; attention mechanism

I. INTRODUCTION

In recent years, with the rapid development of deep learning, convolutional neural networks have achieved excellent performance in many fields, such as computer vision, speech recognition and natural language processing, etc. However, these extraordinary performances are at the expense of high computational and storage demands. Thus neural network compression technique has great significance for deploying a deep convolutional neural network on embedded devices (like mobile phone and IOT device) with constrained resource.

Many works have been proposed to compress deep models, including network quantization [1], [2], matrix decomposition [3], [4], and knowledge distillation [5], [6]. Pruning is one of the most effective compression methods, it aims to remove redundant parameters in neural networks. Which parameters are redundant depends on importance measurement of parameters. Early studies measure the importance of parameters by calculating second derivative of parameters to loss function [7], [8]. In spite of their success, second derivative has expensive calculation and memory overhead. Thus, most recently proposed pruning methods are based on direct impact of parameters, such as parameter magnitude [9] or sparsity of

output [10], which do not take correlation between parameters and loss function into consideration.

In this paper, we propose a filter-level pruning method based on attention mechanism. In our method, an attention module (SEBlock [11]) is added to network to generate scaling factors for channels, then we consider scaling factors as channel importance score to guide filter-level pruning. The attention module adjusts scaling factors of channels according to loss function in backpropagation, which associates the importance score of parameters with loss function. By removing filters and convolution kernels corresponding to low importance score channels, we can effectively reduce size of deep model and maintain prediction accuracy.

We conduct experiments on CIFAR-10 dataset [12], results show that our method can remove about 90% parameters in VGGNet [13], with only 0.67% accuracy drop. Pruning on ResNet-56 [14] also be conducted to verify the effectiveness of our method on the network with shortcut connections. More serious decrease of accuracy appears on ResNet-56 since it is a compact network, but we still remove half of parameters with roughly 1% accuracy drop. Moreover, we compare our method with weight sum [9] and APoZ [10] on CIFAR-100 [12], the result shows that our method has better performance under the same pruning ratio.

II. RELATED WORK

LeCun et al. [8] proposed that some of the neurons connections in neural networks could be removed without decreasing model accuracy. Similar to LeCun's work, Hassibi et al. [7] used hessian matrix to get the second derivative of parameters. However, the spatial complexity of hessian matrix is $O(n^2)$ (n is the number of parameters), which has expensive memory cost on deep models. In order to avoid problem mentioned above, recent studies prefer to prune models according to direct impact of parameters. Han et al. [15] proposed that the magnitude of the parameters could reflect the importance of the parameters, they remove parameters below a certain threshold to get compact model. Deep compression [16] further compress deep neural networks with pruning, trained quantization and Huffman Coding. However, pruning neurons connections produces sparse matrices, which relies on specific operational libraries and hardware to exploit performance advantages [17].

Correspondence: yaowenbin@bupt.edu.cn

DOI reference number: 10.18293/SEKE2019-147

In order to avoid the limitation of pruning neurons connections, structural pruning method was proposed. Lebedev et al. [18] explored a structured sparsity learning method(SSL), which adds the regularization term of parameter group to loss function so that certain groups of parameters would shrink to zeros during training, eventually be removed safely. However, SSL still destroys the network structure and depends on dedicated libraries.

In recent researches [9], [10], [19], [20], filter-level pruning become an effective pruning method that completely avoid using dedicated libraries. Li et al. [9] calculated the sum of the absolute values(L1 paradigm) of weights in filters as their importance score. This method has strong limitations because L1 paradigm of filter does not reflect the feature extraction ability of filter. Hu et al. [10] observed the sparsity of the ReLU activation function and assumed that a neuron is unimportant if most outputs of the neuron with ReLU are zero. Although Hu's method considers more further effects of the filters, it still does not determine the importance of parameters according to loss function. The methods mentioned above are based on the direct impact the parameters, which does not well represent the effect of parameters on neural network's loss function. Meanwhile, they are artificially formulated, which leads to that human intervention is added in training process which violates the rules of end-to-end training in deep learning.

III. OUR METHOD

In this section, we would first introduce filter-level pruning, which determines the granularity of our pruning method. Then, the attention module used in our method would be described. Next, average scaling factor formula would be presented. Finally, we would show overall steps of our method and pruning strategy adjustment on special model.

A. Filter-level pruning

As shown in Fig. 1, each layer of neural network consists of several filters, one filter has a set of convolution kernels. Instead of generating sparse matrices or destroying network structures, filter-level pruning removes entire filter, which maintains the regularity of the network. For example, channel2 would disappear when the filter2 marked by dotted lines are removed. In this case, convolution kernels process channel2 in next layer could be removed as well.

In a convolution layer, if we suppose its original parameter matrix is expressed as $W_{<I,W,H,C>}$, where I is the number of input channels, W is the width of convolution kernels, H is the height of convolution kernels and C is the number of filters. We can calculate the number of parameters in this layer as:

$$|W_{<I,W,H,C>}| = I \times W \times H \times C \quad (1)$$

If we set the filter pruning ratio of this layer to q , $q \times C$ filters in this layer would be removed, so that the number of remaining parameters in this layer can be calculated as:

$$|W_{<I,W,H,(1-q)C>}| = I \times W \times H \times (1-q)C \quad (2)$$

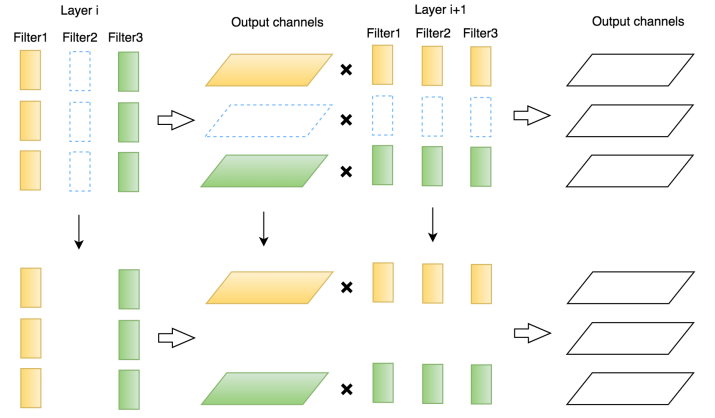

Fig. 1. Filter-level pruning.

If we set the filter pruning ratio of the front layer to p , $p \times I$ convolution kernels in this layer would be removed, so that the number of remaining parameters in this layer can be calculated as:

$$|W_{<(1-p)I,W,H,(1-q)C>}| = (1-p)I \times W \times H \times (1-q)C \quad (3)$$

Obviously, after pruning all layers, the total parameters of the convolution layer would be reduced to $(1-p) \times (1-q)$ of the original layer. In other words, $q + (1-q) \times p$ of the parameters would be removed.

B. Attention module

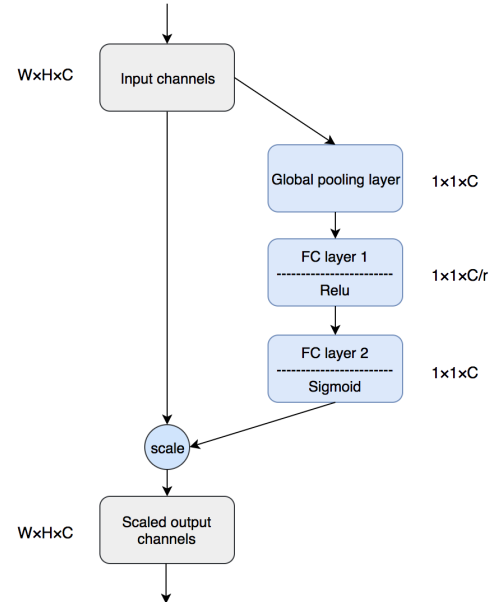

Fig. 2. SEBlock structure, the blue part is SEBlock.

As mentioned in related work, the filter-level pruning methods lack the consideration of correlation between parameters and loss functions due to computational complexity. To calculate importance score of filters according to loss function in a feasible computational complexity, we use attention module

Fig. 3. The overall pruning steps of our method.

to generate scaling factors for channels and adjust scaling factors in backpropagation. In this case, which channel is enhanced or suppressed can be reflected by the scaling factors. Then we can rank channels by their scaling factors with the rule that channels with smaller scaling factors are less important. Because the one-to-one match between each filter and each channel, unimportant filters can be selected according to channel rank.

The attention module (namely SEBlock) used in our method comes from Squeeze-and-Excitation Networks (SENet) [11], which is designed for image classification tasks. SEBlock consists of a global average pooling layer, two fully connected layers, sigmoid activation function and ReLU activation function. SEBlock can be added after convolution layer, take the convolutional layer's output channels as input data, produce scaling factor for each channel.

As shown in Fig. 2, SEBlock takes a C channels as input, obtain a vector with C elements after the global average pooling layer. The number of neurons in first fully connected layer is C/r , where r is a hyper-parameters for controlling module parameter number. Between the first and the second fully connected layer is a ReLU activation function. The second fully connected layer has C neurons in order to produce C output value. Finally, the C output values of are projected between 0-1 by sigmoid activation function to become scaling factors. The output channels of SEBlock can be obtained by multiplying each input channel with corresponding scaling factor.

Although SEBlock was originally designed for improving the accuracy of image classification, its scaling factor reflects the network's choice of feature, which is the embodiment of the channel importance. Channel-level weights introduce more scale features to the network and further enhance the expressive ability of the network. By explicitly describing the importance of inter-layer channels, model would eventually show the phenomenon of restraining or enhancing some channels. Therefore, our method uses the scaling factor produced by SEBlock as channel importance score, and prunes filters in the same layer according to channel rank. Since parameters in SEBlock are randomly initialized, the model would seriously lose its prediction accuracy at first. However, after 1 epoch fine-tuning, the model would quickly return to its original prediction accuracy level, after several epochs it would completely recover from adding SEBlock.

C. Average scaling factor

For SEBlock, scaling factors of channels are data-driven, so we collect a dataset for calculating average scaling factors. Given a collected subset with N images. We calculate average of scaling factor I_C as follows:

$$I_C = \frac{1}{N} F_{se}(X_{<n,H,W,C>}) \quad (4)$$

I_C is a vector having C elements, each element is average scaling factor of corresponding channel, $X_{<n,H,W,C>}$ is C input channels produced by n^{th} image in dataset, W, H is the shape of each channel and F_{se} is the operation of SEBlock.

If the training dataset is not too large, we can directly use the entire training dataset. However, in order to reduce the computational complexity on large datasets, a subset of training dataset is sufficient for calculating average scaling factor. The amount of samples depends on the total number of samples in the training dataset. In our experiments, 10%-20% of the training sample is enough for importance evaluation.

D. Steps of our method

Pruning steps are shown in Fig. 3, the specific steps are as follows:

- 1) **Adding SEBlock.** Given an original model, SEBlock needs to be added after each convolutional layer. Then, we would prune model layer by layer with a predefined pruning rate p , which means p and q in Eq. 3 is equal.
- 2) **Fine-Tuning.** After adding SEBlocks or pruning, the model's prediction accuracy would decrease. By fine-tuning (retraining) the model, it would recover from damage. Meanwhile, SEBlock would scale channels according to their contribution to the loss function.
- 3) **Selecting Channels.** We sort channels in current layer by importance score, and select $p \times C$ channels with small scaling factors as unimportant ones. In our experiment, we set the pruning rate p of each layer to the same.
- 4) **Pruning.** Aiming to remove low-score channels selected in step 3, the filters and convolution kernels corresponding to these channels would be removed as section A describes.
- 5) **Removing SEBlocks** After pruning, in order to compare pruning performance with other pruning methods, we

remove all SEBlocks. In fact, the SEBlock has few parameters(it is mentioned in [10] that SEBlock only leads to about 10% increase in parameter number), which means we could keep SEBlock in practical application.

- 6) **Pruning the Next Layer.** Go to step 2 until all layers are pruned.

E. Pruning Strategy Adjustment

The traditional architecture like AlexNet [21] and VGGNet [22] are often used to verify the effectiveness of pruning methods. In these models, pruning one layer would not change the input shape of other layers except the next layer. But in residual networks like ResNet [14], they have shortcut connections in residual module. Shortcut connection connects the first layer and the last layer in residual module, add them up as the output of residual module. The shortcut connection requires that the shapes of input and output be the same. If the last layer of residual module is pruned, we need to remove the corresponding filters in the first layer without considering their importance score. So it is difficult to prune the last layer of a residual module, in our method, we just prune the first few layers in a residual module, considering that most parameters of residual modules are in these layers.

IV. EXPERIMENTS

We conduct experiments on CIFAR-10 and CIFAR-100 dataset. The CIFAR-10 dataset consists of 60000 images in 10 classes, with 6000 images per class and resolution of each image is 32×32 . The dataset is divided into a training set with 50000 images and a test set with 10000 images. The CIFAR-100 dataset consists of 100 classes, each class contains 500 images for training and 100 images for testing.

On CIFAR dataset, we evaluate our method on two convolutional neural network: VGGNet [13](a variant of vgg16 on the cifar dataset) and ResNet56. The hyper-parameters r mentioned in SEBlock is set to 8 in VGGNet and 4 in ResNet56. For training original model, batch size is set to 128, the learning rate used in first 50 epochs was 0.1, then reduced to 0.01. In pruning process, learning rate is set to 0.01. Weight decay was also used to overcome over-fitting with a coefficient of 0.0001. For calculating average scaling factor, we randomly pick 500 images in each category on CIFAR-10 and 50 images in each category on CIFAR-100. Padding, random cropping and horizontal flipping are applied for data augmentation.

A. Distribution of scaling factors

In this section, the distribution of scaling factors at each layer are visualized. Experiments are conducted on VGGNet with attention module. The distribution of scaling factors are shown in Fig. 4.

The VGGNet contains four stages, distribution of scaling factors in the same stage are similar, so only scaling factors of layer 1,3,5,8 are shown. Fig. 4(a) is the result of the layer 1, which belongs to the first stage. Fig. 4(b) is the result of layer 3, which belongs to the second stage. Fig. 4(c) is the

Fig. 4. Distribution of scaling factors.

result of layer 5, which belongs to the third stage. Fig. 4(d) is the result of layer 8, which belongs to the fourth stage. The results show that the distribution of scaling factors in the same layer is quite different, especially the scaling factor between adjacent channels. This phenomenon is similar to the lateral inhibition of human visual neurons, which is beneficial for extracting the shape feature of objects. With the increase of depth, the distribution range of scaling factor decreases, which implies that the importance of channels near the end of neural network are similar.

B. Results on CIFAR-10

On CIFAR-10 dataset, we evaluate our method on VGGNet and ResNet-56, the results are shown in Table I and Table II. The M in each table means million.

TABLE I
VGGNET RESULTS ON CIFAR-10 DATASET.

Model	Filters pruned	Accuracy	Params	FLOPs
Original VGGNet	0%	92.24%	14.98M	6.27×10^8
	30%	92.18%	7.43M	3.07×10^8
Pruned	50%	91.97%	3.82M	1.57×10^8
	70%	91.57%	1.42M	0.57×10^8

As shown in Table I, we prune 30% filters in VGGNet network without obvious accuracy drop, even get an increase in accuracy when we pruned the first few layers. When we prune 50% filters, we still could maintain the model's accuracy with 0.27% accuracy decrease. We conclude that our method correctly measures the importance of the channel which help model recover from pruning. When filter pruning ratio comes to 70%, accuracy decreases more obviously but still within 1% loss. It is worth noting that, by using filter-level pruning method, number of input channels and output channels for each layer would be reduced by 70%, so reduced parameters can be calculated as section III.D describes: $0.7 + (1 - 0.7) \times 0.7 = 91\%$.

TABLE II
RESNET-56 RESULTS ON CIFAR-10 DATASET.

Model	Filters pruned	Accuracy	Params	FLOPs
Original ResNet-56	0%	92.84%	0.85M	2.51×10^8
	30%	92.43%	0.58M	1.76×10^8
Pruned	50%	91.82%	0.42M	1.26×10^8
	70%	90.86%	0.25M	0.76×10^8

Table II shows the results on ResNet-56, different from VGGNet, pruning on ResNet-56 causes a relatively large decrease of accuracy. We prune ResNet-56 with 3 different compression rates as well: 30%, 50%, 70% filters in each layer respectively. Although it cause more serious accuracy decrease than VGGNet, we still prune more than half of the parameters with 1.02% accuracy drop.

According to our analysis, this phenomenon is reasonable because recent network architectures has an improvement of the utilization of parameters. For example, the shortcut connections of ResNet actually makes network structure in a shallow-deep state, which enhance feature fusion and feature delivery. Thus, the parameter utilization of ResNet is much higher than traditional models without shortcut connections, which leads to poor performance on a large percentage of pruning. This phenomenon reminds us that more attentions should be paid when pruning the networks with shortcut connections.

C. Results on CIFAR-100

Our method was compared with Weight Sum [9] and APoZ [10] on CIFAR-100 by pruning VGGNet.

Fig. 5. Our method, Weight sum and APoZ's results on VGGNet.

As shown in Fig. 5, nine groups of experiments were conducted on all methods. Filter pruning ratio of each experiment range from 10% to 90% in step length of 10%. Weight sum has the fastest decline in model accuracy, the accuracy of model begins to decrease significantly when pruning ratio is higher than 10%. It is easy to understand that weight sum

only takes parameter magnitude into consideration, which is not directly related to the model's loss function. APoZ has a better performance, when the pruning rate reaches 50% it begins to have a significant drop in accuracy. This result is reasonable since APoZ considers more further information, channels with more value of zero have less influence on the following layers. However, when pruning ratio is more than 80%, APoZ performs worse than weight sum.

Our method has the best performance among the three methods mentioned above. When pruning rate is less than 50%, the model has almost no drop of accuracy, even if the pruning rate is higher than 50%, the accuracy of the model still decreases slower than the other two methods. An interesting result is that when we prune 90% filters in each layer, our method still retain a certain degree of classification ability, unlike the other two methods whose ability to classify is completely lost. The result indicates that our method correlates the importance of channels with model loss function, which describes the importance of the channels naturally.

D. Results on Mobile Device

The goal of neural network pruning is to reduce the computational resource consumption of neural networks, so as to facilitate deployment on device with limited resources. Therefore, We deployed neural networks on mobile phones for verifying the performance improvement of our pruning method in real scenarios. We tested the performance of the original VGGNet and the VGGNet after removing 50% filters on mobile phones, the device information is: 4 GB Memory, Qualcomm Snapdragon 632 CPU, 2.0GHz basic frequency, training dataset is CIFAR-10 and the framework is Tensorflow. The results is shown in Table III.

TABLE III
RESULT ON MEIZU NOTE 6 MOBILE PHONE.

Parameter	Original	50% filters pruned
Inference time	1046ms	301ms
FLOPs	6.27×10^8	1.57×10^8
Model file size	59.9MB	15.3MB
Parameter Number	14.98M	3.82M
Parameter pruned	0%	75%
Accuracy	92.24%	91.97%

Due to the inference time is affected by hardware, we calculate the average inferences time of classifying a image. Obviously, the pruned model has a significant reduction in file size and inference time. It takes more than 1000 milliseconds for the original model to classify a image, which results in a significant pause of application. On the contrary, the pruned model only takes 301 milliseconds to classify a image, which greatly improves user experience. In addition, the endurance capability of device also benefits from the reduction of computational resource consumption.

V. CONCLUSION

In this paper, we have described a pruning method based on attention mechanism. Different from existing pruning method

based on direct impact of parameters, we use SEBlock to automatically learn the importance of channel during training. As low-score channels and corresponding parameters are removed, memory and computing cost of model would be effectively saved. We validated our method on different datasets, results show that it surpass existing methods under the same pruning ratio. In addition, our method does not require any dedicated libraries or hardwares, thus can be combined with other compression methods.

In future work, we would conduct our method on latest network and larger dataset to verify the generalization of our method. We tend to explore pruning method based on global importance score instead of pruning fixed percentage filters in each layer.

Abstract—Quantitative approaches for software security are needed for effective testing, maintenance and risk assessment of software systems. Vulnerabilities that are present in a software system after its release represent a great risk. Vulnerability discovery models (VDMs) have been proposed to model vulnerability discovery and have been fined to vulnerability data against calendar time. Though, these models have various shortcomings include changes and development of VDMs for different dataset due to diverse approaches and assumptions in their analytical formulation. There is a clear need for an intensive investigation on these models to enhance predictive accuracy of existing VDMs and adopt the actual behavior of software vulnerabilities which were not modeled previously. This study proposed an integrated model to predict a number of software vulnerabilities by hybridizing the Multi-Layer Perceptron (MLP) artificial neural network and Vulnerability Discovery Models. The proposed model is also widely applicable across various vulnerability datasets and models due to its input diversity by providing improved fitting and predictive accuracy. Further, the experimental results show that this model not only retained the properties of traditional parametric VDM models as well as MLP's good nonlinear mapping ability and useful generalization.

I. INTRODUCTION

With the development of Internet technology, software vulnerabilities have increased rapidly and caused an increasing number of serious security issues. A critical vulnerability provides an attacker with the ability to access full control of a software [1] [2]. Therefore, a quantitative characterization of the vulnerability discovery rates is necessary to assess the risks associated with the product.

VDMs are the specialization of software reliability growth models (SRGM) that focus on security errors. Nonetheless, most previous studies reveal that these models are based on SRGMs, which are not empirically enough to deal with vulnerabilities of software [3] [4]. VDMs intensive evaluating the security profile of software as compared to the vulnerability predications models because they are focusing only on vulnerable components of software [5] [6] [7] [8] [9] [10]. Software vendors and customers are using accurate VDMs to understand security trends and patch management. However, current research studies are focusing to develop

further improved VDMs to maximize their predictive accuracy. First VDM model (thermodynamic model) was proposed by Anderson, which was based on SRGMs. However, this model is considered as worst in terms of fitting empirical datasets.

Similarly, various statistical models are used either attempting to capture the underlying processes or applying the principles used in other fields of science to discover vulnerabilities. These models are classified into two categories: time-based and effort-based. Time-based models measure the total number of vulnerabilities over time while effort-based models count vulnerabilities based on testing efforts. The current study focuses on time-based models, which still need further investigation to enhance fitting and predictive accuracy of VDMs. Numerous time-based VDMs model are proposed in previous studies i.e., linear model [11], Rescorla's exponential (RE) models [12], Alhazmi and Malaiyas logistic (AML) [3] and multiversion models [13], Weibull model [14], Younis folded (YF) model, Kapur's logistic model [15], Anand and Bhatt's hump-shaped model [16], and Anand multi-version VDM [17], and Sharma's changing point model [18] to model the rate at which vulnerabilities discovered.

All of the above models are proposed to obtain better fitting and predicting models for different vulnerability datasets but most of them are against of certain vulnerability datasets. These models try to get a better model under a certain condition, but it cannot give good results with every vulnerability dataset. Nonetheless, these models have numerous shortcomings as discussed below:

- 1) VDMs uses different approaches with respect to the assumptions and parameters. In this regards, VDMs can predict different vulnerability discovery rates by using the same dataset.
- 2) A single software vulnerability discovery model premised on the constant assumptions and can predict different discovery rates using the same data.

As the neural network can be applied for a variety of areas because without an assumption similar to traditional models, the used model is more universal. In this study, we proposed an integrated approach to solve the aforementioned key challenges of traditional software vulnerability discovery models. The purpose of the study is to provide a flexible

TABLE I: Software Vulnerability Discovery models used in evaluation

Models Name	Model function	Description
Rescorla Exponential (RE) model [19]	$V(t) = N * (1 - e^{-at})$	Exponential model is proposed to fit real data. The number of vulnerabilities discovered at time t decays exponentially with the time.
Alhazmi-malaiya Logistic (AML) Model [3]	$V(t) = \frac{B}{B * C * e^{A * B * t} + 1}$	It is based on the capturing the underlying process of vulnerability discovery and the rate of vulnerability depends on two factors.
Weibull model [14]	$V(t) = \gamma \{1 - e^{-(\frac{t}{\beta})^\alpha}\}$	It assumes that the vulnerability discovery rate varies according weibull probability distribution function.
Younis Folded (YF) Model [20]	$V(t) = \frac{\gamma}{2} [erf(\frac{t-\tau}{\sqrt{2\alpha}}) + erf(\frac{t+\tau}{\sqrt{2\alpha}})]$	It shows vulnerability discovery model based on the folded normal distribution.

method with an accurate representation of data frequencies regardless of their different vulnerabilities discovery rates. An integrated model takes the assistance of ANN (MLP), which serve as a non-linear hybrid system of traditional VDMs. The classical software vulnerability discovery models are used as the base models and the MLP technique is used to combine the results of base models, which helps to eliminate the influence of external parameters and other anomalies of VDMs, arise due to the assumptions made by these parametric models. The proposed model can take the advantage of classical VDMS in an application domain, as in the linear combination model, and the generalization ability of a neural network, and can improve the predictive ability of the software vulnerability assessment models.

The rest of this paper is organized as follows. In Section II, the proposed method is defined in detail. Experimentations and Results analysis are performed in Section III. In section IV, we discuss and highlights the threats to validity. In Section V, we have discussed the related work. Finally, we conclude our work in Section VI.

II. PROPOSED MODEL

The proposed method is elaborated in Fig 1. It is divided into two phases: Phase-I and Phase-II. Detailed elaboration of these phases has been presented below:

A. Phase-I

In the proposed integrated model the results of multiple basic vulnerability prediction models serve as input to the MLP neural network. Therefore, the appropriate base models needed to be selected from many of the VDMs. As vulnerabilities identified in software shows three stages of the S-shaped models [3]. The learning phase is started from the release of the system until the onset of sustained growth because of increasing popularity. It is followed by the linear phase when most of the vulnerabilities are to be discovered. The saturation phase is eventually considered as the last stage. Alhazmi and Malaiya defined mathematically the transition point between different phases for the AML model. Therefore S-shaped models are more accurate than non-S-shaped models for vulnerability discovery process. However, S-shaped models fitting and predictive capability also depends on the skewness in target vulnerabilities, therefore they never give good predictive results for every vulnerability dataset. In this regard, we

have used the four most popular VDMs (i.e., models ranging from an exponential to S-shaped models), which are shown in Table 1, with detailed equations.

After selecting the based VDM models, combined results of these models, are used as input to the MLP neural network. We have used the cumulative number of vulnerabilities as a dependent variable, and time which is measured by months, as an independent variable. A set of known cumulative vulnerability data sequences $v_1(t), v_2(t), v_3(t) \dots v_n(t)$ are used as a input to vulnerability discovery models such as:

$$VDM_i = f(v_1(t), v_2(t), \dots, v_n(t), a_1, a_2, \dots, a_r), (i = 1, 2, \dots, n) \quad (1)$$

where a_1, a_2, \dots, a_n are parameters, and t denots specific vulnerability occurence time. We have used it on a monthly basis. The input vulnerability data sequence is denoted as $v_1(t), v_2(t), \dots, v_n(t)$ and the future trend vulnerability discovery rates can be written as: $v_{n+1}(t), v_{n+2}(t), v_{n+3}(t) \dots v_{n+l}(t)$. After applying the input data sequences $v_1(t), v_2(t), \dots, v_n(t)$ in each vulnerability discovery model (VDM_i). Here, i shows the specific number of VDMs. However, n denoted the total number of vulnerabilities used to estimate parameters and $n + j$ shows the future predicted values.

The output of first VDM_1 approximation solution/fitted data and its future trend or predicted values are determined as $VDM_1(fit) = y_1^{(1)}, y_2^{(1)}, y_3^{(1)} \dots y_n^{(1)}$ and $VDM_1(pre) = y_{n+1}^{(1)}, y_{n+2}^{(1)}, y_{n+3}^{(1)} \dots y_{n+l}^{(1)}$ respectively.

Same process is repeated for the i number of VDMs, which generate the specific outputs regarding the input vulnerability data sequences. After applying the input data sequences $v_1(t), v_2(t), \dots, v_n(t)$ in i^{th} vulnerability discovery models, we determine the output of last VDM approximation solution/fitted data and its predicted values as

$$VDM_i(fit) = y_1^{(i)}, y_2^{(i)}, y_3^{(i)} \dots y_n^{(i)}$$

and

$$VDM_i(pre) = y_{n+1}^{(i)}, y_{n+2}^{(i)}, y_{n+3}^{(i)} \dots y_{n+l}^{(i)} \text{ respectively.}$$

In the first phase the input variable v_1, v_2, \dots, v_n are used to get the estimated and predictive results of different VDMs. Assume that the i^{th} number of VDMs have been used to estimate the vulnerabilities and $y^{(i)}$ denotes estimated and predictive outputs of i^{th} models.

B. Phase-II

In the next stage, the results of vulnerability discovery models have been combined by using multi-layer perceptron.

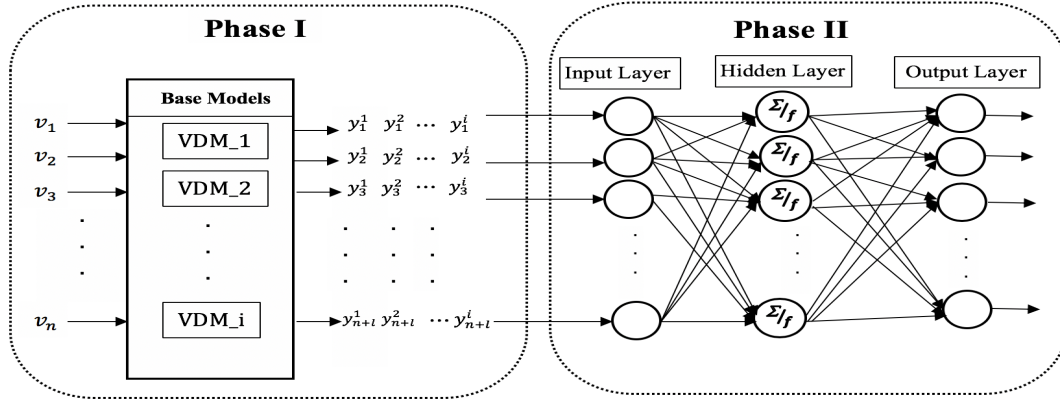

Fig. 1: Detailed diagram of an Integrated VDM model

The MLP is a deep artificial neural network. It is comprised of more than one perceptrons. It works the same way as feed-forward neural network where the back propagation algorithm is in the form of gradient descent function. Almost all algorithms that are applied for MLP training tried to reduce the amount of error by using appropriate functions. In this study, we have used three-layered multilayer perceptron which is composed of an input layer to receive input data and an output layer that predicts input, and in between those two layers, an arbitrary number of hidden layers are present that are the true computational engines of MLP. A nonlinear function is associated with each node like a sigmoid function, except for the input nodes. The MLP network learned a specific target function and adjust weights properly using a general method of linear optimization (gradient function). For this, the derivative of the errors function concerning the network weight is measured. The network weights are changed because of error decreases. The square Euclidean distance is used to compute the error between the actual output and the desired output of a network. The following steps are used, to perform experimentation:

- 1) **Step-1:** The input and output variables are presented first. The vulnerability discovery models outputs from phase 1 are used as input variable ($VDM_1(fit)$, $VDM_2(fit)$, ..., $VDM_i(fit)$) and the actual vulnerability data is used as target variable $v_1(t)$, $v_2(t)$, $v_3(t)$, ..., $v_n(t)$.
- 2) **Step-2:** The entire set of vulnerability data is divided into two parts: training and the testing part. The training dataset is used to train the network for predicting software vulnerabilities. The fitted data of VDMs $y_1^{(i)}$, $y_2^{(i)}$, $y_3^{(i)}$, ..., $y_n^{(i)}$ are used to train the network. For testing the predicted values of different VDMs $y_{n+1}^{(i)}$, $y_{n+2}^{(i)}$, $y_{n+3}^{(i)}$, ..., $y_{n+l}^{(i)}$ are used.
- 3) **Step-3:** The next step in this study is to use 10-fold cross validation method, which divides the data into ten folds. The nine parts are used for training, and the tenth part is used for validation. It is the best validation process to maximize the utilization of vulnerability dataset through

Fig. 2: Models fitting for Window 10

Fig. 3: Models fitting for Internet Explorer

- repeated resampling of the same dataset randomly.
- 4) **Step-4:** After dividing training data into 10-folds, the MLP model is applied for training the models.
- 5) **Step-5:** In this step, the tested data $y_{n+1}^{(i)}$, $y_{n+2}^{(i)}$, $y_{n+3}^{(i)}$, ..., $y_{n+l}^{(i)}$ of VDMs is applied to get the target predicted values $v_1(t)$, $v_2(t)$, $v_3(t)$, ..., $v_n(t)$. The target values are considered as more closer.
- 6) **Step-6:** The statistical efficacy measures are estimated based on the predicted results for all the selected datasets.

III. EXPERIMENTATION AND ANALYSIS

The proposed model has been validated on the security vulnerability data of two software products namely Microsoft

TABLE II: Comparison of VDM models used in evaluation

Models	Windows 10 ($\chi^2_{critical} = 83.6753$)				Internet Explorer ($\chi^2_{critical} = 56.9424$)			
	χ^2	$Pvalue$	DF	R^2	χ^2	$Pvalue$	DF	R^2
RE Model	409.5481	7.467E-52	64	0.9810	428.7739	4.57E-66	41	0.9823
AML Model	1686.6183	0.000E+00	64	0.9739	421.3551	1.33E-64	41	0.9815
Weibull Model	109.5576	3.422E-04	64	0.9938	91.3514	1.06E-05	41	0.9941
Younis Model	245.9183	3.906E-23	64	0.9880	138.7848	1.50E-12	41	0.9913
Proposed Model	34.9911	1.0000	64	0.9990	52.8216	0.102092	41	0.9959

Windows 10 and Internet Explorer obtained CVE details¹. CVE details is a publically available CVE security vulnerability database/information source. Furthermore, a set of models have been used in order to evaluate which model is performing best by comparing their overall performance with the proposed model. We have estimated the parameters of the VDMs using R [21] tool.

A. Model fitting and goodness of fit analysis

To measure the goodness-of-fit, researchers always use Pearson's Chi-square (χ^2) and calculate the statistical value of the curve using the following function.

$$\chi^2 = \sum_{t=1}^n \frac{(O_t - E_t)^2}{E_t} \quad (2)$$

Where O_t and E_t are the observed and expected samples at time t (t^{th} value of the observed sample); E_t denotes the expected cumulative number of vulnerabilities. If the value of χ^2 of VDM for a specific dataset obtains a value less than the corresponding Chi-critical ($\chi^2_{critical}$) value, with the given significant alpha level (0.05) and degree of freedom, it is considered that the model is acceptable. The P-value shows the probability that a statistical value as high as the values obtained by Equation (2) could have occurred by chance. The experimentation data is obtained from the analysis of four VDMs estimated and predicted results. The fitting results of the four VDMs (RE, AML, Weibull and Younis) for both of the software datasets, with there fitted entries based on the χ^2 test P-values.

For Windows 10, the proposed models fit has remarkable improvement than other models in Table II, and the fit is considered very good since the P-value of the χ^2 test is higher than 0.05. Also, the R^2 values are more close to 1 than other single VDMs. From Fig 2, of the fitted vulnerabilities and the predicted vulnerabilities for the selected models, shows clearly that the hybrid approach performing best results than others. Thus, it is required to combine the output results of different models than only depend on single model results. It not only retains the properties of traditional software discovery models but also combines neural network (MLP) good nonlinear mapping ability and useful generalization.

For Internet Explorer, the proposed model also shows good fit than other models, as shown in Table II. The P-value

obtained is 0.102092, which is higher than χ^2 test P-value 0.05. Also, the R^2 values are more close to 1 than others. Fig 3, shows that the fitted and predicted curve of the proposed model has better predictive ability among all other models under consideration.

Thus, it is also concluded that the proposed integrated model can produce good results with different types of vulnerability datasets than the single traditional VDMs. It is also clearly visible in Fig 2 and 3 that the integrated model developed by combining four models have better fitting and end-point predictive capability than the models alone.

TABLE III: Average Bias and Average Errors comparison

	Windows 10		Internet Explorer	
	AB	AE	AB	AE
RE	0.2881	0.9990	-1.7984	1.7984
AML	-2.7989	0.0000	-1.5529	1.5529
Weibull	-0.4353	0.0000	0.3348	0.3348
Younis	-0.9040	0.0000	1.5041	1.5041
Proposed	0.0143	0.0000	-0.1472	0.2443

B. Improved predictive capabilities of VDMs

Goodness-of-fit tests often used to assess the applicability of VDMs. The main use of these models is to predict future trends based on the previous data, rather than reviewing the past behavior. Therefore, predictive capability should also be considered important than just model fitting. The estimated final values for each time point produced by the four existing and proposed integrated VDM are compared with the actual number of vulnerabilities to calculate the predicted errors. The prediction time span is selected as long term, which is the main concern of software users to decide whether the select the software for inclusion in a product with a longer lifetime [22]. Therefore, the last 12 months vulnerability data is predicted for both software. The two normalized prediction capability measures [23], average error (AE) and Average bias (AB), as shown in Equation 3 and 4 respectively, are evaluated.

$$AE = \frac{1}{n} \sum_{t=1}^n \left| \frac{\Omega_t - \Omega}{\Omega} \right| \quad (3)$$

$$AB = \frac{1}{n} \sum_{t=1}^n \frac{\Omega_t - \Omega}{\Omega} \quad (4)$$

In the above equations, n is a total number of time points (in months), and Ω_t is the estimated number of total vulnera-

¹www.cvedetails.com

Fig. 4: Predicted Errors of different VDMs for Windows 10

Fig. 5: Predicted Errors of different VDMs for Internet Explorer

bilities at time t , and Ω is the actual number of a total number of vulnerabilities.

The normalized error values ($\frac{\Omega_t - \Omega}{\Omega}$) for windows 10 and Internet Explorer 11 are plotted in Fig 4 and 5. The values of AB and AE are given in Table III. AE always give positive values and AB may give both positive and negative. Fig 4 and 5 shows that the improved models give better predictive results. As in Table 4, the AB and AE values for both yields good results after applying HPEIAM method on each of the models. The results yields after applying our technique give lower AB and AE values than the base models itself.

IV. DISCUSSION AND THREADS TO VALIDITY

In this study, we put forward MLP based integrated vulnerability discovery model, and verify the model's superiority over other models with experimentation. This integrated model is comprised of two phases including the first phase, which reflects the linear combination VDMs, and a second neural network phase, which serve as non-parametric modeling of input data sequences. The proposed approach focuses on the relationship of the performance of VDMs with the specific vulnerability discovery datasets. The fitting capabilities of four VDMs along with the chi-square goodness of fit test as well as R-squared metric indicate that the integrated model fits well, for both of the datasets. Besides, the future trend predictive capability can also be estimated using the two main predictive measuring criterion: AB and AE. The results reveal that the integrated model's predictive results also show more accuracy than the other existing VDMs predictive capability. Therefore, we conclude that the proposed method can be applied as a

solution for software vulnerability rates estimation problems, outperform competing VDMs investigated in this study.

As the proposed integrated model makes the results of multiple basic vulnerability models (base model) as input to the MLP neural network, the accuracy is in part dependent on the predictive accuracy of these models. Therefore the appropriate base models need to be selected from many software vulnerability models. In this study, only four VDMs have been selected as base models, however to analyzing the characteristics of software vulnerability data, and using the appropriate model selection based on specific criterion is required to get more accurate results. Another limitation is the sample data. Our study analyze publicly reported vulnerabilities without considering unreported data. While this is a common drawback among vulnerability research, overcoming this limitation requires direct contact with software vendors.

V. RELATED WORK

Recently, many VDMs have been proposed by researchers, to model the software vulnerabilities accurately. These models either attempting to capture the underlying processes or applying the principles used in other fields of science to discover vulnerabilities. Each model uses a different approach and with different assumptions and parameters.

Among them, the exponential model is designed to fit the real data [12]. In this model, two possible trends were examined, such as the quadratic model and the exponential model. The logarithmic model shows the total number of vulnerabilities as logarithmic growth that was first proposed by Poisson [24] and later it is used by Rahimi [25] adjusting fitting of the model to the vulnerabilities of a specific application. Alhazmi and Malaiya proposed a logistic model called AML model in [26] and analyzed AML in [27]. The predictive capabilities were evaluated in [28] and [4] by using a different set of data. Chan et al. proposed a multi-cycle vulnerability discovery model, which helps to extend the scope of existing models [29]. Younis et al. [20] inspected the applicability of Folded VDM and compared it to AML on Win7, OSX 5.0, Apache 2.0 and IE8, and stated that YF was somewhat better than AML. Joh and Malaiya proposed different S-shaped models based on the distribution of Weibull, normal, beta and gamma distribution to evaluate the applicability of the models using different approaches [30]. Kapur et al. proposed models for the prediction of software vulnerabilities and determine whether software reliability growth models can be used to predict the vulnerability discovery process and show good prediction results [31]. Recently, Anand and Bhatt [16] proposed a hump-shaped model to capture the vulnerability exposure pattern due to the attractiveness of a software product in the market using weighted criteria based ranking approach. Joh and Malaiya analyze vulnerability data using the seasonal index and auto-correlation function approaches, which can be used to improve the vulnerability discovery models [32]. Sharma and Singh proposed a new vulnerability discovery model based on the gamma distribution [33].

Each model defined above uses different approach with different assumptions and parameters. As a result, the VDMs can predict different vulnerability discovery rates using the same data and there is no guidance available about which model should be used in a given situation. This paper attempts to address these problems by integrating the classical VDMs and neural networks.

VI. CONCLUSION

In this study, based on the analysis of the neural network modeling and the linear combination model, we proposed a neural-network-based integrated model. The proposed model achieved better fitting and predictive capability and perform similar or superior as compared to classical and state of art VDM models. It not only retains the properties of vulnerability discovery models but also combines the MLP's good nonlinear mapping ability and generalization. To our knowledge, this is the first study which combines the VDMs and neural network to predict the number of vulnerabilities. Since, the proposed integrated method utilizes the results of classical software vulnerability discovery models serve as input to MLP neural network, so the further study is needed to select appropriate base models from number of software VDMs. In addition, a number of further investigations are possible such as replicate the experiment with advance machine learning techniques and more vulnerability datasets.

Abstract—Learning how to build software systems using new tools can be a daunting task to anyone new to the job. This is especially true of tools that provide a large number of functionalities and views on the system under development, such as IDEs for Model-Driven Development (MDD). Applying Machine Learning (ML) techniques can help in this state of affairs by pointing out to appropriate next actions to rookie or even intermediate developers. AutoFOCUS3 (AF3) is a mature MDD tool we are building in-house and for which we provide regular tutorials to new users. These users come from both the academia (e.g. students/professors) and the industry (e.g. managers/software engineers). Nonetheless, AF3 remains a complex tool and we have found there is a need to speedup the learning curve of the tool for students that attend our tutorials – or alternatively and more importantly for others that simply download the tool and attempt using it without human supervision. In this paper, we describe a machine learning-based recommendation system named MAGNET for aiding beginner and intermediate users of AF3 in learning the tool. We describe how we have gathered data and trained an ML model to suggest new commands, how a recommender system was integrated in the AF3, experiments we have run thus far, and the future directions of our work.

Index Terms—Model-Driven Development (MDD), AutoFOCUS3, Machine Learning, Intelligent Recommendation Systems (IRS), Eclipse IDE, Domain-Specific Languages () development interaction data

I. INTRODUCTION

Modern IDEs are extremely rich in functionality. Environments such as the Eclipse IDE [4] or the whole range of tools proposed by JETBRAINS [6] are complex, offer an ever-increasing amount of functionalities and are highly customizable. Clearly, over the past decade, IDEs have become increasingly competent at their jobs and help the user in a smart manner, by offering intelligent auto-completion, contextual quick fixes and intentions that help with development productivity while lowering learning curves.

For the past 15 years, we have been developing at fortiss the Eclipse-based AF3 tool [14], [28], for building embedded systems. AF3 is mature and stable and includes articulated perspectives for the complete lifecycle of the development

of embedded systems: from requirements, to architecture, deployment, code generation, simulation and verification.

The goal of AF3 is to demonstrate the feasibility, applicability and relevance of MDD tools. It is an open source tool with a 6-month release period and has served and serves as a means to demonstrate state-of-the-art MDD technology. It is also used as a boiler plate to develop proof-of-concept projects with industrial partners [15], [16], [22], [23].

We have recently started offering a tutorial on AF3 [2] to the academic community and to partner or interested companies. The tutorial involves creating and deploying control software onto a real vehicle and implies manipulating different types of software development perspectives (mostly graphical but also textual) via the Eclipse IDE. Given the learning the necessary IDE manipulations requires effort and constant attention and explanations from dedicated human tutors, we have decided to develop an intelligent and non-invasive automated tutor that can be invoked at the press of a button.

Because AF3 offers interconnected visual (model-based) perspectives of the logic of a system under development, providing automated help in such settings differs from doing so for code-based IDEs. Similar tools to AF3 are MATLAB SIMULINK [7] or LABVIEW [10]. AF3 also partly falls in the category of Domain-Specific Language (DSL) workbenches such as MPS [6], METAEDIT+ [9] or ATOM3 [21] – although building DSLs in AF3 must be done programmatically and outside the tool itself, by using EMF facilities.

In this paper we report on our first steps in the usage of ML to aid beginner students in the discovery and understanding of the AF3 tool. In particular, we have implemented an Intelligent Recommendation System (IRS) called MAGNET, that suggests next steps in the context of an AF3 tutorial. The next steps are shown to the user as short videos illustrating the completion of a low-level task, e.g. building states, transitions or simulating the system.

This article is organised as follows: in section II we present the main functionality of the tool, as seen from the point of view of an AF3 developer. Section III details how we have trained and deployed a recommender system in AF3. We then go on to discuss some preliminary results in section V and to place our work regarding the state-of-the-art in section IV. We conclude with future directions in section VI.

II. HIGHLIGHTS

The MAGNET tool is at its core an Intelligent Recommendation System. Core to MAGNET are:

- a *multiclass classification* model trained by using a machine learning algorithm using anonymized sessions of previous students of AF3, and
- recommendation videos that illustrate accomplishing certain tasks in AF3.

The Multiclass classification model in the IRS predicts, with a very short delay, the state of advancement of the student in the tutorial. The prediction is based on the previous interactions of the student with AF3, as well as on the previously learned *multiclass classification* model. Based on the predicted state, the user is then presented with relevant hints that suggest ways of continuing the tutorial – in the form recommendation videos that demonstrate common low-level of AF3. The videos themselves independent from the tutorial and were built by the Human-Centered Engineering department at fortiss [5] having in mind further reuse for an enlarged IRS. The recommendation videos illustrate common modelling tasks such as how to create a component or a state automaton, how to add transitions or action code to the transitions of an automaton or how to simulate a given software model. The aim is that the new users quickly familiarize themselves with the common visual manipulations of the tool while going through the tutorial.

The recommendation videos can be accessed by a user of AF3 in two ways:

- Via a “*Help Me*” button on the AF3 toolbar (as illustrated in figure 1). In this case the IRS proposes three recommendation videos that were top-ranked by the multiclass classification algorithm. After the press of the button, the top ranked video starts playing. If desired, the user can switch to the other two videos in the order in which they were ranked by the IRS. The time taken by the IRS to display the video after the press of the “*Help Me*” is under 2 seconds.
- Through a global help button. In this case the user does not necessarily want the IRS to predict next tasks, but only to provide a full list of possible help videos with common functionalities of AF3. This global help can be accessed via the menu item “Show All Hints” in the AF3 3 tool bar, under the “AI assistance” drop down menu.

We have also implemented the means to activate/deactivate data acquisition directly through the AF3 interface, keeping in mind data privacy and that some students may not want to have their interaction data stored.

III. MACHINE LEARNING PIPELINE

The user-assistance functionality we wish to implement in MAGNET is providing tips to the user based on a predicted next step in the tutorial. In order to achieve this, it is required to predict the next step of the user and then to provide an adequate hint for it, from the set of predefined short videos. The machine learning pipeline we have implemented to achieve

this consist of the following steps: 1) Data collection, 2) & 3) Data processing including data cleaning, feature selection and data labelling, 4) ML model selection consisting of model training, validation and testing and 5) model deployment. This pipeline is depicted in figure 2 and each of its steps is discussed in the subsequent paragraphs.

1) **Data Collection:** In order to acquire the user interaction data, we instrumented the AF3 framework such that interactions of a user with the tool’s graphical user interface are recorded. The instrumentation is achieved using SWT-BOT [13] and does not interfere with AF3’s functionality. Specifically, we have added an SWTBOT plugin on top of AF3. The plugin starts along with the AF3 tool as a server that listens to events that occur in widgets of AF3’s graphical user interface (GUI). Additionally, we have implemented a thin client that communicates via sockets with the SWTBOT server and records to a file all such interactions. The raw data was collected from 11 users during one tutorial session. Altogether, the collected files contain approximately 28000 lines where each line denotes a specific action at a time instance.

2) **Data Cleaning:** Each line in the collected data contains UNIX Epoch time in milliseconds followed by a string for each of the user’s actions/ interaction. The string consists of two sub-parts, a) a GUI contextual description of the user interaction, and b) a general description of the user action initiated via mouse/ keyboard inputs. During analysis of the data, several characteristics of the data were discovered. Some of the actions recorded in the file are correlated with the preceding actions: for instance, closing of a window is mostly followed by default relocation to last visited window. The same trend is observed with respect to few other attributes in the data. Therefore, the data was filtered to remove such correlations and reduce dimensionality, while ensuring minimum loss of significant information. The filtered data consists of approximately 5000 lines.

3) **Feature selection and Labelling:** After having achieved a basic understanding of the data, two features were extracted from the data namely, **Action** (mouse action/ key board action) and **Property** (task dependent description of users state) in a time ordered sequence. A single line of data in isolation at a particular time may be of a practical use from the point of view of task prediction. This is because each line defines a user action at lower/ micro level e.g., one line may indicate opening of a GUI window. On the other hand, a task is defined at a higher level of abstraction which contains lower level actions and conveys a practical meaning such as for example: opening of a window, followed by defining parameters therein and finally moving to a different window perspective. It therefore became essential to label the data in relation to a set of specific AF3 tasks – the classes to be used by the ML classification algorithm. This forms the basis for the machine learning model to understand the lower level data, recognize the current task and predict the next task at an adequate level of abstraction. Nine labels relevant to the tutorial were defined. The labels consist of user tasks such as *navigating to component architecture, creation and specification (definition)*

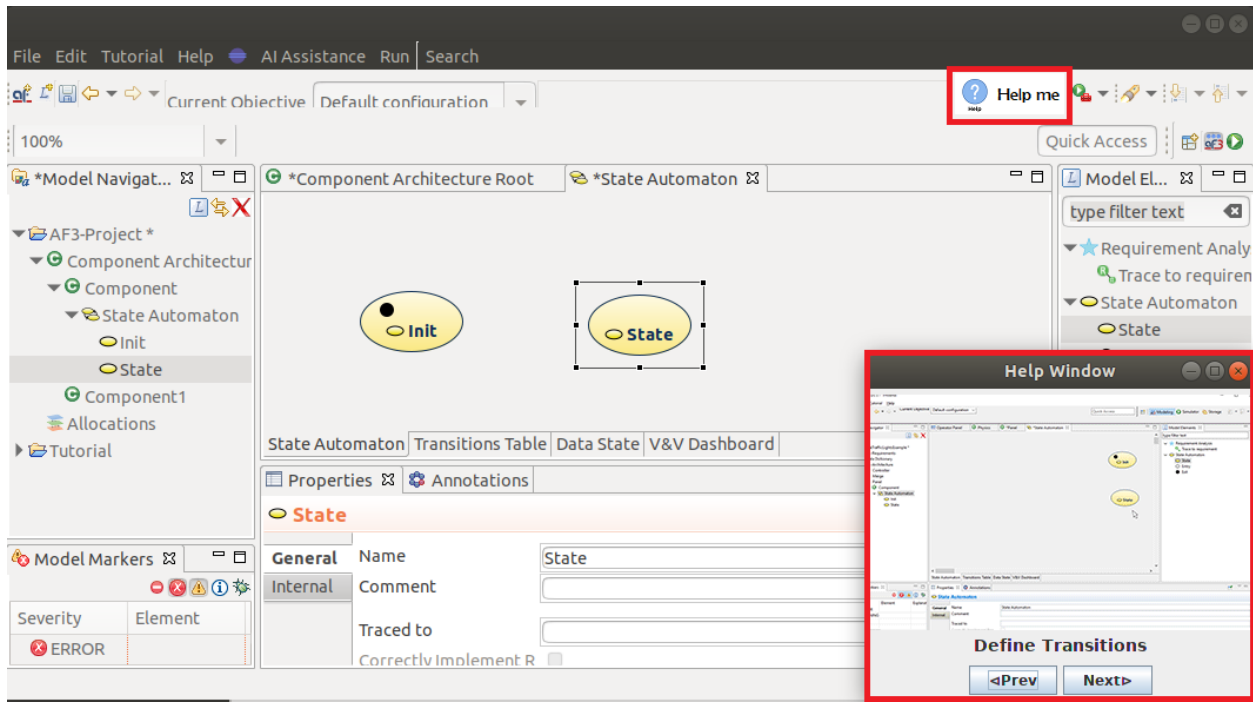

Fig. 1. Recommendation Video in AF3 using “Help Me”

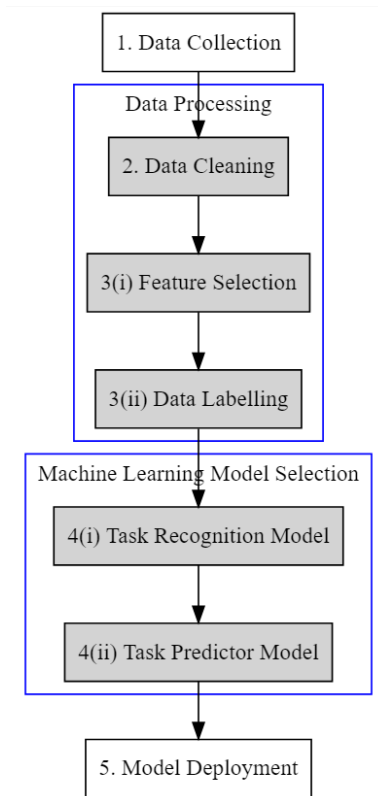

Fig. 2. Machine Learning Pipeline

of components, specification of transitions, creation of ports, writing code and simulation. While defining labels, we kept in mind that these labels should neither be too generic nor too specific, in order to aim for a reasonable granularity that a machine learning algorithm can meaningfully build a model for. The data was labelled manually (approx. 2800 lines) after correlating features in the data with specific tasks. In some cases, when the tasks could not be specifically identified from the features, preceding and succeeding labels were used to infer the current task.

4) **Model Selection:** Learning an objective during the tutorial can be understood as a multi-classification problem based on the features described above. Two levels of abstraction are necessary for predicting the next state of user. The visual representation of the two models is shown in figure 3.

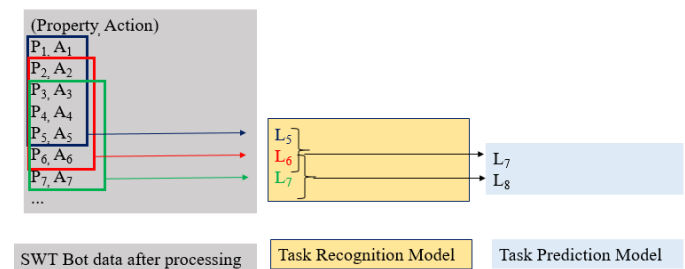

Fig. 3. Visual representation of the models (Recognition and Prediction)

The first level model referred to herein as **Task Recognition Model** takes the input consisting of features: Property (P)

and Action (A) in a time sequence of length u and predicts the corresponding label (L). Figure 3 shows how the **Task Recognition Model** uses a sequence of 5 previous steps i.e., $u = 5$ to predict the current task (label) at a given time t . These predictions act as an input for the second level model. The second model referred herein as **Task Predictor Model** uses the sequence of output labels of length v from Task Recognition Model as an input and predicts the next task of the user at future time step $t + 1$ as an output. As an example, figure 3 shows **Task Predictor Model** uses a label sequence of 2 previous steps i.e., $v = 2$ to predict the label L at future timestep $t + 1$.

Three different machine learning models were tried for training the task recognition model. Due to the similarity of the problem with sequence to sequence prediction, an LSTM model was the first choice [24], [31]. The labelled data was split into training and validation sets in a proportion of 80:20. The LSTM model achieved an accuracy of 20% on the validation data in 100 iterations whereas the training accuracy was very high. The results of LSTM model are shown in figure 4. We attribute the poor performance of the LSTM model on validation data to the model overfitting the training data.

Fig. 4. Training and Validation Accuracy for LSTM Model

Given the weak results obtained from the LSTM, we subsequently moved on to a Random Forest model. This model achieves the best validation and test accuracies of 66% and 58% of all tried models, for $u = 5$. These results show that random forest model outperforms the LSTM model in our setting. To attempt further improvement of the accuracy, we also experimented with XGBoost [18]. The results from XGBoost are comparable with those of Random forest model, with validation accuracy and test accuracy of 65% and 60% respectively. Random forest was selected as the final task recognition model on account of its simplicity in terms of fewer tuning parameters, as compared to XGBoost.

Random Forest is also used for the **Task Predictor Model** and it achieves validation and test accuracies of 51% and 56% respectively for $v = 1$.

5) **Model Deployment:** The complete architecture after deployment is shown in figure 5. Without the MAGNET plugin, the user interacts with AF3 but there is no active guidance or feedback from AF3 (1). If SWTBoT is activated, it records the user interaction continuously in the background (2). The model is deployed as a task predictor plugin in Autofocus. The user clicks on the “Help Me” button and actions the trained machine learning model (3). The data from SWTBoT (4) is processed & analysed by the model to predict the user task(s) (5). The video hints according to the predicted task are displayed on the AF3 interface (6), thus providing active guidance for the user and completing the feedback loop.

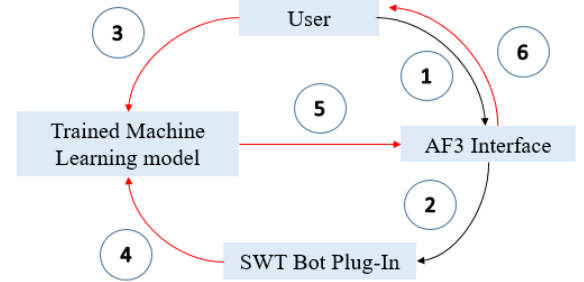

Fig. 5. Architecture of the Recommender System

IV. STATE OF THE ART

The published research that exists focuses on auto-completion mechanism for code-based IDEs, which differ from MDD tools in many ways, chiefly that IDEs for MDD typically deal with many levels of abstraction, often encoded as multiple graphical or textual DSLs. In these tools the process of building software involves mastering a set of different programming paradigms, as well as the inter-relations between different views of the system being developed.

The study of how developers use IDEs was initiated more than a decade ago, at the beginning of the 2000s. The Mylar framework [25] from Kersten and Murphy (later renamed to Mylyn) was one of the first of its kind to provide the developers with the means to define and follow tasks when building software. The framework, distributed as an Eclipse project, allows tracking low-level user commands to keep the state of the task up-to-date while dynamically adapting the IDE such that the navigation possibilities of the IDE are adapted to the developer's needs at each point of the development.

Several authors have concentrated specifically on gathering interaction information from IDEs. The work of Murphy on Eclipse for development in Java [30] was seminal, but more recent efforts exist such as the work from Amann *et al.* for Visual Studio. A survey of methods for collecting IDE interaction data has been proposed by Maalej *et al.* [29].

The natural step after collecting data is to analyse it for patterns that reveal developers' implicit development processes and habitudes, having as goal improving the usability of IDEs. Given the advent of advanced mining tools in the

2010s, authors such as Khodabandelou [26], Damevski [19] and Shepherd [20] have worked on what is now known as *process mining*. The authors have placed importance in not only coming up with models of developer behavior from low-level IDE logs of user-machine interaction, but also in automatically building models of those processes (e.g. using Markov chains) that can be understood by humans.

Since the past 5-10 years researchers have also started exploring how recommender systems can come to the help of software developers. Although the infamous “clippy” that shipped with early versions of the Microsoft office suite was a put off to having recommender systems as part of production software, advances in machine learning and human-computer interaction spawned new attempts at developing such functionality. Autodesk has implemented one such system for AutoCAD to improve the learnability of their tool by contextually proposing previously unseen commands. The company has then conducted a large study with more than 1000 users [27]. The authors of the study conclude that recommender systems are indeed useful and have a rich future in software applications. Damevski [27] as well as Bullmer [17] have explicitly explored classification algorithms to predict developer’s behavior, much as we do. They report accuracies between 20-60%, which are in general lower than the accuracies we achieve. However, it is relevant to mention that the IDEs these authors explore are for code-based development, as opposed to our work on IDEs for model-driven development. In particular, their predictions are made on a large set of commands (e.g. 61 for the study in [17]) for which it will be naturally harder to reach high accuracies as for our work presented here (where 9 labels were used). The same study reports that neural networks have yielded a better accuracy, whereas in the study we present here they have performed the worst.

Outside academia, AF3 strongly relates to modern low-code tools, which employ model- and graphical-based software development principles to enable developers to quickly build, deploy and update applications. The two market leading tools at the time of the writing of this article are *mendix* [8] and the *OutSystems* [11] platform. *mendix* has implemented an AI-based system similar to MAGNET, where most likely steps are suggested to finish a logical workflow. Additionally, a “mentoring” mode is available to teach new developers how to build applications. *OutSystems* is currently investing very strongly in AI-based techniques to aid in software development, having created a laboratory [12] just for this purpose. As with AF3, the AI assistant of the *OutSystems* framework also predicts next steps in the development of the application, which *OutSystems* claims increases developer productivity by 25%. Note that both *mendix* and *OutSystems* are proprietary systems, while AutoFOCUS is distributed as open source.

JetBrains, the developers of a large range of code-based tools for software development, have recently started collecting data to improve their auto-completion systems since 2016 [3]. Additionally, a plugin for predictive coding [1] has been developed for the *IntelliJ* tool from JetBrains that uses machine learning for intelligent auto-completion, as well as

for inserting snippets of code based on comments written in plain English.

V. PRELIMINARY RESULTS

As mentioned in section I, at fortiss we often offer workshops to demonstrate the various functionalities of AF3 to the new users. We have used one of such workshops to evaluate the usefulness of our IRS in one of the AF3 tutorial workshops. The focus group comprised 9 participants and was of mixed technical skills ranging from non-technical (e.g. managers and head of technical departments) to technical (e.g. software engineers). The existing format of the AF3 workshop is such that a human tutor demonstrates the different functionalities of the AF3 at the beginning of the tutorial. The current workshop setting made a few of our recommendation videos redundant for the 3 participants having good programming skills. Nonetheless, the remaining 6 participants having less knowledge of programming (i.e., 5 managers and 1 professor) reported our system was helpful during the workshop giving their lower technical expertise. All feedback from the participants in the study was collected via a formal questionnaire.

As expected, we observed that providing information on AF3 to new users (i.e., technical or non-technical) reduces the use of our IRS. Seen from the reverse perspective, this points towards reducing human intervention in the tutorial (which is desired), which should lead to more usage of the IRS and a better evaluation of our proposal. It is worth mentioning that two participants (1 professor and one software engineer) were very enthusiastic about MAGNET during the workshop, while the others were reticent to using it. This may indicate a polarized view on the usage of MAGNET, although such a claim calls for a future study.

In other interesting (and unexpected) feedback given to us during the workshop, it was suggested having to-the-point videos targeting the logical programming steps related to the tutorial exercise in the workshop. This is reminiscent of our earlier work on building process-aware modelling environments [28], where we proposed a DSL to express static development processes in MDD tools, to help for instance with meeting software certification rules in certain domains (e.g. avionics). Such feedback suggests fusing our previous work on process-aware modelling with the IRS we propose here to allow for both explicit and implicit (machine-learned) software development processes in AF3.

Another point worth discussing is the utilization of *SWT-Bot* [13] for the purpose of gathering the interaction data. The *SWTBot* tool has been built for performing the functional testing of the software interfaces. To the best of our knowledge has not been, up to now, utilized to gather interaction data for machine learning tasks.

VI. FUTURE DIRECTIONS

We have discussed an implementing a recommendation system using ML to ease the learnability of AF3, in particular in a tutorial setting. The results we present are preliminary but encourage us to further pursue this avenue of research. In

particular, are currently considering a number of follow-ups to this work:

- Improving data collection and labelling, as these processes have been up until now long and painstaking. We believe this can be partly achieved by building a “data acquisition” mode in AF3, where users can label sets of their own interactions directly in the tool.
- Focusing specifically on improving user experience by studying how different hint delivery mechanisms (e.g. textual hints or highlighting certain parts of the IDE) improve user satisfaction. The Human-Centered Engineering group at fortiss is currently performing a study on the desirability these mechanisms in AF3. The results of such study should percolate into the MAGNET tool.
- Applying and evaluating different ML techniques to achieve more accurate next-task predictions. The study in this paper indicates that Random Forest achieves good performance – nonetheless these results should be taken with a grain of salt, given the low amount of labels (classes) that data acquisition has been done in the context of a tutorial. When broadening the scope of hints to the whole AF3 tool, it might very well be the case that other machine learning models will perform better.
- Studying how non user interaction data (e.g., AF3-model related data) can improve in task predictions for the new users. For the time being all predictions are based on user/widget interaction and no information about the state of the model of the embedded software system under construction is taken into consideration. Due to its size, it will is not possible to use the complete state of the model for either training or classification. But, by identifying deltas in the state of the model from one moment of time to the next and taking this information into consideration for training and prediction, we believe the accuracy of next task prediction will increase. Note that a system implementing the measurement of such deltas has already been implemented in AF3. We have indeed used this system to evaluate the state of a model in order to locate a developer in a pre-defined development process [28].
- Recalibrating the AF3 tutorial format to maximize the usage of the IRS during upcoming tutorial sessions.
- Extending the number of videos to include help for other parts of the AF3 tool, such as deployment, requirements engineering or formal verification. This is important not only to the IRS, but also as a means to improve the learnability of AF3 in general.

Abstract—Design Smell detection has proven to be an effective strategy to improve software quality and consequently decrease maintainability expenses. In this work, we explore the influence of the size category of the software project on the automatic detection of God Class Design Smell by different machine learning techniques. A set of experiments were conducted with eight different learning classifiers on a dataset formed by 12,588 classes of 24 systems. The results were evaluated using ROC area and Kappa tests. The classifiers change their behaviour when they are used in sets that differ in the value of the selected size information of their classes. This study concludes that it is possible to improve results, mainly in agreement, of God Class detection feeding machine learning classifiers with project size information of the classes to analyze.

Index Terms—Design Smell Detection; Machine Learning; God Class.

I. INTRODUCTION

Software systems available in different departments of organizations to provide many services in different domains. Even though the provided services are essential, but the more critical is the software continues operating without problems and mistakes. Software quality is an important concern for software industries, academic, and researchers. Identifying problems in source code or design of software, correcting and modifying them are some of the main activities of the maintenance process in order to increase quality.

All problems related to the software structure that does not make compile or run-time errors are described by "Design Smell" [11]. The presence of Design Smells negatively affects software quality factors, though technical debt increases [6]. Smells can appear in several software artifacts including variables, instructions, operations, methods, classes, packages, subsystems, layers, and their dependencies.

God Class Design Smell is one of the most detected smells in software according to our systematic mapping study [1]. It has attracted the attention of the research community. God Class is defined with different names as the Large Class Bad Smell [10], the Blob Antipattern [5], and the God Class Disharmony [15]. The term God Class Design Smell is the name we use for bringing both together. It is considered as a class level Design Smell.

Several approaches, tools, and techniques have been proposed to improve the detection of God Class Design Smell. However, some studies evidence the lack of agreement among different tools and human experts. Moreover, they have a set of limitations represented in understanding the precise definition of God Class Design Smell and the process of mapping the definition into effective detection algorithms. The current trend in Design Smell detection has adopted machine learning for deriving detection rules [12], [21].

This paper aims through an exploratory study to investigate whether the size category of the project is relevant in God Class detection. A set of experiments were conducted with eight different classifiers. The selected classifiers are the most recently reported in the literature and they jointly involve all families of classifiers. Results are evaluated using ROC area [4] and Kappa tests [2].

The main contributions of this study can be summarized by determining the influence of project size information on God Class Design Smell detection using machine learning techniques. Moreover, a large dataset for God Class Design Smell detection.

The rest of this paper is organized as follows: Section II describes the related work. Section III presents the problem statement, research question, and hypothesis. Section IV describes the dataset we built. Section V exposes the methodol-

ogy we follow to identify the effectiveness of project domain information in God Class Design Smell detection. Section VI discusses the results of experiments. Section VII presents the main threats to the validity and Section VIII explains our conclusions.

II. RELATED WORK

In this section, we present studies exploiting machine learning techniques for Design Smell detection.

Jochen Kreimer [14] presents a method to detect Design Flaws by combining object-oriented metrics and machine learning. The proposed approach was validated using five Design Flaws: Big Class also known as (The Blob), Feature Envy, Long Method, Lazy Class and Delegator and two software systems: IYC (91 classes) and WEKA (597 classes). Khomh et al. [13] introduce BDTEX (Bayesian Detection Expert) a Goal Question Metric-Based approach to detect Antipatterns using Bayesian Belief Networks (BBNs) stood on rule-based representation. The approach was validated using three Antipatterns: The Blob, Functional Decomposition and Spaghetti Code and two Java programs: Xerces v2.7.0 (589 classes) and GanttProject v1.10.2 (188 classes). Maiga et al. [16] introduce SVMDetect, an approach to detect Antipatterns based on support vector machine. They compute the object-oriented metrics for each class. The empirical study involves four Antipatterns: The Blob, Functional Decomposition, Spaghetti Code and Swiss Army Knife and three open source software: ArgoUML v0.19.8 (1,230 classes), Azureus v2.3.0.6 (1,449 classes) and Xerces v2.7.0 (513 classes). Fontana et al. [9] present their approach based on machine learning techniques for outline the common problems in the previous Design Smells detection. The dataset has formed by the 59,333 classes of 76 systems and a large set of relevant metrics. A set of six code smells: God Class, Data Class, Feature Envy, God Method, Brain Method, and Long Method were detected in the experiment.

As we can see, the related works principally focused on numerical information (mainly object-oriented metrics and other well-known sets of metrics) on classes to detect a set of smells. In our work, we focus the attention on certain nominal project information (size category) and try to explore its influence in God Class detection in order to take this information into account in future work, in the aim of obtaining better results that can be more useful for developers, improving agreement among tools and experts.

The aim of this paper is analyzing if clarifying the size category can lead to variations in the detection. The detection problem is seen as a classification problem; using automatic classifiers that separate classes in having God Class Design Smell or not. Our dataset is formed by the 12,588 classes of 24 systems with different sizes and domains. In order to define our dataset, we analyze these systems using five different tools common in detecting God Class Borland Together [3], PMD [8], iPlasma [18], DÉCOR [20] and JDeodorant [22].

III. PROBLEM STATEMENT

The problem that we examine in this study that most of the research community has not taken into account the impact of nominal project information on Design Smell detection. The suspicion that we have raised involves this type of information can be useful for developers to obtain better detection results. For this reason, in this work, we address the effectiveness and importance of project size nominal information in the detection of God Class Design Smell. To address the study problem, we introduce the following research question:

RQ: Does the differences between the size category of the whole project influence in the detection of God Class Design Smell?

We want to reject the null hypothesis formulated as:

H_0^{size} : Project size does not influence on God Class detection.

We propose to obtain several classifiers trained with and without the project size information under examination, working with the dataset taken as a whole in order to verify whether this kind of information will affect on the behaviour of classifiers or not. If this first exploration succeeds, the next step should be to design the same experiment to investigate the impact of the project size category in detecting God Class as explained in Section V. The behaviour of classifiers is evaluated by ROC area and Kappa performance measurements as we will see in Sections V and VI.

IV. DATASET

Our dataset is formed by the 12,588 classes of 24 open source systems written in Java obtained from SourceForge source code repository which involved different domains and size categories. We selected the SourceForge repository because it is the most widely known and used in the context of open source software, and it supplies useful metadata for projects. The projects are selected according to particular criteria, such as should be written in Java, long life cycle with several version, has a significant change history information (development, maintenance), and the projects should be of different size categories.

The high number of projects and classes is intended to discard the probability of dependencies between classifiers and a particular subset of data. Table I presents the main characteristics of our dataset where includes [Project name, Category of size, Number of Classes, Total Line of Code in the project (TLOCP)].

The dataset is formed as follows: rows x_1 to x_{16} represent numerical attributes (metrics), x_{17} , represent the project size information and x_{18} , the result of classification if a class is God Class or not (resulting from the selected tools as a logical or among them). Table II shows the full list of selected variable x_1 to x_{18} and their definition.

x_{12}	DIT	Depth in Tree
x_{13}	NOC	Number of Children in Tree
x_{14}	DIP	Dependency Inversion Principle
x_{15}	LCOM	Lack of Cohesion of Methods
x_{16}	NOA	Number of Attributes
<i>Project level information (nominal scale)</i>		
Var	Information	Values
x_{17}	Size category	L, M-L, M, M-S, S
<i>Smell detection (binary)</i>		
Var	Design Smell	According to
x_{18}	God Class	PMD, iPlasma, JDeodorant, Décor, Together

The chosen projects are analyzed with RefactorIT v2.7 tool¹ [19] to compute a set of important class and package level metrics. The selected metrics are widely used in state of the art [13], [14], [17] for Design Smell detection, and some of them are particularly related to God Class characteristics such as cohesion (Lack of Cohesion (LCOM)), size (Line of Code (LOC)), Number of Attributes (NOA), Number of Children in Tree (NOC), and complexity (Weighted Methods per Class

(WMA). The second part of Table II is regarding projects level information, and we can see the size consists of different categories. We follow the same approach as [7] to classify the projects based on categories.

As can be seen, the nominal data of size categories refers to the size of the Total Line of Code in the whole project (TLOCP). The project size is divided into six categories based on the TLOCP include (Small (S) $\leq 4,999$; $5,000 \leq$ Small-Medium (S-M) $\leq 14,999$; $15,000 \leq$ Medium (M) $\leq 39,999$; $40,000 \leq$ Medium-large (M-L) $\leq 99,999$; $100,000 \leq$ Large (L) $\leq 499,999$; Very large (VL) $\geq 500,000$). In fact, this is more precisely an ordinal scale. But we are not going to treat it as ordinal just as a nominal category.

The final part of the table focused on the selected God Class detection tools. To obtain the value of variable x_{18} , we used the following five Design Smell detection tool: The five tools are DÉCOR, JDeodorant, iPlasma, PMD, and Together. The tools were selected based on the results of a systematic mapping study [1] we conducted on the state of play in the field of Design Smell detection for the period 2000 to 2017. The selected tools are one of the most cited and used in the literature, and are commonly employed in God Class detection. Moreover, all the tools support projects implemented in the Java language and the input source is source code while the output is text in different formats such as CSV, txt, XML. Also, most of the tools focus only on smell detection, except for JDeodorant which includes a refactoring operation that is performed after the Design Smells have been identified. Nearly all of the tools have a GUI except for PMD, which is the only tool that has been developed to support both a Textual User Interface (TUI) and a GUI.

We use the output of these tools considered as experts for feeding the data mining algorithms according to the following criteria. If one tool or more detect God Class Design Smell in a particular class, we assign a true value in the God Class attribute. Otherwise, this attribute is set false (as a logical or among them). According to this strategy, the presence of the God Class smell is distributed along the different size categories of the data we are dealing with. Dataset is available on the web².

Despite the high number of projects, our dataset includes 1,958 God Classes against 12,588 classes. According to our experience in the area, the nature of God Class Design Smell leads to obtaining low ratios of smelly classes detected in each project. As we can observe from Table III, the number of God Classes in all categories are enough as inputs to the classifiers for God Class detection. Our dataset includes only one God Class smell in the small size category (S). In our experience it is normal in a small size project to detect one or at most two God Classes if the project is not a complete disaster. We can either discard this category or add more projects if we find. But we do not, because in this case, the small category do not represent a subset of all dataset or cause a problem if the H_0^{size} . We decide to include this category in our experiments

¹<http://RefactorIT.sourceforge.net>

²<https://citius.usc.es/investigacion/datasets/project-nominal-information>

because we choose all classes in each project to send feedback to the project developers.

TABLE III

BUILDING SET, TESTING SET, AND GOD CLASS DISTRIBUTION BY THE SIZE CATEGORIES. (NP: NUMBER OF PROJECT, NOC: NUMBER OF CLASS, GC: GOD CLASSES)

Category	#NP	#NOC	#GC	%GC
L (Testing set)	6	4,763	967	20%
M-L (Building set)	8	5,123	623	12%
M-L (Testing set)		1,281	132	10%
M (Testing set)	7	1,281	198	16%
S-M (Testing set)	2	112	34	30%
S (Testing set)	1	28	1	4%

The high number of projects in a specific category of the size does not mean having more God classes such as (L, M) categories, but when the number of classes increases in a particular category, it implies increasing the number of God Classes. Therefore, it is difficult to balance the dataset categories. The high number of categories implies a lot of subsets to have God classes distributed across them. We would need to increase the number of projects (and classes) significantly to obtain God Class in all of them. Instead of this, we modify our intention and only will use the M-L size category to build classifiers as explained in the next section.

V. METHODOLOGY

In state of the art for Design Smell detection with machine learning algorithms, a different set of classifiers have been used. We choose a set of eight supervised machine learning techniques that are available in Weka version 3.7 [23], which is a comprehensive collection of machine learning algorithm tools used for data analysis and predictive modeling. The high number of selected techniques allows discarding one of them if it is obtained a particular behaviour or it seems to depend on specific data. We work based on different approaches with the default parameters [NaiveBayes (NB), J48, RandomForest (RF), JRip, SMO, IBK, CHIRP and RandomCommittee (RC)]. We decide training with default parameters in all cases because we are not tuning for obtaining the best classifier. What we want to show is that whatever the classifier is, it is a better classifier if the project size category is taken into account.

Firstly, as an exploratory work, we have trained several classifiers with and without size information (x_{17}) to verify whether the use of this type of information increases the quality of classifiers or not. Secondly, the methodology we propose consists of obtaining a classifier trained with projects with the same value for size nominal variable (x_{17}).

As we stated in Section III, the null hypothesis was formulated as size project information does not affect on God Class detection. The intention is to reject each null hypothesis (H_0^{size}). We assume in our experimental design that if size information is not important, a classifier built for the category Medium-Large (M-L) of size category info (x_{17}), should behave the same when classifying projects from different size categories. If this does not happen and the classifiers behave

worse, we can reject the null hypothesis H_0^{size} and say that the size category information is important.

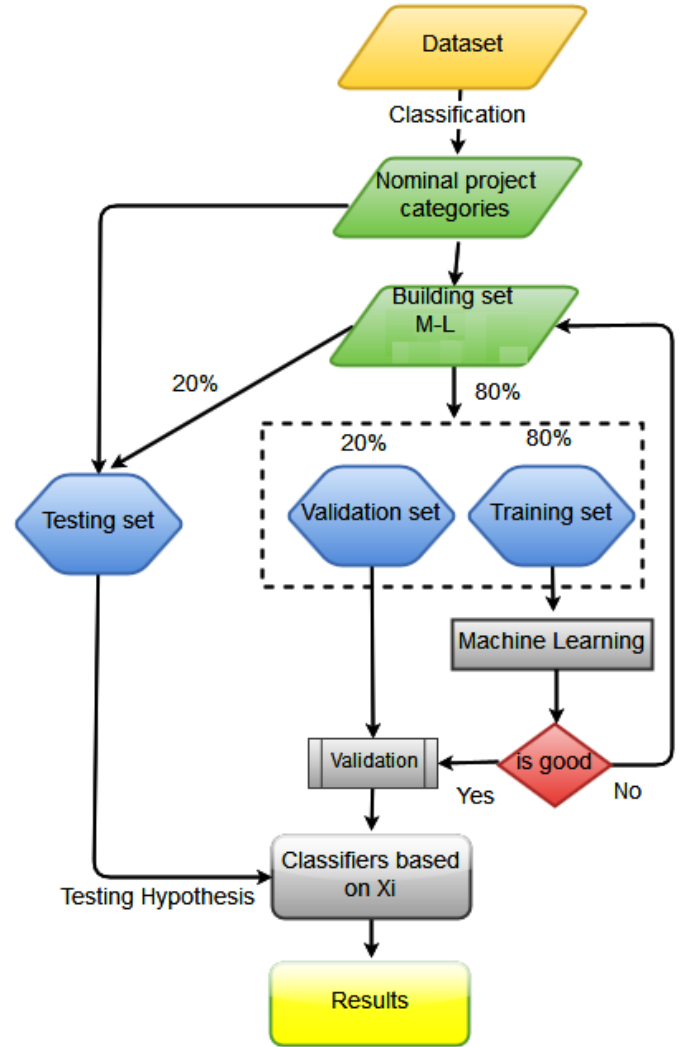

Fig. 1. proposed approach.

Figure 1 summarizes the proposed methodology to obtain the trained classifiers that we will use in the hypothesis testing process. The building set, i.e., the set devoted for building a classifier uses the 80% of the projects in M-L category for x_{17} . The testing set contains the projects in the rest of the categories of size (L, M, S-M, S) plus the remaining 20% from the category that has the highest number of classes (M-L) previously selected to be the building set. This is the set used to test the hypothesis. The set of classes in building and testing data are completely different and are distributed on different project categories.

The building set is divided into two parts. The first part includes 80% to be the training set and the remaining 20% to be the validation set. The training set is supplied to the machine learning algorithm to obtain the required classifier. After that, the validation set is used to validate it. If the classifier is good, the testing set is supplied to the classifier to test the hypothesis. Otherwise, we repeat the process of

using the training and validation set until a good classifier is obtained.

The ROC area test obtains a comprehensive effectiveness evaluation of classifiers. This test shows the relation between the sensitivity and the specificity of the classifiers. Table IV shows the traditional classification of this test.

TABLE IV
INTERPRETATION OF THE ROC AREA (R).

ROC value	Interpretation
$0.5 < ROC \leq 0.6$	Fail
$0.6 < ROC \leq 0.7$	Poor
$0.7 < ROC \leq 0.8$	Fair
$0.8 < ROC \leq 0.9$	Good
$0.9 < ROC \leq 1$	Excellent

Kappa measures the degree of agreement (or concordance) of the nominal or ordinal assessments made by appraisers when assessing the same samples. Kappa can range from -1 to $+1$. The higher the value of Kappa, the stronger the agreement. Table V shows the interpretation of this coefficient.

TABLE V
INTERPRETATION OF THE KAPPA VALUES (K).

Kappa value	Degree of Agreement
$k < 0.20$	Poor
$0.21 \leq k < 0.40$	Fair (Weak)
$0.41 \leq k < 0.60$	Moderate
$0.61 \leq k < 0.80$	Substantial (Good)
$0.81 \leq k \leq 1.00$	Almost perfect (Very Good)

VI. RESULTS AND DISCUSSION

In this section, we present the results of our experiments regarding the influence of the size category nominal information on the detection of God Class to reject the null hypothesis.

Table VI shows the classifiers results when we trained them with all dataset as a whole without size category information (cat. info.) and with size category information. In the ROC area, the majority of classifiers obtain a Good to Excellent behaviour with and without size information except for IBk and SMO in the first case (without size) and JRip in the second case (with size). In particular, SMO's behaviour according to ROC is fair and almost fair in both cases. On the other hand, in the Kappa test, which is considered better indicator because the ratio of detected God Class in the most categories is less than 20%, the classifiers obtain a better result with the selected size information than without this information. In this case, SMO and NB obtained the worst results in general (0.467, 0.4967), respectively. According to Kappa analysis, the behaviour of classifiers is improved with the size information. Based on this, we conducted the experiment explained in Figure 1 on the size in order to analyze H_0^{size} .

Figure 2 shows the ROC area results of the classifiers trained regarding a single category (M-L building set) for project size information x_{17} . All classifiers when exercised with the testing set for the same values of the categories (M-L) for size,

TABLE VI
TRAINED CLASSIFIERS

RF	0.944	0.5479	1	0.9982

that were used for building the classifiers obtain the highest values of ROC area compared with the rest of the categories in size nominal information (the top black line of the figure). It deserves to say that we are not training the classifiers to be the best. As we stated before, we are just working with default parameters. What we are showing here is that the same algorithm is better being sensitive to the project size category in which it was trained. So, it is considered good evidence that taking into account the information we are analyzing in this work for God Class detection would improve results.

Fig. 2. ROC area performance.

Figure 3 presents the results of the Kappa test for the classifiers trained regarding a single category (building set) for project size information. The testing set with the same value in the size category (M-L) is marked as the black highlighted line in the top of the figure. The better Kappa values are obtained, compared with the rest of the categories except NB in the (M-L) category. Based on the Kappa results, we can say, the size nominal information influence on the detection of God Class. Therefore, we can reject the null hypothesis H_0^{size} .

VII. THREATS TO VALIDITY

In this paper, we highlighted a set of threats to internal validity that affects negatively on our experiment such as the disproportionate number of project in every category of the size nominal information. On the other hand, as threats to external validity, all project is written in Java in order to use the selected set of tools. We did not include the "very large" size projects. Also, the dataset did not include a set of different versions of the same project. This work is focusing on one type of smell (God Class). We need to study other smells that can be detected in different software artifacts. Another threat is

Fig. 3. Kappa values.

the limited number of class level metrics we use and the tools used to analyze the projects (in the metric collection and smell detection).

VIII. CONCLUSIONS AND FUTURE WORK

Our study presented an experimental approach based on machine learning techniques to identify the effective influence of the size category of the project regarding the detection of God Class. In this paper, we present an exploratory study to check whether this information is relevant to be supplied to the classifier and can lead to variations in the classification usefulness, mainly concerning effectiveness (ROC) and agreement (Kappa). All classifiers behave worst according to ROC area and Kappa value tests for categories that were not present when building the classifiers. This study concludes the importance of the size category of the project in the Design Smell detection through machine learning classifiers and should be taken into account in the future works in order to obtain more useful classifiers.

A large dataset formed by the 12,588 classes of 24 systems with different domains and size categories was defined. The classes in the dataset were analyzed by the five different tools selected as experts for God Class detection.

Our future work will focus on replicating the experiments reported in this work rather than using automatic tools as experts we will involve professional human experts from the industry in identifying true God Classes. The same approach could also be extended to study other software context information, such as domain, programming language. Also including other types of design smell, machine learning techniques, and metrics, to confirm whether the proposed methodology has general applicability.

Abstract—With development of the infrastructures supporting smart home which has entered in a new stage featured by intelligent services. The services based on natural language instructions are aimed at simplifying and improving our lives. To customize and develop these services more efficiently, this paper proposes an approach to model and execute services based on natural language instructions at runtime which introduces the knowledge graph into development process. Firstly, a concept model of knowledge graph is introduced for smart home services. Secondly, we put forward the mechanism to construct the instance of knowledge graph for smart home services. Finally, rules of transformation are provided to achieve mapping from natural language instructions to the services of knowledge graph. We evaluate our model on a prototype system and the experimental results show that our approach can develop services at runtime and effectually reduce the lines of code by 90%.

Index Terms—services development, smart home, knowledge graph, runtime model, natural language

I. INTRODUCTION

The continuous development of smart home infrastructure has ushered in a new era characterized by smart services. A large number of new devices which are complex and heterogeneous such as intelligent robots, smart wearable devices and smart home appliances will access to the network for interaction and collaboration [1] [2]. Human-computer interaction based on natural language has become the main interaction method in smart home like Amazon Echo [3] and Google Home [4].

Smart home service based on natural language commands is actually a process of decision-making and implementation according to the instructions given by users and the information of their environment [5]. At present, the management interface of the device is directly invoked by a programming language such as C or Java to implement services development of smart home. Although this kind of programming has good adaptability, it will bring high price. Developers must be familiar with the management interfaces of different smart devices in order to implement the interaction. In addition, the application system is based on the underlying code bound to a specific intelligent device, which makes it impossible to reuse its management logic. It is hard to expand the manage system

when the devices change, though the management mechanism is similar.

Due to the gap between problem domains and system implementations, accomplishing mapping between them can create significant programming complexity. The knowledge graph is used to describe the concepts, entities, events and relationships between the object, which can serve as a bridge between system requirements and system implementation. Moreover, it turns to be easier to integrate the devices into control system of smart homes. If we want to introduce knowledge graph into the development of smart home services, there are two problems which need to be solved. One is how to define the knowledge graph model to describe the smart home scene. The other is how to map natural language utterances to services provided by devices in the knowledge graph.

In this paper the method is proposed to quickly customize and develop smart home service on the basis of natural language instructions. Our contributions are as following:

- A concept model of knowledge graph is introduced for smart home services.
- We put forward the mechanism to constructing the instance of knowledge graph for smart home services.
- Transformation rules are proposed to achieve mapping from natural language instructions to the services of knowledge graph.

II. RELATED WORK

In the development process of IoT applications, programming is usually carried out at the operating system level. This situation makes the programmer to focus on the underlying related issues rather than the application logic [6]. Guang et al. [7] proposed a top-down IoT application development method and support system. The system could automatically generate platform-specific configuration and execution code by given the platform-independent application management logic. In addition, some research work [8] [9] proposed a service-oriented architecture-based solution that provided a device access interface in the form of RESTful service to shield the heterogeneity and complexity of the underlying system.

The Peking University team conducted research on runtime model theory and construction methods [10] [11]. When the system meta-model and a set of management interfaces

was given, the SM@RT tool [14] can automatically generate code. When the systematic meta-model changed, SM@RT can generate new mapping code automatically.

III. APPROACH OVERVIEW

A. Concept model of knowledge graph

The concept model of knowledge graph provides an abstract representation of smart home services, and aim to describe the concepts and relationships of abstract elements for smart home scene, as shown in Figure 1.

Fig. 1. Concept model of knowledge graph for services of smart home

As Table I illustrates, the concept model defines the concepts of the smart home scenario such as location, user, context, device and service. We give further explanations for those concepts and their properties in this model.

TABLE I
CONCEPTS AND PROPERTIES IN THE CONCEPTUAL MODEL OF SMART HOME KNOWLEDGE GRAPH

Concept Name	Conceptual Properties
Location	<LName>
User	<UName, LName>
Context	<UName, LName, CType, CValue>
Device	<DName, LName, {Key ₁ , Key ₂ , ..., Key _n }>
Service	<DName, LName, DFunction, CType, Effect>

Location indicates a specific area and the name of the area is expressed by *LName*. *User* is used to describe the service object and *UName* is the name of user. The attribute *LName* is the area where the user is located. *Context* represents an environment state of users. *UName* is the name of current service object. *LName* represents the area where the users are located. *CType* is to describe an type of environment status (eg brightness, temperature). *CValue* is the value of status. *Device* represents the equipment object and it contains three properties *LName*, *DName* and *Key_i*. *Key_i* means the configuration parameter or system indicator of device. *Service* indicates a service to change the environment or operating the device and it contains five properties. We need to emphasize the *DFunction* and *Effect* here. *DFunction* is the function interface of the device corresponding to the service. *Effect* is an operation of changing the environment or managing the devices meeting the instruction given by user.

The conceptual model also defines the relationship between concepts mentioned above, as shown in Figure 1. For example,

$X \xrightarrow{\text{Located}} L$ indicates node *User*, *Context*, *Device* and *Service* are located in area *L*. $U \xrightarrow{\text{Sense}} C$ represents user is aware of the state of the context. $S \xrightarrow{\text{Increase}} C$ shows that the service is used to raise the state value of the context.

B. Mapping natural language to service

The implementation of the smart home services in natural language is based on the knowledge graph model of smart home. The goal is to map natural language commands to specific service and the knowledge graph contains all the information of services. Hence, we have two main tasks in this part.

Firstly, the task of information extraction is to identify the semantics in natural language commands. At present, information extraction methods are mainly divided into two categories, one is based on statistical learning method and the other is based on rule pattern matching method. Statistical learning method is portable and robust. However, it needs a lot of training data to set parameters and optimize the system. Rule-based matching method has high efficiency and accuracy. The text of smart home domain has the characteristics of domain, regularity and simple logic. The rule-based method can achieve better extraction effect.

Secondly, the conversion rules are builded to map the information to services of knowledge graph. When services matching the commands are found, it is available to execute the device functional interfaces satisfied with users' need. The specific transformation rules are given in Section V.

IV. RUNTIME MODELING

In this part, we will introduce the runtime modeling method of knowledge graph for smart home. With the purpose of describing the context knowledge of smart home, we establish knowledge graph instances by constructing concept instances and relationship instances.

A. Concept instances modeling

The concept instances are constructed based on the developer configuration. For realizing bidirectional synchronization between concept instances and the real-time information of the scene, a set of rules for mapping are proposed. Developers need to provide relevant configurations to describe specific objective facts in the scenario, including scene information, the mapping of concept instances to smart devices and the environment of service objects.

The configuration of scene information provides a collection of locations $L = \{L_1, L_2, \dots, L_n\}$. The mapping between concept instances and devices provides a collection of devices $D = \{D_1, D_2, \dots, D_n\}$, a collection of services $S = \{S_1, S_2, \dots, S_n\}$ and the relationship between them. The configuration of users' environment provides data which include collection of users $U = \{U_1, U_2, \dots, U_n\}$, positioning devices $T = \{T_1, T_2, \dots, T_n\}$, and environmental state of users $C = \{C_1, C_2, \dots, C_n\}$. Then the corresponding concept instances are generated by the collections mentioned. Moreover,

TABLE II
MAPPING RULES FOR MODEL OPERATIONS OF LOCATION, USER AND CONTEXT INSTANCES

	Location	User	Context
List	$List * L \rightarrow \{L_1, L_2, \dots, L_n\}$ $Get L_i.properties \rightarrow L_i.properties$	$List * U \rightarrow \{U_1, U_2, \dots, U_n\}$ $Get U_i.properties \rightarrow U_i.properties$	$List * C \rightarrow \{C_1, C_2, \dots, C_3\}$ $Get C_i.properties \rightarrow C_i.properties$ $Get C_i.UName \rightarrow C_i.UName$
Get	$Get L_i.LName \rightarrow L_i.LName$	$Get U_i.UName \rightarrow U_i.UName$ $Get U_i.LName \rightarrow \mathbf{RTModel}(Get T_i.location)$	$Get C_i.LName \rightarrow Get U_j.LName \left((\exists U_j) U_j \xrightarrow{Sense} C_i \right)$ $Get C_i.CType \rightarrow C_i.CType$ $Get C_i.CValue \rightarrow Get D_j.key_n \left((\exists D_j) D_j \xrightarrow{Provide} S_i \right)$
Set	-	-	-

TABLE III
MAPPING RULES FOR MODEL OPERATIONS OF DEVICE AND SERVICE INSTANCES

	Device	Service
List	$List * D \rightarrow \{D_1, D_2, \dots, D_n\}$ $Get D_i.properties \rightarrow D_i.properties$	$List * U \rightarrow \{U_1, U_2, \dots, U_n\}$ $Get S_i.properties \rightarrow S_i.properties$
Get	$Get D_i.DName \rightarrow D_i.DName$ $Get D_i.LName \rightarrow D_i.LName$ $Get D_i.key_m \rightarrow \mathbf{RTModel}(Get D_i.key_m)$	$Get S_i.DName \rightarrow S_i.DName \left((\exists D_j) D_j \xrightarrow{Provide} S_i \right)$ $Get S_i.LName \rightarrow S_i.LName$ $Get S_i.CType \rightarrow S_i.CType$ $Get S_i.Effect \rightarrow S_i.Effect$ $Get S_i.DFaction \rightarrow S_i.DFunction$
Set	$Get D_i.key_m \rightarrow \mathbf{RTModel}(Set D_i.key_m)$	-

the SM@RT tool [10] [11] is used to construct the runtime model of the smart devices and positioning devices.
